Cryptorchidism can be caused by a multitude of genetic and hormonal disorders, as well as complex syndromes with midline and caudal defects. In addition, lifestyle factors and the environment may have adverse effects on testicular descent in humans.[25] Disorders of the hypothalamic-pituitary-gonadal (HPG) axis and testosterone biosynthesis have more frequently been reported in association with isolated cryptorchidism than other genetic defects, such as androgen receptor mutations.[26] However, there are familial cases of cryptorchidism, and one study estimated the relative risk of cryptorchidism to be increased to 6.9 if a brother and 4.6 if the father also had cryptorchidism.[27] However, the concordance of cryptorchidism between monozygotic and dizygotic twins is rather similar (27.3% vs. 24.1%, respectively), emphasizing the role of shared pregnancy rather than heritability.[28]

Epidemiologic studies have revealed a multitude of risk factors for congenital cryptorchidism,[25] the most established being low birth weight, being small for gestational age, and prematurity. Pregnancy complications such as placental insufficiency, preeclampsia, and maternal diabetes have also been associated with cryptorchidism. Even mild gestational diabetes appears to increase the risk of cryptorchidism in the offspring, potentially via reduced levels of maternal sex–hormone-binding globulin (SHBG) and fetal hyperinsulinemia leading to an imbalance in the fetal estrogen-androgen action.[29]

Risk factors in maternal behavior, such as continuous smoking, drinking, caffeine intake, and use of mild analgesics during pregnancy, seem to have adverse effects on the development and descent of the testis in their offspring, although these findings are still controversial.[25] Some discrepancies in the results between studies are caused by the differences in the inclusion criteria related to mild and transient forms of cryptorchidism in some and only persistent or severe forms in others. Different types of cryptorchidism may not share the same etiology.

Several epidemiologic studies suggest an increased prevalence of cryptorchidism and related urogenital malformations in specific professions such as farmers and males from geographic regions with high agricultural activity.[25] In animal studies, prenatal exposure to many man-made chemicals with endocrine-disrupting properties can cause cryptorchidism. Data in humans are still sparse, although they are exposed to a multitude of chemicals over their entire lifespan. There is some evidence that halogenated compounds such as polychlorinated compounds and polybrominated flame retardants may be associated with an increased risk of congenital cryptorchidism and hypospadias.[30-33] In addition, phthalate exposure of the fetus and infant was associated with testicular hormonal function[34] and reduced AGD as a sign of reduced virilization.[15] Short AGD was also linked to cryptorchidism and hypospadias[35] and to testicular cancer and semen quality in adults.[36,12,12a] In most cases with cryptorchidism, a distinct etiology cannot be ascertained, suggesting that genetic predisposition together with environmental and lifestyle factors may exert adverse effects.

Prevalence

The reported prevalence of cryptorchidism varies considerably, depending on the type of study, geographic region, the selection, age, and ethnicity of participants, and the clinical classification. At birth, reported rates from prospective studies vary between 1.6% and 9% if premature boys are also included and between 1.8% and 8.4% for boys ≥2500-g birth weight.[22,37] Some countries, such as Denmark and Great Britain, have noted an increase of cryptorchidism over the past decades. A doubling of congenital cryptorchidism was also reported in the United States, Canada, and South America in the 1970s and 1980s. In contrast, orchiopexy data from registries suggest a decrease since the 1990s. In general, rates of cryptorchidism reported in registries tend to be lower than from prospective studies because ascertainment and registration traditions differ from systematic studies. For orchiopexies, registries may also reflect changes in treatment traditions and surgical referrals.

Owing to the spontaneous postnatal descent of retained testes during the first months of life, prevalence rates drop to between 0.9% and 1.8% at 3 months of age. During childhood, retractile testes and ascensus testis become more common, and reported prevalence data from prospective studies increase up to 7%. Most ascended testes seem to descend spontaneously during puberty, thus the age and pubertal stage at examination has a major impact on reported rates.

Treatment

Cryptorchidism should be treated early in life, preferably between 6 and 12 months of age or as soon as the diagnosis is established, in order to prevent further damage to spermatogenesis. There have been two treatment modalities available for cryptorchidism: hormonal or surgical treatment. Recent recommendations strongly favor surgery,[20,38] which offers the best balance between efficacy and side effects and improves testis growth.[39] Routine biopsy at surgery is not recommended except in cases of chromosomal abnormality or ambiguous genitalia, where there is an increased risk of gonadoblastoma or GCNIS.

The success rate (defined as a scrotal testis without atrophy) after surgical treatment in expert hands has improved over the years and is now approaching >95% for inguinal testes and 85% to 90% for abdominal testes, with slightly varying results depending on techniques and patient age. Side effects include pain, hematoma, infection, and anesthetic complications. Complications such as testicular atrophy and damage of the vas deferens are rare but become more frequent if surgery needs to be repeated due to relapse.

Hormonal treatments with human chorionic gonadotropin (hCG), gonadotropin-releasing hormone (GnRH), or luteinizing hormone–releasing hormone (LHRH) are now rarely used; their overall efficacy is only 20%, and reascent appears in approximately 25%.[40] The lower the initial testis position, the higher the rate of success. Acute side effects include pain at injection site, penile growth, pubic hair, erection pain, behavioral problems, and pain in the groin. More severely, germ cell apoptosis and inflammatory changes in the testes with the risk of long-term reduction in germ cell number and testis size in adulthood have been reported, especially for the youngest children.[41] Hormonal treatment after orchiopexy has been proposed to have beneficial effects on sperm count,[42] but this treatment regimen remains controversial and needs further scrutiny.

Treatment of retractile testes and high scrotal testes is currently not recommended because systematic studies are not yet available to assess whether treatment would be of long-term benefit. However, some retractile testes may show histologic deterioration and a reduction in volume over time.

Long-Term Effects

Impairment of spermatogenesis is a major problem of cryptorchidism. This impairment is partly related to a dysgenetic development *in utero*, but failure or delay to treat will additionally damage future semen quality and fertility. The precise adverse mechanisms that affect testicular function in untreated cryptorchid testes are not yet clear. Testes with a history of cryptorchidism grow slower and end up smaller in puberty than normal testes,[43] but there is no difference at the age of the onset of puberty. Although semen quality is reduced in unilateral cryptorchidism, reported fertility rates are usually not compromised. In contrast, bilateral cryptorchidism will lead to azoospermia if not treated. Long-term follow-up studies show that treatment before 4 years of age improves semen quality outcome. Whether the current recommendation for treatment at an even younger age will lead to further improvement of the long-term outcome remains to be seen. In a prospective study of unilateral cryptorchidism, the affected testis grew better over the first 2 years of life if orchidopexy was performed early.[39] Surgical techniques vary and may affect fertility outcome.[44,45]

Hormonal effects related to cryptorchidism are very subtle in childhood, and controversial results have been reported. At 3 months of age, increased follicle-stimulating hormone (FSH) and decreased inhibin B levels were found in patients with persistently cryptorchid testes.[46] Low serum inhibin B levels at orchiopexy may reflect a low number of germ cells at biopsy. In adults, in addition to reduced semen quality, the predominant effect of cryptorchidism is impaired Sertoli cell function, reflected in higher FSH and lower inhibin B levels. The effect on Leydig cell function, reflected by increased luteinizing hormone (LH) and low or normal testosterone level, is quite common but more pronounced if the orchiopexy was performed at a relatively late age.

Cryptorchidism increases the risk of testicular cancer, and both conditions share several prenatal and perinatal risk factors.[2,47] The relative risk of neoplasia is greatest in the undescended testis (RR = 6.3) but is also slightly increased in the contralateral, normally descended testis in unilateral cryptorchidism. Historical data suggest that orchidopexy before the age of 11 years lowered the risk of testis cancer, but the outcomes of surgery at even earlier ages require further long-term follow-up to determine if testicular cancer rates decline further.

KEY POINTS

- Cryptorchidism can be congenital or acquired, with one or both testicles positioned from high scrotal to abdominal.
- Prematurity and low birth weight are the greatest risk factors, and the prevalence varies from 1.8% to 8.4% at birth according to the geographical region to 0.9% to 1.8% at 3 months of age.
- Treatment of choice is by surgery, preferably between 6 and 12 months of age to prevent further damage to spermatogenesis.
- Cryptorchidism increases the risk of germ cell cancer (RR = 6.3).

HYPOSPADIAS

Hypospadias is a penile malformation in newborn boys and traditionally categorized into mild or distal (glanular, coronal) and severe or proximal (penile, penoscrotal, perineal) forms. Recently, another classification was proposed into four categories: *forme fruste* (incomplete), standard, severe hypospadias, and hypospadias variations.[48] The lack of a standardized nomenclature is a considerable limitation in the hypospadias literature.

Embryology

After formation of the testis from the undifferentiated gonad, the primitive phallus begins to grow from week 8 in gestation under the influence of fetal androgens, especially dihydrotestosterone. In parallel, the inner genital folds fuse in midline, and the penile urethra forms from the endodermal urethral plate in a proximal-distal direction. Thereafter, the glandular urethra is formed by distal proliferation and canalization of the urethral plate into the glans penis. The preputial skin enlarges from a dorsal fold to eventually cover the ventral surface of the glans and fuse. Hypospadias usually arises in the first trimester (gestational weeks 8 to 14), leading to a ventral positioning of the meatus and agenesis of the surrounding tissues.[49]

Very mild types of hypospadias may present with a normally shaped prepuce or with isolated chordee and normal placement of the urethral meatus. In rare cases, only a hooded foreskin is found, with a normal urethral opening. In contrast, severe hypospadias with early disturbances of urethral fusion may compromise the growth of the periurethral tissue and thereby lead to chordae and ventral curvature of the penis. In very severe cases, which are often combined with bifid scrotum and cryptorchidism, the clinical appearance of the external genitalia at birth may cause difficulties in gender assignment. Such cases need thorough assessment according to the guidelines for children with differences of sexual development, DSD.[50] A large number of complex syndromes are associated with hypospadias, that is, the Smith-Lemli-Opitz syndrome or the hand-foot-genital syndrome. Such entities should be kept in mind, especially in cases with other concomitant malformations and/or psychomotor developmental delay.

Etiology

The etiology of hypospadias remains obscure in many cases, and evidence suggests that it is a multifactorial disease with genetic, hormonal, and environmental components. Familial cases account for approximately 10% of all hypospadias, but truly monogenic disorders, such as 5α-reductase gene (*SRD5A2*) mutations and polymorphisms, MAMLD1 (CXorf6) mutations, Wilms tumor gene 1 (*WT1*) mutation or chromosomal aberrations are seldom found.[51,52] Monozygotic twinning appears to increase the risk of hypospadias by yet unknown mechanisms.[53] Fathers of sons with hypospadias present with reduced semen quality, increased need for fertility treatment, and a higher rate of genital disorders.[54] Assisted reproduction may contribute to a higher prevalence of hypospadias, potentially through the higher rate of twinning, compromised *in utero* growth, and paternal subfertility.[55]

Hypospadias shares some risk factors with other diseases of the male reproductive tract, that is, low birth weight, being a twin/triplet, being born small for gestational age and low parity.[56,57] Maternal obesity, hormonal contraception, preeclampsia, placental insufficiency and retention, weak contractions during delivery, increased rate of cesarean sections, and increased need for assisted reproductive techniques due to parental infertility have also been reported in hypospadias.

Environmental and lifestyle factors play a role in the etiology of hypospadias, that is, exposure to pesticides, residency close to hazardous waste sites, and vegetarian diets.[58,59] The use of some medications such as diethylstilbestrol and mild analgesics in pregnancy has also been linked with hypospadias.[60,61]

AGD measurement in rodents is a biomarker of prenatal androgen effect and used in toxicologic research. One study reported shorter AGD in boys born after high phthalate exposure in the second trimester of pregnancy[15] and another showed that boys with hypospadias and cryptorchidism had a significantly shorter AGD than controls.[62]

Prevalence

The reported prevalence of hypospadias ranges from 2 to 90 per 10,000 male births, depending on the geographical region, ethnicity, study design, and quality of public registries.[63] In registries, mild forms are often underreported and mild hypospadias with an intact prepuce may not be recognized at birth because of the high rate of physiologic phimosis.[56] The reported relative contribution of mild (glanular) forms to the total prevalence of hypospadias ranges from 29% to 72% and is highly dependent on the age and selection criteria for participation in studies and the completeness of recruitment. This causes considerable difficulties in comparing data across countries and over time. Nevertheless, a large metaanalysis of datasets from 27 surveillance birth defect programs around the world reported a continuous increase in the prevalence of hypospadias in the period 1980 to 2010.[64]

Treatment

Very mild types of hypospadias may not require any treatment, but severe cases will require surgical correction. The aims of surgical treatment are to extend the urethra to the glans penis to allow normal micturition, straightening of the penile shaft to allow normal intercourse, and improvement of cosmetic appearance. There is consensus that surgery should be done by experts in the field and current guidelines favor an early operation timing during infancy. However, parents may find decision-making difficult.[65] There is an ongoing debate as to whether surgery should be postponed obtaining informed consent from the patient himself.

Some surgical centers use preoperative hormone treatment with testosterone, dihydrotestosterone, hCG, or promestriene,[66] but very few clinical trials exist. While androgens induce penile growth, it remains to be seen if such treatment affects postoperative complication rates.[67] Cosmetic results with surgery are overall good, but complications such as wound infections, hematoma, urethral fistula, and strictures can cause severe problems.[68]

Long-term Effects

An increasing number of studies now focus on the consequences of hypospadias and hypospadias repair on semen quality, fertility, sexual function, cosmetic satisfaction, and quality of life. Men with hypospadias have fewer partners, fewer children, a higher need for fertility treatment, and sexual problems such as genital pain, mechanical difficulties, and ejaculation difficulties.[69] Men with severe forms of hypospadias combined with cryptorchidism may have poor semen quality, whereas most men with mild hypospadias have normal semen quality, indicating that isolated hypospadias is not necessarily associated with testicular dysgenesis.[70] There is still a considerable lack of knowledge on long-term outcomes including patient-reported outcome measures, and several countries have established international reference groups, that is, eUROGEN[71] to improve future care for patients.

KEY POINTS

- Hypospadias is the most common congenital abnormality of penis, with a prevalence ranging from 2 to 90 per 10,000 male births.
- It can be mild (glanular, coronal) or severe (penile, penoscrotal, perineal).
- Severe forms can be part of disorders/differences of sex development (DSD) or other complex syndromes.
- The mild forms are likely caused by environmental or lifestyle factors that adversely affect fetal androgen synthesis or action.
- Severe cases require surgical correction.

MINIPUBERTY

Activation of the HPG axis happens in three phases: in fetal life, in early postnatal life (minipuberty), and at puberty. Minipuberty consists of the neonatal activation of the HPG axis, mainly in the first 1 to 6 months of postnatal life.[72-74] Minipuberty has been suggested as a critical window of programming with lifelong implications. It has been proposed that minipuberty is linked to the timing of puberty and that it may be a marker of reproductive capacity in adult life, although the physiological role and clinical importance of the elevated sex steroids levels during minipuberty still remain to be elucidated. We suggest that minipuberty may be used as an early "window of opportunity" to detect and even treat reproductive disorders.

Minipuberty in Healthy Infants

At birth, serum concentrations of LH and FSH are low due to the suppressive effects of the high concentrations of placental hormones,[72,73] which are gradually cleared after approximately 1 week. This removes the restraint, leading to elevated gonadotropin levels until 6 to 9 months of age, with the exception of FSH, which remains elevated in girls for up to 3 to 4 years.[72,73]

In boys, the postnatal rise in LH and FSH is associated with increases in INSL-3 and testosterone from the Leydig cells and inhibin B and anti-Müllerian hormone (AMH) from the Sertoli cells.[75,76] Likewise, testosterone levels are low in cord blood but increase soon after birth and reach peak levels between 1 and 3 months of age, with levels reported just below adult concentrations, before declining and stabilizing after approximately 4 to 6 months at undetectable levels.[72,73] The number of Leydig cells increases concomitantly until 3 months of age, when the fetal Leydig cells go into apoptosis.[77] Similarly, the Sertoli cells develop and the number of germ cells increases in the first months of life[78] but do not express androgen receptors (ARs) during infancy. Thus the Sertoli cells produce AMH at very high concentrations during infancy, peaking at around 3 months of age, even in the presence of high levels of testosterone.[79]

Minipuberty and the associated sex steroid levels are important for genital development in boys. Thus penile growth is positively associated with testosterone levels from birth until 3 years of age. Likewise, minipuberty is associated with testicular growth due to FSH stimulation of Sertoli cells and seminiferous tubule volume. A positive correlation between FSH levels and testicular growth has been found, with testicular volume increasing from 0.27 to 0.44 cm from birth until 5 to 6 months and then decreasing to 0.31 cm at 9 months of age.[80]

Minipuberty in Various DSD and TDS Conditions

The HPG axis can readily be evaluated in newborns suspected of DSD conditions during minipuberty. A few studies on reproductive hormones in infants with DSD conditions exist. Infants with congenital hypogonadotropic hypogonadism (CHH) have extremely low FSH, LH, and inhibin B levels in minipuberty,[81] and the postnatal surge is absent in boys with CHH, who often present with cryptorchidism with or without micropenis. By contrast, hypospadias rarely occurs in CHH because first-trimester placental hCG secretion ensure sufficient androgen production needed for early urethral closure, whereas testicular descent and penile growth are primarily dependent on sufficient testosterone and INSL3 secretion in the second half of pregnancy.[76,81] In newborns with cryptorchidism, reproductive hormones during minipuberty may be altered. Thus higher FSH and LH levels and reduced inhibin B and INSL3 have been demonstrated in cryptorchid boys.[46,76] Newborn boys with nonpalpable testes remain a diagnostic challenge, and it is difficult to distinguish boys with anorchia who do not have residual testicular tissue from boys with bilateral cryptorchidism with intraabdominal testes. However, serum concentrations of LH, FSH, AMH, inhibin B, and testosterone hormone levels in minipuberty can be used as a clinical tool to determine the presence of functional testicular tissue in infant boys.[82]

Klinefelter syndrome (47,XXY) is characterized by primary testicular failure and infertility in adulthood, whereas data on the HPG axis during minipuberty are sparse and contradicting. However, a pivotal study showed that testosterone concentrations (measured by liquid chromatography/tandem mass spectrometry [LC-MS/MS]) in infants with Klinefelter syndrome were lower than age-matched controls, while INSL3 levels were normal.[83] Infants with AR mutations resulting in complete androgen-insensitivity syndrome (AIS) have lowered LH and testosterone levels in minipuberty, whereas infants with partial AIS have normal or high LH and testosterone levels, suggesting some physiological role of androgen signaling in in the HPG axis activation during minipuberty.

In conclusion, the regulation of the HPG axis is quite complex with many biological and environmental factors playing a part. The mechanisms behind the quiescence of the HPG axis between minipuberty and puberty remain to be elucidated. Nevertheless, minipuberty allows for the maturation of sexual organs and forms a platform for future fertility. It provides a window of opportunity in the early detection of disorders of sexual development, offering the possibility of initiating treatment at an early age in some cases.

KEY POINTS

- Minipuberty is a term for the transient activation of the HPG hormone axis during the first months of postnatal life (mainly between 1 and 6 months).
- This period is positively associated with penile and testicular growth, and maturation of germ cells, and may be a marker of reproductive capacity in adult life.
- Abnormal hormone levels at minipuberty can potentially alert about TDS.

TESTICULAR TUMORS

It is important that endocrinologists keep in mind a possibility of neoplasia in patients with fertility problems or other reproductive disorders, especially in view that testicular tumors have become more common in recent decades. In the vast majority of cases, the neoplasm is derived from germ cells, and most of these tumors occur in young men. The rapidly changing incidence trends suggestive of predominantly environmental causative factors and links to development have led to TGCT being considered a part of TDS. Tumors derived from testicular somatic cells, termed sex cord stromal neoplasms, which include Leydig cells, Sertoli cells, and other rare types, are not considered to be a part of TDS.[1,2] Regardless of the pathogenesis, all types of overt testicular neoplasms may cause endocrine effects, and the management nearly always causes some degree of late endocrine complications.

Classification

The latest classification proposed by the World Health Organization in 2016 is presented in a slightly simplified form in Table 115.1.[84] TGCT are divided into two major groups according to their association (or lack thereof) with GCNIS. The most common TGCT that typically occur in young adult men, seminoma and nonseminoma, are derived from GCNIS—and these tumors are considered a part of TDS. Infantile/childhood TGCT and spermatocytic tumor of older men are not associated with GCNIS.

Testicular tumors derived from somatic cells are jointly termed sex cord-stromal tumors and include quite common Leydig cell tumors

TABLE 115.1 Classification of Testicular Tumors, Based on the WHO Consensus (2016)

Testicular Germ Cell Tumors (TGCT)

- **TGCT derived from germ cell neoplasia *in situ* (GCNIS)**
  - Preinvasive lesions
    - GCNIS
    - Specific forms of intratubular germ cell neoplasia
  - Seminoma, pure
  - Nonseminomatous TGCT, pure
    - Embryonal carcinoma
    - Yolk sac tumor, postpubertal type
    - Trophoblastic tumors, including choriocarcinoma
    - Teratoma, postpubertal type
  - Nonseminomatous TGCT of more than one type (mixed)
- **TGCT unrelated to GCNIS**
  - Spermatocytic tumor
  - Childhood (infantile/pediatric) tumors
    - Teratoma, prepubertal type, including (epi)dermoid cysts
    - Yolk sac tumor, prepubertal type
    - Mixed prepubertal-type tumors

Sex Cord-Stromal Tumors (SCT) of the Testis

- **Leydig cell tumors (malignant or benign)**
- Sertoli cell tumors
  - Sertoli cell tumor, NOS (not otherwise specified)
  - Malignant SCT
  - Large cell calcifying SCT
  - Intratubular large cell hyalinizing SCT
- **Granulosa cell tumors**
  - Juvenile-type granulosa cell tumors
  - Adult-type granulosa cell tumors
- **The fibroma-thecoma tumors**
- **Mixed and unclassified sex cord-stromal tumors**
- **Unclassified sex cord-stromal tumors**

Tumors Containing Both Germ Cells and Sex Cord Stromal Elements

- **Gonadoblastoma**

Other tumors and malignancies

- **Miscellaneous** (including xanthogranuloma, hemangioma)
- **Hematolymphoid tumors**
  - Large B-cell, NK/T-cell or follicular lymphoma
  - Plasmacytoma
  - Myeloid sarcoma
- **Tumors of collecting ducts and rete testis**
  - Adenoma or adenocarcinoma

and rare tumors derived from Sertoli cells, granulosa cells, and other cell types. A similar to GCNIS precursor lesion, gonadoblastoma, which occurs in individuals with DSD and the presence of the Y-chromosome material, is currently classified as a separate entity grouping both germ cells and somatic cells, but this has been discussed because of a strong overlap with GCNIS. Finally, it is also important to remember that the testis can be a site of hematolymphoid malignancies.

Testicular Germ Cell Tumors

Tumors derived from germ cells account for an estimated 90% to 95% of cases of testicular cancer and are by far the most frequent neoplasms of the testis. TGCT can occur in any age: they are rare in infants and toddlers but common in postpubertal adolescents and young men, with subsequently decreasing prevalence with age, which is unusual for solid tumors. TGCT of each age group are derived from different stages of germ cell maturation and have very distinct pathogenesis (Fig. 115.3). TGCT are characterized by a striking morphologic variety, with teratomas mimicking any cell type of the body, including undifferentiated and even extraembryonic elements.[85,86] The majority of TGCTs are extremely radio- and chemosensitive, except the highly differentiated mature teratomas, hence, survival prognosis is excellent and mortality is relatively low.

TGCT Derived From GCNIS. This major group of TGCT, comprising seminomas and nonseminomas, is characterized by the origin from a common precursor lesion GCNIS, previously known as *carcinoma in situ testis*.[87] GCNIS is a prototypic sign of TDS, because of its biological features of an undifferentiated germ cell.

Epidemiology and Risk Groups. In accordance with the origin from the common precursor, the relative distribution of seminomas and nonseminomas is about half and half, but the two main types differ somewhat regarding their age-specific peak incidence. Seminoma peaks around 30 to 35 years of age, while nonseminoma occurs in relatively younger men and peaks around 20 to 25 years. Even if the incidence of testicular cancer is much lower than other cancers (e.g., prostate or lung cancers), TGCT is the most common cancer in young White American men, while among young Black men, it is close second after colorectal cancer.[88] The incidence rates are highest in some areas of Europe (>10/100,000) and lowest (<0.5/100,000) in African and East-Asian populations.[89] The incidence has been rising in recent decades but with marked geographic differences. The highest rates have been seen in Northern and Western Europe, but the incidence has been stabilizing in this region.[89,90] Conversely, steep increases have been seen among men in Southern-Eastern Europe, which previously has been a low incidence area, and among the Latin/Hispanic populations in the Americas.[89]

Cryptorchidism is a strong risk factor for testicular cancer, and approximately 5% of patients with a history of the undescended testis would develop a TGCT. The two conditions have an almost identical pattern of risk factors, consistent with a pathogenetic link between them.[47] Most of the risk factors are operating pre- or perinatally: premature birth, birth weight, birth order, high maternal age or body weight of the mother, neonatal jaundice, inguinal hernia.[91] There is a relative paucity of occupational and adult lifestyle-related risk factors, and no strong associations have been found, except that heavy smokers of marijuana have a slightly increased risk of nonseminoma (but not seminoma).[92] Tall stature during childhood and in adulthood have also been associated with TGCT risk.[93]

Individuals with decreased AGD[12b], developmental abnormalities of the gonads and DSD are at risk of germ cell neoplasia, but the risk is variable depending on the diagnosis, with the mildest forms of DSD overlapping with TDS.[3] Sex chromosome aneuploidy and structural abnormalities of chromosome Y carry the greatest risk of GCT.[50,94] Individuals with AIS are also at risk of TGCT, but those with the complete AIS (usually phenotypic females) rarely develop overt tumors.[95]

Patients with a unilateral TGCT are at increased risk for a tumor in the contralateral testis, especially if the remaining testis is small.[96] Among other phenotypic associations or comorbidities of importance for endocrinologists and andrologists, patients with testicular atrophy and impaired spermatogenesis have increased TGCT risk and should be carefully screened for malignancy.[97,98]

Genetics. TGCT have a relatively high heritability but are characterized by complex polygenic background. The familial risk of testicular GCT is quite strong: brothers and sons of cases have, respectively, 8- to 10-fold and 4- to 6-fold increased risk. However, a

Figure 115.3 Histogenesis of testicular germ cell tumors *(TGCT)* in relation to the normal development of germ cells over the lifetime (shown at the *top* part of the picture). Cell types expressing embryonic pluripotency factors are in *red*. The most common TGCT of young adults are considered a part of testicular dysgenesis syndrome (TDS), derived from fetal germ cells (delayed gonocytes) via the stage of germ cell neoplasia *in situ (GCNIS)*, which progresses to invasive tumors (seminoma and nonseminoma) in young adulthood. Rare TGCTs that are unrelated to GCNIS include infantile germ cell tumors derived from primordial germ cells (PGC) and spermatocytic tumor of the older men, which originates from mature spermatogonia /early primary spermatocytes. *CHC,* choriocarcinoma; *ICM,* inner cell mass; *EC,* embryonal carcinoma; *TER,* teratoma; *YST,* yolk sac tumor. (Updated from Rajpert-De Meyts E, Developmental model for the pathogenesis of testicular carcinoma in situ: genetic and environmental aspects. *Hum Reprod Update.* 2006;12:303–323.)

specific oncogenic driver mutation, similar to *BRCA1* for breast cancer, has never been identified, and this was confirmed by large whole-exome sequencing studies.[99] Invasive TGCT are characterized by polyploidization and a pathognomonic amplification of chromosome 12p.[86] These tumors also develop secondary adapting mutations; gain-of-function *KIT* mutations occur mainly in seminomas, while *KRAS* mutations have been mainly detected in nonseminomas.[100,101]

Genome-wide association studies (GWAS) identified a large number of genetic variants significantly associated with testicular cancer. Among the significant loci and candidate genes, several are associated with germ cell development, *KITLG, SPRY4, DMRT1*, *DAZL*, *PRDM14*, but also several informative loci have implicated the centrosome cycle, telomerase, and DNA-repair pathways.[102,103] It is interesting from the biological point of view that a large proportion of the predisposing genetic markers implicate pathways involved in sex differentiation and germ cell development. The strongest genetic marker, *KITLG*, encodes a tyrosine kinase receptor KIT, which has been long known as essential survival factor for germ cells and for their interaction with Sertoli cells (which express KITLG).

Etiology and Environmental Factors. The etiology of TGCT remains unclear. The changing incidence in well-developed countries, with striking geographic differences, and the epidemiologic association with other components of TDS jointly suggest a predominant influence of environmental factors acting prenatally or in early infancy. This hypothesis is supported by studies of the aforementioned risk factors, a greater risk for brothers than for sons of the cases and by a consistent association of the prevalence rates with the birth calendar year (birth cohort effect) and with the geographic location at birth.[2,90]

The link to early development is consistent with the biological features of the GCNIS, which is similar to fetal gonocytes.[1,9] Clinical and experimental evidence suggest that an imbalance in the hormonal and paracrine microenvironment of the developing gonad, in particular a disturbance of the differentiation and cross talk between germ cells and somatic cells (fetal/perinatal Sertoli cells and fetal Leydig cells), can lead to testicular dysgenesis and arrested development of gonocytes.[1,10,104] Possible mechanisms can be deduced from studies of DSD with specific genetic defects, for example, *AR*, *SRY* mutations, or 45,X/46,XY aneuploidy. But the causative lifestyle or environmental factors that can mimic these effects remain largely obscure. Since a couple of decades, attention has been on environmental endocrine disrupters, but few conclusive results were obtained, except weak associations with maternal exposure to organochlorides and organohalogens.[104a] Further studies in large and well-characterized cohorts are needed to identify the causative factors, and these studies need to take into account the constellation of genetic predisposing variants of the studied individuals, which undoubtedly modulate the risk.

Histopathology and Tumor Markers. The preinvasive GCNIS cells are located inside seminiferous tubules, with usually suppressed

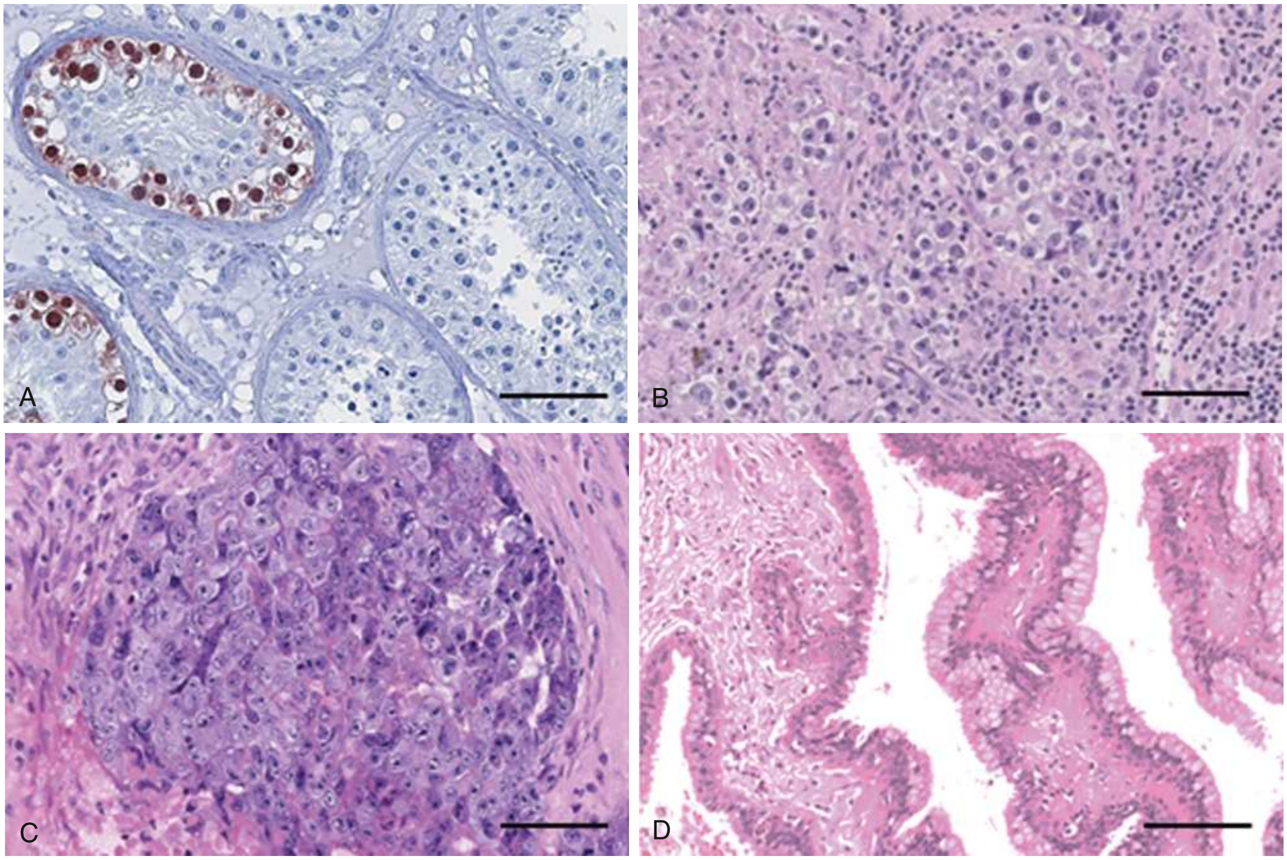

Figure 115.4 Histology of germ cell neoplasia *in situ* (GCNIS) and typical germ cell tumors. **A**, Tubules with GCNIS shown side by side with healthy tubules containing ongoing spermatogenesis. GCNIS cells are stained immunohistochemically for OCT4 (nuclear pluripotency factor). **B**, Seminoma with tumor cells closely resembling GCNIS cells and typical prominent infiltration with immune cells. **C**, Embryonal carcinoma, the undifferentiated component of nonseminomas. **D**, Teratoma, the most differentiated component of nonseminomas, mimicking morphology of somatic tissues. All bars 50 μm.

spermatogenesis, in the place normally occupied by spermatogonia and can be distinguished by large and irregular nuclei (Fig. 115.4). In testes with GCNIS, the tubular structure is usually preserved, but some dysgenetic features are frequently seen, such as undifferentiated Sertoli cells or intratubular hyaline bodies (also visible as microlithiasis in the scrotal ultrasound) (Fig. 115.5). Gonadoblastoma, found predominantly in individuals with DSD, is composed of tumor germ cells (similar to GCNIS cells) intertwined with immature somatic cells resembling Sertoli or granulosa cells, and the tubular structure is usually distorted. The presence of gonadoblastoma or GCNIS depends on the relative degree of virilization of Sertoli cells surrounding the germ cells; the less virilized the cells are, the more likely is the presence of gonadoblastoma-like structures but the two entities can overlap in some patients.[3,87]

GCNIS cells (and to a large extent seminoma tumor cells) share the gene expression profile with a subset of fetal and early infantile gonocytes, which retain embryonic stem cell-related pluripotency markers, such as OCT4/*POU5F4*, NANOG, AP2 gamma/TFAP2C, LIN28, but also express immature germ–cell-specific genes, for example, placental-like alkaline phosphatase (PLAP).[9] This expression profile, normally not present in normal adult germ cells, can be exploited for diagnosis by immuno- or cytochemistry in the adult testis or semen smears.[105]

Seminoma tumor cells resemble GCNIS cells and grow as a relatively homogeneous tumor, usually with a pronounced infiltration by immune cells[106], as shown in Fig. 115.4. Seminoma can secret lactate dehydrogenase (LDH, LD-1), a serum tumor marker used in the clinics. Nonseminomas display a variety of histologic forms, ranging from undifferentiated embryonal carcinoma to mature teratoma (see Fig. 115.4), and can contain clusters of seminoma.[85] Because of this heterogeneity, there is no uniform expression profile, and each component has to be investigated separately.[105] Among nonseminomatous components, two extraembryonic types deserve special note because of their endocrine activity. These are choriocarcinoma, which resembles gestational trophoblast and produces large quantities of hCG, preferentially in a hyperglycosylated form, and yolk sac tumors (YSTs), which are similar in morphology to the embryonic yolk sac and secrete α-fetoprotein (AFP). Both hormones, and LDH are commonly used in the clinics as *biochemical serum tumor markers*, currently indispensable for TGCT diagnosis and staging. However, TGCT rarely occur in pure histologic forms, and the presence of just a few giant cells in a seminoma may be sufficient to detect hCG in serum, hampering the specificity of this marker for nonseminomas.[107] A relatively recently discovered *specific micro-RNA* (miRNA) secreted by malignant TGCT (also in children) are very promising, and commercial assays are under development in several countries.[107,108] Clinical studies suggest that miR371a-3p is currently the most robust marker, but it has a drawback of not being secreted by teratomas.[109,110]

Diagnosis, Staging, and Management. **Preinvasive Lesions.** GCNIS is usually asymptomatic, so diagnosis at this early stage

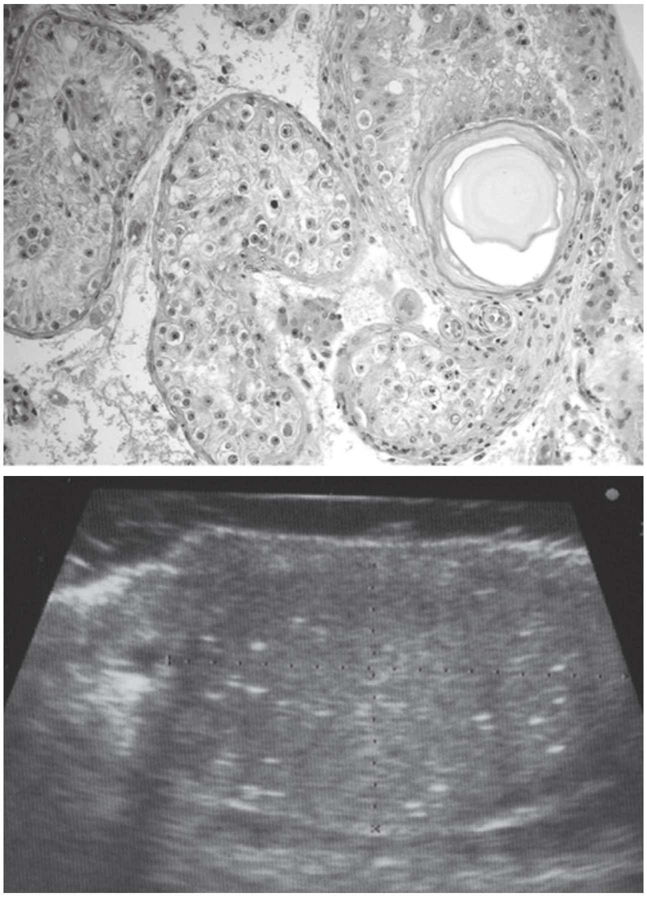

Figure 115.5 Signs of testicular dysgenesis revealed by testicular biopsy or scrotal ultrasound examination. *Top,* Germ cell neoplasia *in situ* and microcalcifications (microliths) in a biopsy of a young adult man. *Bottom,* Ultrasound image of testicular microlithiasis.

is sporadic and happens mainly in men with fertility problems or men with a TGCT who are screened by a contralateral biopsy. Ultrasonographic examination is helpful in many cases. Testicular dysgenesis and GCNIS or incipient TGCT are frequently associated with an irregular echo pattern or microcalcifications (see Fig. 115.5). It is important to remember that ultrasonic microlithiasis can be present in mild disorders or in normal men. A testicular biopsy is indicated only if other risk factors are present, for example, history of cryptorchidism, atrophic testis, and poor semen quality.[111] If a biopsy is performed, technical aspects and immunohistochemical staining for specific markers are important. The presence of genital malformations and abnormal karyotype in a patient with focal microlithiasis is suggestive of a DSD and gonadoblastoma, and these patients require additional genetic investigation.

GCNIS is present in the testis contralateral to a testicular tumor in approximately 4% to 8% of cases. Therefore, many European centers advocate performing a contralateral surgical biopsy simultaneously with an orchidectomy procedure, especially in men with small testes (<12 mL) and history of cryptorchidism, and only in young men below 40 years of age.[96,112] To increase the chance of GCNIS detection, some centers suggest taking two biopsies.[112a] In the United States, contralateral biopsies are usually not performed.

The management of GCNIS depends on a specific situation of the patient. If GCNIS is found in one testicle, without signs of malignancy in the other testis, the patient is treated by orchiectomy and surveillance. If GCNIS is detected in the testis contralateral to a TGCT or is bilateral, low-dose radiotherapy is currently preferred treatment, because the patient can avoid bilateral castration and retain hormone production. Radiation will destroy both neoplastic and normal germ cells, so radiotherapy can be delayed in patients who wish to secure biological fatherhood, and surveillance is practiced in some centers. The patient must be informed about the risk of progression to invasive cancer and should undergo careful monitoring with ultrasound examinations. Chemotherapy is not recommended to treat GCNIS, because it is not successful in a high proportion of patients. However, chemotherapy for the primary disseminated TGCT will decrease the prevalence of bilateral TGCT, apparently by eradicating GCNIS is some cases.[113] All patients with GCNIS should be offered semen analysis and cryopreservation of sperm and they should be monitored after treatment for androgen insufficiency and hypogonadism.

Overt Tumors (Seminoma and Nonseminoma). The most common manifestation of an overt testicular cancer is a scrotal mass, with pain reported by only a few patients. In the differential diagnosis, it is important to distinguish between the TGCTs and other benign malignancies. Other conditions ought to be considered, such as orchitis, epididymitis, hydrocele, varicocele, and inguinal hernia. In a small percentage of cases of TGCT, the initial symptoms are those of metastatic disease. These symptoms are usually uncharacteristic and may include lumbar pain, a palpable abdominal mass, supraclavicular lymph node enlargement, and rarely, pulmonary symptoms.

Ultrasound examination should be performed in each patient with a suspicion of TGCT. Seminomas are more homogeneous, whereas nonseminomas are heterogeneous with frequently occurring calcified hyperechoic areas. Cystic intratesticular lesions are usually benign, while solid and mixed echogenicity lesions are usually malignant.

Prior to treatment, all patients with TGCT should be offered andrological consultation, semen analysis, and cryopreservation of sperm. Endocrinological evaluation of the patient is recommended, including serum testosterone, gonadotropins, and inhibin B, if possible. Differential diagnosis of TGCT requires measurements of circulating tumor markers, which should be performed prior to the histological analysis of the tumor, which though is the decisive diagnostic procedure. Careful staging is necessary in each case to determine the most appropriate treatment strategy.[114,115] Possible spread of disease has to be evaluated by various imaging procedures such as retroperitoneal computed tomography (CT) or magnetic resonance imaging (MRI) scans, bipedal lymphangiography, thoracic radiography, or ultrasonography.[115,116] Histopathological evaluation of the orchidectomy specimen is indispensable for the staging. The important risk factors include tumor size, vascular/lymphatic or rete testis invasion, and the presence of pure embryonal carcinoma.[117] These procedures help classify patients into three stages according to the TNM (tumor, node, metastases) System of the International Germ Cell Cancer Collaborative Group and the American Joint Committee on Cancer[118] presented in Table 115.2.

As far as the treatment of TGCT is concerned, radical orchiectomy remains the primary method. Primary dissection of retroperitoneal lymph nodes (RPLND), previously commonly practiced, is currently performed only in selected patients by nerve-sparing techniques, preferably in high-volume experienced centers.[119] Postsurgical management is variable, depending on the histologic type of tumor, levels of serum markers, stage of disease, and the presence of residual retroperitoneal masses.[112,115,116] For details concerning the treatment of testicular tumors, the reader should consult specialist oncologic literature.

A surveillance strategy is currently preferred for patients in clinical stage I seminoma, which has a good prognosis. Nonseminomas have a relapse rate of around 30% and a poorer than seminoma prognosis, hence, even though surveillance is currently advised,[116,120] some

TABLE 115.2 Stage Grouping of Testicular Germ Cell Tumors According to TNM Classification

Stage 0 (pTis): Germ cell neoplasia *in situ*
Stage IA (pT1, N0, M0, S0): Tumor limited to testis and epididymis
Stage IB (pT2-4): as IA but with vascular/lymphatic, tunica or scrotal invasion
Stage II (any pT, N1-3, M0, S0-1): Metastasis in lymph nodes, serum markers normal or moderately increased
  IIA (N1): lymph nodes <2 cm
  IIB (N2, S1): lymph nodes >2 cm but <5 cm
  IIC (N3, S1): lymph nodes >5 cm
Stage III (any pT, any N, M1, S0-3): Distant metastasis (spread beyond regional nodes)
  IIIA (M1a, S0-1): Spread to non-regional nodes or lung
  IIIB (M1a, S2): as IIIA but high serum markers
  IIIC (M1a-b, S3): distant metastasis to sites other than IIIA, or very high serum markers

M, Distant metastasis; *N,* regional lymph nodes, *pT,* primary tumor; *S,* serum tumor markers (X = unknown, not available).

Lyon: IARC Press; 2016.

centers opt for more aggressive treatment protocol, with one course of adjuvant chemotherapy.[121] Seminomas with increased serum hCG > 200 IU should be treated as nonseminomas.

KEY POINTS

- Seminoma and nonseminoma are the most frequent types of testicular germ cell tumors (TGCT) and occur in young adults.
- These TGCT are derived from germ cell neoplasia *in situ* (GCNIS), which has characteristics of fetal gonocytes (oncoantigens, fetal miRNAs), and this expression profile helps in diagnosis.
- The incidence of GCNIS-derived TGCT depends on ethnicity and geographic location and has been increasing worldwide, consistent with the action of environmental factors acting on genetically susceptible individuals.
- GCNIS is often found in testis biopsies from men with infertility or history of cryptorchidism.
- TGCT are highly curable by radical orchiectomy (most cases) or cisplatin-based chemotherapy regimens in disseminated cases.

The most common therapy of disseminated disease after orchiectomy is a systemic combination chemotherapy with cytotoxic drugs, and the standard first-line regimen is BEP (bleomycin, etoposide, and cisplatin), administered for 3 or 4 cycles, depending on the patient's prognosis.[115,116] Dynamic monitoring of serum markers is obligatory for accurate prognosis and assessment of treatment, especially in metastatic disease. Endocrinological/andrological follow-up should be coordinated with the postsurgery oncological management. TGCTs are in general sensitive to both chemotherapy and radiotherapy and have become a model of a highly curable malignant disease, with more than 80% of patients reaching a sustained complete remission. The majority of relapses occur within 2 years after primary treatment, but some relapse can occur much later, therefore lifetime follow-up is advocated by some centers. In patients with resistance to chemotherapy and poor prognosis, salvage regimens and complex surgery for residual tumors need to be performed in specialized oncology tertiary centers.

Pediatric (Infantile) Germ Cell Tumors

Biological Features. This group includes germ cell tumors of early childhood, also called infantile TGCT. These tumors are diagnosed in boys from birth to 4 years, with occasional cases until 6 years of age, and rare cases even later. No increase in the incidence of childhood TGCT has been observed.[122] The childhood TGCT are not associated with GCNIS and present two main histological types (see Table 115.1): mature teratoma (including dermoid and epidermoid cysts) and pure YST, termed prepubertal type to distinguish them from similar TGCT that occurs in adults.[85] Prepubertal-type teratomas have also been described in very rare cases of young adults. In contrast to GCNIS-associated tumors, there is no isochromosome 12p in the tumor karyotype, which is pathognomonic for TGCTs of young adults. These distinct biological features are consistent with a different pathogenesis of childhood TGCTs, without association with testicular dysgenesis. The childhood TGCT are apparently caused by yet unknown gene aberrations/mutations that affect differentiation of primordial germ cells.[86,123]

Diagnosis and Management. Pediatric teratomas are well differentiated and benign in clinical course. There are no specific markers, so the tumor is diagnosed by its characteristic morphology. YST is malignant and in about 20% of cases is metastatic, so an early diagnosis is important.[124] The most helpful in differential diagnosis is serum tumor marker, AFP. Importantly, neonates have high physiological levels of AFP, which persist until approximately 2 years of age, when they fall to normal "adult" levels (<10 kU/L or around 100 ng/mL), so dynamic assessment of measurements is needed. AFP can also be detected in tumor tissue, together with SALL4 as an additional useful immunohistochemical marker for YST.[125] A novel blood test, based on the detection of GCT-specific miR-371-3 cluster, is promising for diagnosis of YST, but not mature teratomas.[107,123]

Orchiectomy is a treatment of choice for malignant YST, whereas clinically benign tumors, mature teratoma and epidermoid/dermoid cysts, which are never associated with GCNIS, should be treated by testis-sparing surgery. Postsurgical histopathological description of the tumor, possible extragonadal spread, and AFP levels are used to classify each child into a clinical stage, using the staging system recommended by the Children Oncology Group (USA) and World Health Organization (WHO).[84,126] For chemotherapy regimens used to treat children with metastatic YST, the readers should consult specialized pediatric oncology literature.

Spermatocytic Tumor

This very rare tumor (<1% of TGCT in adults), previously called spermatocytic seminoma, is the only TGCT without an extragonadal or ovarian counterpart.[85,86] Spermatocytic tumor occurs in relatively older men, with median age at diagnosis of around 52 to 56 years.[115,127] This tumor is not associated with GCNIS and has a different pathogenesis than tumors of young adults, which are a part of TDS. Spermatocytic tumors grow from clonally expanding mature spermatogonia or early primary spermatocytes through a stage of intratubular clusters of increasingly aneuploid germ cells. Hence, immunohistochemical markers of spermatogonia, for example, MAGE-A4 or SSX, are helpful in differential diagnosis.[105] Spermatogonial proliferation is caused by *de novo* genetic aberrations, including rare gain-of-function mutations in genes promoting survival of spermatogonia, especially in the RAS-MAKP signaling pathway (*FGFR2, FGFR3, PTPN11, HRAS, NRAS*) or large chromosomal gains of chr9 and chr20 combined with a loss of chr7.[128,129] These mutations are associated with aging of germ cells (the so-called "selfish mutations") and if transmitted to next generation by older fathers, can cause severe diseases in children, such as thanatophoric dysplasia, achondroplasia, Noonan syndrome, or Costello syndrome.[128]

The clinical course of spermatocytic tumors is benign and asymptomatic in most cases, and the tumors can grow quite large. Only up to 7% of the patients can either develop metastatic disease or their tumor undergoes malignant transformation to rhabdomyoid sarcoma, and these complications are associated with a poor prognosis.[127] Treatment of choice is radical orchiectomy.

KEY POINTS

- Two rare types of testicular germ cell tumors (TGCT) are not derived from GCNIS: childhood TGCT (malignant yolk sac tumor and benign teratomas) and spermatocytic tumor of older men (median age of diagnosis around 50 years).
- These tumors are treated by orchiectomy, except some benign tumors in children.

Fertility Preservation and Long-Term Effects of Testicular Cancer

Fertility Preservation. Testicular dysfunction and imbalance in reproductive hormones are an important clinical problem, especially in view of the fact that the vast majority of patients with testicular cancer are of reproductive age. Adult patients with TGCT associated with GCNIS and TDS have in general decreased fertility and poor spermatogenesis even before the overt tumor has developed.[130] Abnormalities include smaller testicular volume, elevated serum FSH levels, frequent oligozoospermia, and in some cases microlithiasis in the ultrasonic examination. A variable degree of testicular dysgenesis, undifferentiated Sertoli cells, and hyaline bodies (microcalcifications) are often revealed in the orchiectomy tissue or in a testicular biopsy of the contralateral testicle. The contralateral biopsy will detect GCNIS in 4% to 8% of patients, with the greatest risk in patients with low sperm count and small testis volume.[96,111]

All patients treated for testicular cancer require careful evaluation of their reproductive hormones, spermatogenic capacity, and sexual function, in consideration of their wishes of fatherhood in near or distant future. In many patients, fertility is impaired and signs of Leydig cell dysfunction and testosterone deficiency are common.[130-132] Testicular function in patients with testicular tumors may be further disturbed by treatment, especially if cytotoxic therapy is required in addition to orchiectomy.[115,116,133] Radiotherapy and chemotherapy induce severe and dose-dependent impairment in spermatogenesis and sperm DNA damage. In many patients, treatment-induced azoospermia recovers within 1 to 2 years.[132] However, in many cases, the therapy induces irreversible infertility, especially if the patient undergoes scrotal irradiation for example to eradicate GCNIS.

Even though established chemotherapy protocols should be followed in general, it is important to refine the dosage individually in each patient in order to eradicate the malignancy with least possible damage to the endocrine function. Men treated for testicular cancer require careful counseling about their reproductive function with respect to the chance of recovery of spermatogenesis and fertility, and they should all be offered sperm banking before treatment. Cryopreservation of sperm will allow assisted reproductive treatment if spermatogenesis is affected by the cancer therapy. If sperm banking is not possible due to azoospermia or severe oligoasthenozoospermia, testicular sperm extraction (TESE) may be attempted at the time of orchidectomy ("onco-TESE" or "onco-micro-TESE") with subsequent intracytoplasmic sperm injection (ICSI).[132,134] The success of TESE depends on the size of the tumor (worse in large TGCT) and is greater if the targeted seminiferous tubules are as far from the tumor as possible.[135] Adolescent boys who are unable to produce a semen sample by masturbation can be offered penile vibratory stimulation or electroejaculation, and in experienced centers, TESE can be considered.[136,137]

Fertility preservation in prepubertal children who are subjected to cytotoxic treatment is challenging. In young boys, the attempts to preserve testicular tissue are still experimental but the developing methodology of cryopreservation and inducing spermatogenesis is improving and is increasingly promising.[138]

Long-Term Effects and Quality of Life Issues. The most common types of TGCT affect young adults, adolescents, and children, so long-term effects are a concern for the survivors who have life expectancy of several decades. After cancer treatment, most of the patients should have essentially a lifelong follow-up. In addition to the usual oncology follow-up, all patients should be carefully monitored by an endocrinologist or andrologist for signs of metabolic syndrome and hypogonadism with respect to the possible need for androgen-replacement therapy.[131,133] Metabolic syndrome and a risk of cardiovascular disease are a concern especially in patients treated with chemotherapy or with bilateral testicular cancer. However, the risk of cardiovascular disease is most pronounced in the first period of follow-up and decreases later in life.[139] Survivors of disseminated/advanced TGCT treated with cisplatin-based complex chemotherapy regimens face also increased risk of peripheral neuropathy, hepatotoxicity, and ototoxicity.[140]

Survivors of TGCT have excess mortality compared to the general male population. In a study from Norway, a great majority of excess deaths within 5 years from diagnosis were caused by the testicular cancer itself, but during longer follow-up, 65% of excess deaths were caused by second cancers, primarily gastric, pancreatic, or bladder cancer.[141] A large study reported significant excesses of second non-TGCT solid tumors 30 years after radiotherapy and a 2.7-fold increased risk of leukemia after chemotherapy.[142] The increased risk of secondary malignancies has been noted in numerous previous studies in several countries, causing increasing calls to reduce as much as possible radiotherapy and radiologic imaging diagnostic procedures during the follow-up.[143] In addition to inducing DNA damage and mutations in patients' somatic cells and spermatozoa, the latter potentially transmissible to the next generation;[144] there is some evidence that cytotoxic treatment can cause accelerated development of cellular senescence, resulting in secretion of inflammatory factors contributing to early ageing phenotype in survivors of testicular cancer.[145]

Psychological health issues are also of concern in the survivors of testicular cancer. Reported problems are mainly related to prolonged stress and anxiety, often linked to the reproductive problems and sexual dysfunction, but also unemployment or loss in socioeconomic status. Hence, depending on the individual patient's need, a psychologist or social advisor should participate in the long-term follow-up and care for testicular cancer survivors.

KEY POINTS

- Patients with TGCTs are at an increased risk of infertility and androgen deficiency.
- Cryopreservation of semen should be offered to all patients prior to treatment, and onco-TESE can be considered in some patients.
- The patients require lifelong andrological/endocrine follow-up.

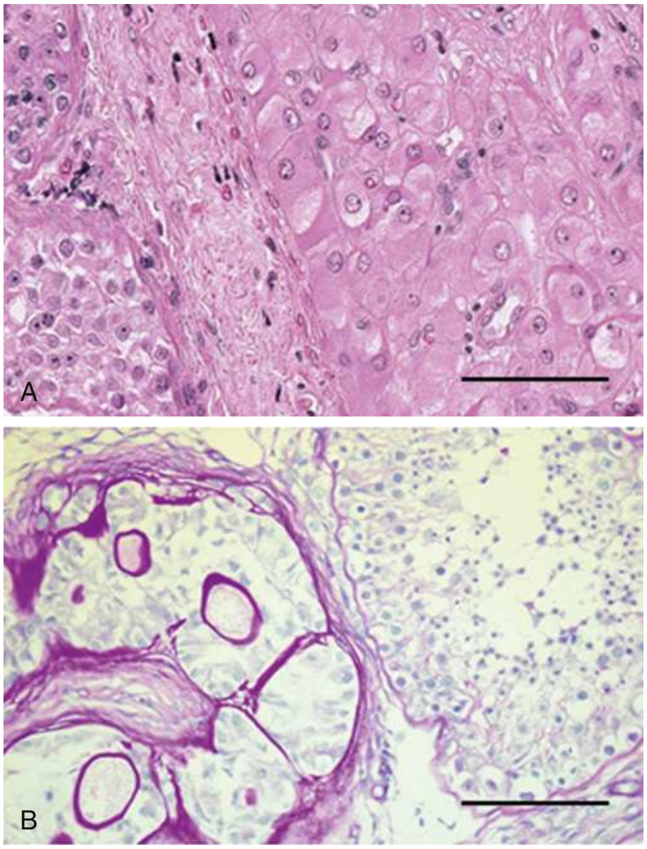

Figure 115.6 Histology of the most common testicular sex cord-stromal tumors. A, Leydig cell tumor in an 8-year-old boy, shown adjacent to preserved seminiferous tubules *(on the left)*. B, Large cell calcifying Sertoli cell tumor isolated from a 12-year-old boy. The tubule with the tumor contains only large pale Sertoli cells and visible calcifications in the lumen. The adjacent normal tubule shows advanced spermatogenesis.

Sex Cord-Stromal Tumors of the Testis

These tumors originate from testicular somatic cells. The classification of sex cord-stromal tumors of the testis according to the WHO[84,146] is presented together with TGCT in Table 115.1. The tumors can occur as pure or mixed types. In contrast to adults—in whom sex cord-stromal tumors are rare and account for 2% to 5% of testicular neoplasms—children develop these tumors in approximately 25% of cases.[112,146] The majority of these tumors (95%) are benign, and some types are a part of specific syndromes.

Leydig Cell Tumors

Histopathology and Genetics. Leydig cell tumors histologically resemble a mass of normal Leydig cells (Fig. 115.6), although malignant tumors can show some cellular atypia often with DNA aneuploidy, mitotic figures, and angiolymphatic invasion.[146] Malignant Leydig cell tumors are relatively rare and have only been reported in adults. Immunohistochemical markers include inhibin A, calretinin, SF-1, melan A, INSL3, vimentin, AR and WT1, AR, chromogranin, synaptophysin, and CD99.[146,147]

Tumors derived from Leydig cells are the most common in the testis besides TGCTs. Leydig cell tumors occur in any age but approximately 20% are found in children between 5 and 10 years of age, and the second peak is in adulthood.[146] There is a perception that the incidence of Leydig cell tumors in adults might have increased in recent decades, but the increase may reflect improved diagnostics of nonpalpable nodules with modern imaging techniques. There is an overlap between Leydig cell tumors, Leydig cell adenoma, micronodules, and florid hyperplasia, most of these belonging to nonpalpable testicular lesions. An extreme example of large Leydig cell nodules is Klinefelter syndrome, although these usually do not progress to malignant tumors. In various disorders of testicular function, including TDS-related cryptorchidism and infertility with testicular atrophy, Leydig cell nodules of variable size are common and their functional insufficiency is often reflected by decreased testosterone/LH ratio,[147,148] whereas patients with overt Leydig cell tumors usually have an increased testosterone/LH ratio and high estradiol.

The etiology of the majority of Leydig cell tumors remains to be elucidated. Genetic defects have been identified only in a small subset of patients. In children with precocious puberty, activating mutations of the LH receptor, *LHCGR* or G proteins can be the cause of Leydig cell tumors.[149,150] In adults with Leydig cell tumors, somatic-activating *GNAS* mutations were identified in a few cases[151] and mutations of germline fumarate hydratase (*FH*) in association with hereditary leiomyomatosis and renal cancer.[152]

Diagnosis and Treatment. The most pronounced symptoms of Leydig cell tumors are in children and young adolescents because of excess of steroid hormones, with precocious puberty often the presenting manifestation (sometimes called testotoxicosis). The typical signs are enlarged penis, pubarche, accelerated growth, skin changes (e.g., acne), and an adult-type odor of sweat. Required hormone profiling in boys with precocious puberty must include serum testosterone, estradiol, LH, FSH, 17-OHP, and androstenedione. Despite signs of puberty, LH and FSH usually remain low because the androgen secretion is gonadotropin-independent.[153] A subset of boys can also have gynecomastia as a result of high aromatase activity in some of the tumors or peripheral aromatization of testosterone. The attending physician should bear in mind that young infants often have physiological transient gynecomastia, obese boys can have pseudo-gynecomastia, and transient gynecomastia can be caused by a quick rise in estradiol at puberty.[154,155]

In adults, adverse hormone effects of a Leydig cell tumor are found in less than half of the patients, most often manifested as gynecomastia, impairment of spermatogenesis, and occasionally sexual dysfunction with loss of libido.[156] Malignant Leydig cell tumors are usually not hormonally active and present as a palpable testicular mass or in about 10% of cases as metastatic disease. Risk factors for metastatic disease include the age >42 years and a large tumor.[148] The ultrasound examination helps in diagnosis in most cases (children and adults), revealing solid well-demarcated hypoechoic lesions, with internal vascularization and occasionally necrosis or cystic areas.[156]

Treatment of Leydig cell tumors is surgical, with testis-sparing surgery recommended for benign tumors. In children, Leydig cell tumors are always benign and should be treated by surgical excision, especially if the tumor is encapsulated. Likewise, in adults, testis-sparing surgery should be attempted if the examination of the frozen preparation does not show signs of malignancy. Malignant tumors have been reported in 10% to 15% of adult patients, and these are usually treated by radical orchiectomy. Testis-sparing surgery can be attempted in isolated and well-demarcated malignant tumors, especially that local recurrence is low (<7%).[148] Adjuvant retroperitoneal lymphadenectomy is no longer recommended as treatment of choice, but some centers practice it in cases with risk factors or when micrometastatic disease is suspected.[148,157] Metastatic tumors, which can appear several years after the initial diagnosis, require salvage surgery and a combination chemotherapy and palliative radiotherapy, but the prognosis is poor.[148,157] Therefore lifelong follow-up of patients with malignant Leydig cell tumors is recommended.

Sertoli Cell Tumors

Histopathology and Genetics. Sertoli cells are the somatic cells in the seminiferous epithelium (sex cord cells) that support differentiating spermatogenic cells. The classification of Sertoli cell tumors according to the WHO[84] is shown in Table 115.1. These tumors are rare (around 1% of all testicular tumors) and are reported in a wide range of age, from 18 to 80 years, but most of them occur in young adults. Sertoli cell tumors are frequently found in association with two distinct multiple neoplasia syndromes, the Carney complex and Peutz-Jeghers syndrome.[146,158]

Isolated Sertoli cell tumors are referred to as *not otherwise specified* (NOS). These tumors occur primarily in adults, are usually unilateral, and occur in descended testes. Juvenile Sertoli cell tumors often showed infiltrative growth into adjacent tissue and considerable proliferative activity, but after surgical excision, no local recurrences or metastases occurred. Histologically, the tumors are composed of sex cord cells with tubular differentiation, frequent lipid vacuoles, and lymphocytic infiltrates, with a subset of tumors hyalinized.[146] Immunohistochemical markers include inhibin, β-catenin, SOX9, SF1, melan A, and WT1.[146] The molecular origin is known only in a subset of tumors, mainly with sclerosing appearance, in which *CTNNB1* mutations causing nuclear accumulation of β-catenin were identified.[159]

In the *Carney complex*, patients have skin myxomas, heart myxomas, typical skin pigmentations, and pituitary, adrenal, and testicular tumors, other tumors can also occur.[158] The testicular tumors typical for this syndrome are *large cell calcifying Sertoli cell tumors* (LCCSTs) that are usually multifocal and bilateral (see Fig. 115.6). The tumors often appear in adolescents and are in most cases benign. Only one malignant case has been reported in association with the Carney complex, whereas malignant course is more frequent in young adult men and in sporadic cases (about 60% of LCCSTs occur sporadically).[84,146] The tumors have characteristic histology, with numerous calcifications, and are typically positive for inhibin and SF1.[146] LCCSTs are usually not hormonally active, although elevated levels of serum inhibin have been reported,[160] but other tumors of Carney complex, including Leydig cell tumors, can cause endocrine manifestations. Genetic loci for Carney complex have been identified on chromosome 2p16 and 17q23-24.[158] The identified germline mutations most often occur in type I-alpha regulatory subunit of protein kinase A, *PRKAR1A*. Inactivating mutations of phosphodiesterase 11A212 *(PDE11A)* and phosphodiesterase 8B213 are associated with bilateral adrenocortical hyperplasia in Carney complex patients. Genetic variation of the phosphodiesterase 11A gene can modify the development of the testicular tumors.[161]

Sertoli cell tumors associated with *Peutz-Jeghers syndrome* are practically exclusive for this syndrome and exhibit a benign behavior. These tumors can be distinguished from those associated with the Carney complex by typical intratubular proliferation, hence are called *intratubular large cell hyalinizing Sertoli cell neoplasia* (LCHSCN). Histological features include prominent basement membrane deposits and annular tubules, and the tumors are usually positive for inhibin and aromatase.[146] Peutz-Jeghers syndrome and the associated tumors are caused by germline loss-of-function mutations in the *STK11/LKB1* gene, encoding a serine-threonine kinase.[162]

Diagnosis and Treatment. Differential diagnosis of Sertoli cell tumors should focus on identification of a possible underlying multicancer syndrome. Clinicians should bear in mind the association with other neoplasms, particularly heart myxomas and adrenal or pituitary tumors in the Carney complex and gastrointestinal tumors in Peutz-Jeghers syndrome, to reach an early diagnosis of these diseases. The patients with Peutz-Jeghers syndrome have a highly increased risk of other neoplasms, especially colorectal, breast, and pancreatic cancers. Patients with the Carney syndrome can usually have spotty skin hyperpigmentation and adrenocortical disease. In addition, the patients with Peutz-Jeghers syndrome often have bilateral gynecomastia, because the associated Sertoli cell tumors can exhibit strong aromatase activity.[163]

Ultrasound examination is helpful, but Sertoli cell tumors have no specific features and can appear as single or multiple masses, either hypo- or hyperechoic, with the presence of large calcifications suggestive of the Carney complex. There are no specific serum tumor markers, but a reproductive hormone profiling should be done, especially in patients with gynecomastia. Final diagnosis is based on the intra- and post-surgery histopathological analysis.

Conservative watchful surveillance management of Sertoli cell tumors is recommended in children, at least until adulthood is reached and sperm banking can be secured, because the tumors are multifocal and bilateral. The follow-up protocols should include ultrasound examinations every 3 months to assess possible changes in size of the lesions and endocrine assessment of testicular function. Growth of the tumors can necessitate orchiectomy. In patients with precocious puberty and/or gynecomastia, aromatase inhibitors and antiandrogens can be used to block estrogen formation and androgen action.

Other Sertoli cell tumors (NOS), which are most often small and well demarcated, usually benign and without adverse endocrine activity, should preferably be treated by orchiectomy or testis-sparing surgery. The prognosis is good, except in exceedingly rare malignant metastatic cases.

Juvenile- and Adult-Type Granulosa Cell Tumors. *Juvenile-type granulosa cell tumors* are rare but are the most common testicular tumors in infants; the diagnosis is usually made before the age of 6 months, sometimes soon after birth.[164] Juvenile granulosa cell tumors have been found in children with ambiguous genitalia and undescended testes, usually with sex chromosomal DSD, primarily XY aneuploidy. The tumors are characterized by the presence of follicles of variable sizes mixed with cord-like structures and are typically positive for inhibin, CD99, SOX9, and FOXL2.[146] In contrast to their ovarian counterparts, testicular juvenile granulosa cell tumors do not show endocrine activity. Juvenile granulosa cell tumors have a benign clinical course and a good prognosis. The treatment should be a part of a multidisciplinary DSD management and may include orchiectomy in selected cases.

Adult-type testicular granulosa cell tumors are extremely rare and occur in adolescents and adults, with mean age of 42 years.[146] These tumors are similar to the ovarian granulosa tumors, which are common in women. Only some of the patients have manifestations of feminization, primarily gynecomastia, resulting from the hormonal activity of the tumor. Most of the tumors are benign, but malignant cases have also been reported. Mutations in *FOXL2* have been described in a subset of male granulosa cell tumors.[165] Treatment is only surgical, with orchiectomy as the primary modality.

Mixed Sex Cord-Stromal Tumors. These rare tumors, which can occur at any age, can contain combinations of Leydig, Sertoli, granulosa, and theca cells and are therefore called *mixed or unclassified sex cord-stromal tumors.*[84,146] These tumors are always benign in children but can be malignant in adults. Most of the patients can be treated by orchiectomy.

Other Testicular Tumors

Testicular Adrenal Rest Tumors

Excessive secretion of adrenocorticotropic hormone (ACTH) in patients with Congenital Adrenal Hyperplasia or Nelson's syndrome (postadrenalectomy status) may lead to the development of testicular adrenal rest tumors (TART).[166] These cells may resemble Leydig cell hyperplasia or tumor and have been hypothesized to originate from persistent fetal Leydig cells or precursors of adult Leydig cells.[167] TART has to be distinguished from Leydig cell hyperplasia and malignant Leydig cell tumors. Histopathological and endocrine evaluation covering both testicular and adrenal steroids and pituitary gonadotropins and ACTH are important to make differential diagnosis.[166,168] Careful endocrine evaluation is necessary to distinguish from TGCT, because TART should not be treated surgically. Some but not all newly appearing TART may regress if appropriate glucocorticoid replacement is initiated, whereas longer-lasting TART does not regress, most likely due to fibrosis and hyalinization. In those rare cases, testis-sparing surgery (nodule enucleation) can be considered.

KEY POINTS

- Testicular tumors derived from somatic cells (sex cord-stromal testis tumors) are rare, except Leydig cell tumors that are considered underdiagnosed and more common than previously thought.
- These tumors can occur at any age.
- Histopathological diagnosis is essential for management planning.
- These tumors are usually benign, and testis-sparing surgery should always be considered.

Secondary Malignancies

The attending physician must be aware that the testis can be a sight of malignancies not originating from testis-specific cell types. In children and adolescents, the most common secondary malignancies involving the testis are acute lymphoblastic leukemia, neuroblastoma, nephroblastoma (Wilms tumor), and rhabdomyosarcoma.[84] In the adults, hematolymphoid malignancies are common and malignant lymphoma (predominantly diffuse large B-cell lymphoma) is the most common testicular malignancy of men older than 50 years.[84] Other malignancies include plasmacytoma, myeloid sarcoma, Rosai-Dorfman disease (histiocytosis), leukemia, myeloid and monocytic sarcoma, and adenocarcinomas of the rete testis. In addition, secondary tumors can metastasize into the testis from other organs, most commonly from the prostate gland, gastrointestinal tract, kidney, lung, pancreas, bladder and urinary tract, and skin (malignant melanoma).

CONCLUSION

The concept of TDS has unified pathogenesis of several male reproductive disorders into one entity, with the underlying cause being an impaired development and paracrine cross talk between multiple cell lineages in the developing testis, resulting in postnatal genital malformations, reduced spermatogenesis, and germ cell cancer. The etiology is multifactorial and polygenetic, with the predominant role of adverse environmental factors acting on genetically susceptible populations and/or individuals. More research is needed to identify the adverse factors in the environment or related to the lifestyle and elucidate the mechanisms of gene-environment interactions, including epigenetic modulation. It is also imperative to increase research efforts to understand the pathogenesis of non-TDS types of testicular tumors and improve their diagnosis and treatment.

Diagnostic tools and therapy of patients with testicular disorders have improved considerably in recent years, but there is a need for more individualized therapy for each patient. Furthermore, most of the patients are young and face long posttreatment life. Endocrinological/andrological participation in a multidisciplinary follow-up team is essential to preserve fertility, prevent late effects of testicular dysfunction, and ensure quality of life of the survivors.

Acknowledgment

The authors wish to thank Professor Niels E. Skakkebæk for his contributions to the previous editions of this chapter.

  Management and Treatment of Advanced Prostate Cancer, 1945
Summary and Future Challenges, 1946

INTRODUCTION

The prostate gland is a hormonally regulated organ that becomes bothersome in some men as they become older. Emerging as part of the normal aging process, benign disease or benign prostatic hyperplasia (BPH) is due to enlargement of the prostate gland and changes in smooth muscle tone. Malignancy or prostate cancer has a different etiology, but also becomes more prevalent as men reach late middle and older age.

Both BPH and prostate cancer have an inestimable impact on the quality of life of patients and their families. The worldwide prevalence of BPH is estimated as 26.2%, that is, nearly 1 in 4 men will suffer from BPH over their lifetime.[1] Worldwide, more than 1.2 million men were diagnosed with prostate cancer in 2018 and there were >350,000 deaths.[2] Australia has the highest age standardized (world) incidence and mortality rates at 86.2 and 10.2 per 100,000 men, respectively. Nearly half of all Australian/American men will develop prostate cancer, and one in four will die from the disease. Although BPH and prostate cancer can occur simultaneously in the aging male prostate, there is no direct relationship between the two pathologies and they are regarded as separate diseases that mainly occur in different regions of the prostate gland (see Fig. 116.1).

The prostate gland is a lobular structure and in 1968, McNeal described the anatomy in terms of four anatomic zones using the urethra as the primary anatomic reference point, that is, peripheral, central, and two transition zones (TZs) (see Ref. 3). The TZ is the site of development of BPH, whereas prostate cancer more commonly occurs in the other anatomic zones.

BENIGN PROSTATIC HYPERPLASIA

Diagnosis

Many men will have BPH; however, if it remains asymptomatic and never causes complications, it is an unnecessary diagnosis. A histological diagnosis of BPH is defined as a hyperplasia of the epithelium, stroma, or both in the periurethral TZ of the prostate. In men aged >80 years old, 80% had BPH at autopsy, whereas no men aged under 30 had histological BPH.[5] A clinical diagnosis of BPH is more complex due to the variation in case definition used by different studies. BPH plays a key role in male lower urinary tract symptoms (LUTS), but it is not the only cause. It is important to distinguish symptoms related to bladder outlet obstruction (BOO) from symptoms related to storage disorders as their cause and treatment are significantly different. The interrelationship between BPH, LUTS, and BOO is represented as a 3-ring diagram, known as Hald's rings, to portray BPH as a syndrome of 3 overlapping, yet distinct entities (see Fig. 116.2). BPH histology, enlargement, obstruction, and symptoms while linked are not always the cause and effect. There are certainly people who will get obstructive symptoms from a modest-sized gland and others who will remain symptom-free with a large gland. As a result, bothersome LUTS due to BPH causing symptomatic BOO are of more concern.[6]

A diagnosis of BPH includes the patient history, examination, and investigations. The **patient history** is a guide to both symptom severity and the likely chance of progression of risks of the sequelae outlined above. It is also critical to identify other potential causes of LUTS unrelated to BPH. These include medical diseases and neurological risk factors. The European Association of Urology (EAU) guidelines state that current medications, lifestyle habits, and emotional and psychological habits must be a part of the history. Reassuring the patient of no definite link between LUTS and prostate cancer is also critical. Common tools used to assess the severity of the patient's symptoms include the **International Prostate Symptom Score (IPSS) and a Bladder diary**. The IPSS is an eight-question screening tool written by the patient and used to screen, diagnose, and track the symptoms of BPH. Seven questions are about symptoms related to BPH and one is related to the patient's perceived quality of life. The **mnemonic** "FUN WISE" can be used to remember the questions where the first 3 relate to bladder function and the last 4 to prostate function (see Box 116.1). A score out of 35 correlates with mild, moderate, or severe symptoms (see Box 116.2).

In addition to diagnosis, the IPSS can be repeated and chart disease progression. For patients whose main complaint is nocturia, a **bladder diary** is a cheap, simple, reliable assessment of the patient's symptoms[7] (see Box 116.3). It can outline other causes for LUTS, track the progress of treatment, and understand the lifestyle causes and impact of the symptoms on lifestyle in a more formal process.

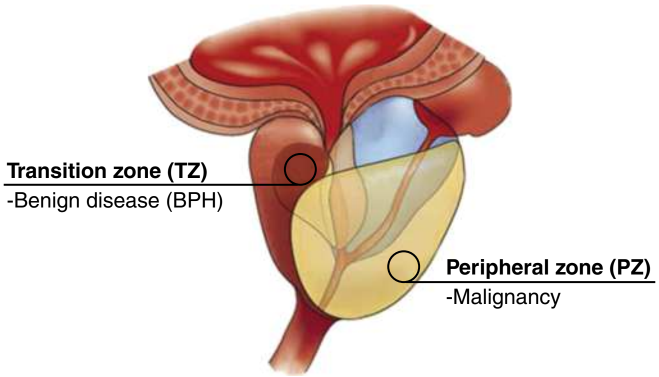

Figure 116.1 **Diagram showing the zonal anatomy of the human prostate gland.** Benign disease most commonly occurs in the TZ, whereas malignant nodules are most prevalent in the peripheral zone (PZ). (Reproduced with permission from Ellem SJ, Risbridger GP. Treating prostate cancer: a rationale for targeting local oestrogens. *Nat Rev Cancer*. 2007;7(8):621-627.)

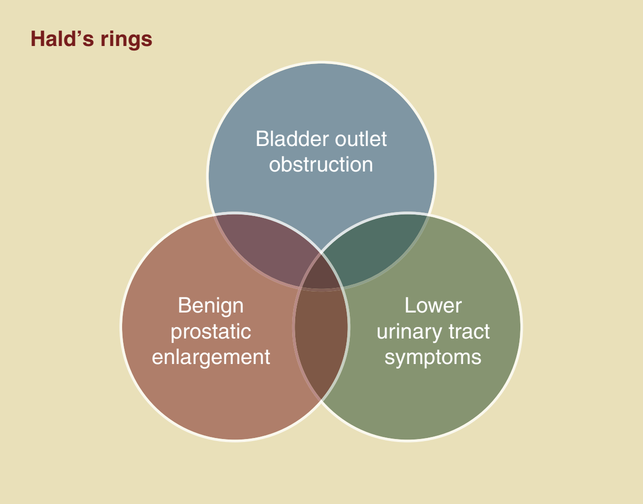

Hald's rings
Bladder outlet obstruction
Benign prostatic enlargement
Lower urinary tract symptoms

Figure 116.2 Hald's rings demonstrate that while linked, BPH, LUTS, and BOO can also occur independently of each other.

BOX 116.1 The IPSS Mnemonic "FUN WISE" Is a Reminder of the Seven Questions to Ask the Patient About Bladder and Prostate Function

F	Frequency
U	Urgency
N	Nocturia
W	Weak stream
I	Intermittency
S	Straining
E	Sensation of incomplete emptying

BOX 116.2 IPSS (Out of 35)

Score	Correlation
0 to 7	Mildly symptomatic
8 to 19	Moderately symptomatic
20 to 35	Severely symptomatic

Examination of the patient should include a lower abdominal examination, an inspection of the genitalia, and a digital rectal examination. Key findings from the abdominal examination would include a distended, palpable bladder and scars indicative of previous surgery. On digital rectal examination, anal tone, prostate size, and texture (e.g. smooth, irregular) should all be assessed. The genital examination is essential to assess for signs of phimosis, lichen sclerosis, meatal stenosis, previous genital surgery, hypospadias, and penile cancer, which can all give obstructive LUTS.

Commonly used **investigations** include flow rate and post-void residual (PVR). This is a simple and cheap test that can give guidance as to the severity of the disease. A maximum flow rate of >15 mL/s is normal and a maximum flow rate of <10 mL/s usually indicates obstruction. A PVR is a highly variable number even on the same day, but a rising residual over time usually indicated progressive disease.[8] To investigate prostate size, ultrasound scan (either transabdominal or transrectal) or MRI can be performed and is a helpful guide to treatment, although size does not always correlate with worsening disease. A test for PSA (prostate-specific antigen) can be conducted and this may be elevated due to the size of the prostate. PSA can also be used to help guide treatment options with some treatments more effective at higher PSAs. It is also useful to detect cancer.[9]

Management and Treatment of BPH

The absence of testicular function from a young age, from either castration or hypopituitarism, prevents the occurrence of BPH in elderly men (<55 years). The link between testicular androgens and BPH led to early attempts to remove androgenic stimulation in BPH patients by castration, a cheap and simple, but understandably unpopular treatment. Antiandrogens and luteinizing hormone-releasing hormone (LHRH) agonists/antagonists block the effects and production, respectively, of androgens. While producing measurable increases in urine flow in ~50% of patients, this form of treatment does have significant associated morbidities, many of which become progressively worse with the longer duration of therapy. These include gynecomastia, osteoporosis, loss of libido, erectile dysfunction, altered serum lipid profiles, decreased insulin sensitivity, and perhaps cognitive decline.

Due to the interrelationship between testosterone and BPH, there has been considerable debate and concern about worsening LUTS and BPH by replacing testosterone. If the testosterone is replaced adequately and supratherapeutic levels are not achieved, testosterone replacement will not make BPH-related LUTS worse.[10] It may even improve the LUTS.[11]

The success of inexpensive and effective medical treatments for BPH has dramatically changed the paradigm for the clinical management of BPH such that this is now first-line treatment for BPH (see Box 116.4).

5-Alpha-reductase inhibitors (such as finasteride and dutasteride) block the conversion of testosterone to the more potent dihydrotestosterone (DHT) and are used therapeutically for the management of BPH.[12–15] This medication induces apoptosis of prostate epithelial cells resulting in reduction in prostate size (by 18 to 28%), PSA level (50%), and symptoms (by 15 to 30%) within 6 to 12 months. The advantages of reductase inhibitors are the reduction in risk of urinary retention by 68% and the risk of requiring surgery by 64%; the amount of bleeding caused during surgery in patients who have been on 5-ARIs is also reduced. The main adverse events caused are loss of libido, erectile dysfunction, decreased ejaculatory volume, and also gynecomastia. One study suggested that they may increase the likelihood of significant prostate cancer, but this was not confirmed in other studies.[9]

Phosphodiesterase-5 inhibitors (PDE-5i) are most widely used for erectile dysfunction and have also been used to treat **BPH.**[16] These medications are thought to cause smooth muscle relaxation in the bladder, prostate, and surrounding arterioles. They do appear to be better

BOX 116.3 A Typical Bladder Diary Used to Chart Patient's Symptoms

Bladder Diary

Please complete your bladder diary each day for three continuous days.

Name: ____________________

URINE					DRINKS		
Date/time AM/PM	Amount in mL	How strong was the urge to go? 0, +. ++	Did you experience accidental leakage?	Comments What were you doing?	Time	Amount in mL or cups	Type what kind?
This "sample" line shows you how to use the diary							
Tuesday 6.30 AM	150 mL	0	No	Got out of bed	7 AM	500 mL 2 cups	Tea

BOX 116.4 Medical Management of BPH

5-Alpha-Reductase Inhibitors

Block conversion of testosterone to the more potent dihydrotestosterone (DHT)

Reduce prostate size, PSA level, and symptoms in 6 to 12 months

Finasteride and Dutasteride

Alpha-Adrenergic Receptor Antagonists

Relax prostate smooth muscle

Improve symptoms but do not reduce risk of urinary retention

Tamsulosin and Silodosin—Selective alpha1 blockers

Combination

5-alpha reductase inhibitor combined with an alpha blocker

Dutasteride/tamsulosin available as a single tablet

than placebo in reducing IPSS—(mean difference [MD] 1.89 lower, 95% confidence interval [CI] 2.27 lower to 1.50 lower; $n = 4293$), and also aid in combination with an alpha blocker (MD 2.56 lower, 95% CI 3.92 lower to 1.19 lower; $n = 193$), but these changes are small.

Alpha-adrenergic receptor antagonists relax the muscle of the prostate and thus improve clinical symptoms. *Alpha blockers* can be selective, particularly targeting the alpha 1a receptor, or they can be nonselective, targeting all alpha receptors. However, the view that alpha blockers work by relaxing the bladder neck appears now to be an oversimplification of their action, since they also appear to work on patients without obvious BOO, and also work without changing the BOO in other men. Tamsulosin and silodosin are the most widely used selective alpha blockers. The nonspecific alpha blocker choice varies widely globally depending on access and funding issues. Silodosin and tamsulosin appear to have very similar efficacy, but the rates of sexual side effects may be higher with silodosin. Alpha blockers do improve symptoms but do not reduce the risk of urinary retention. They can improve symptom scores (IPSS) by 30% to 40%.[9]

Many **herbal medicinal products** are sold for treatment of BPH. These include *Serenoa repens* (saw palmetto), *Cucurbita pepo* L. (pumpkin seed), *Prunus africana* cortex (Pygeum africanum bark), and *Epilobium angustifolium* (Willow herb). The quality of these trials is poor, so it is difficult to make definitive statements based on evidence, about their use.

Combinations of therapies can be even more effective for BPH than single agents. The combination of an alpha blocker combined with a 5-ARI is used widely and dutasteride/tamsulosin is available on single tablet combination. This allows for short-term symptom relief by the alpha blocker and the long-term effects of the 5-ARI. It reduces rates of retention by 68%, BPH-related surgery by 71%. COMBAT TRIAL. It works best in men with PSA >1.4 and prostate size >40 cc. The alpha blocker component can be discontinued after 6 months. Fig. 116.3 demonstrates the effect of placebo versus alpha blocker versus 5 alpha reductase inhibitor vs combination of both.[17]

Surgical intervention for BPH is now considered a second line therapy (see Box 116.5) and the numbers of surgical procedures for BPH have significantly reduced compared to those in the early to mid-1990s. Classical **transurethral resection of the prostate (TURP)** is still the standard treatment to which all others are compared. It can be done with a monopolar system or bipolar system. They are of equivalent efficacy, but bipolar TURP eliminates the risk of water or glycine toxicity. Noted changes include improvement (+162%), a significant reduction in IPSS (−70%), QoL score (−69%), and PVR (−77%). **Laser ablation** is used to vaporize prostatic tissue. It results in the immediate removal of tissue. There are many lasers that perform this task. The most widely used is the KTP 532Hz "Green light laser." These are considered to be safe in patients on anticoagulant therapy although the evidence is weak.[9] This technique is not inferior to TURP in terms of symptom score (IPSS), maximum flow rate, prostate volume reduction, PSA reduction, and quality of life scores. Postoperative storage symptoms may last up to 1 year after photoselective vaporization laser treatment; however, nonsteroidal anti-inflammatory drug (NSAIDs) may address this issue as they cause a cytokine-induced T-cell response.[18]

Laser enucleation is a technique performed endoscopically with the use of a high-power holmium laser. Using the principles of an open prostatectomy, the entire TZ of the prostate is removed by dissecting the pseudocapsule. The holmium laser enucleation of the prostate (HoLEP) is at least as effective as TURP and possibly better in terms of flow rates, symptom score (IPSS), and need for reoperation. This procedure is technically more difficult to perform than other options, which has hindered its take up.

Open prostatectomy is the most invasive option requiring the longest recovery time in hospital, but efficacy is maintained for up to 6 years. It will improve symptoms by 63% to 86% as demonstrated by an improvement in IPSS of 12.5 to 23.3 points. The quality of life scores improves by 60% to 87%. The urodynamics, both PVR and maximum flow, are also improved; the flow rate increases the mean Qmax by 375% (+16.5 to 20.2 mL/s) and PVR was reduced by 86% to 98%.

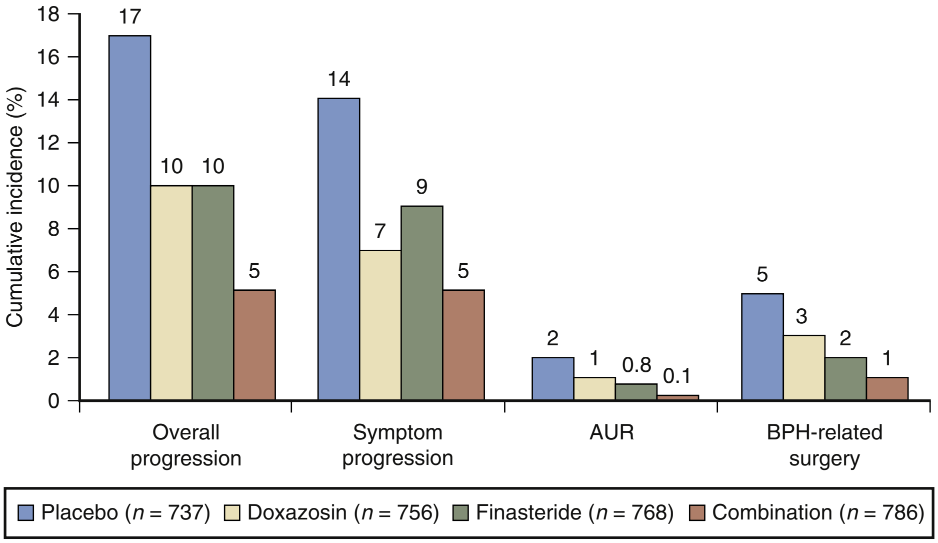

Figure 116.3 MTOPS Clinical Trial results demonstrated that while both alpha blockers and 5ARIs work well, the combination is more effective than individual treatment. *AUR,* acute urinary retention.

BOX 116.5 Surgical Management of BPH

Considered Second Line Therapy

Transurethral Resection of the Prostate (TURP)

The standard treatment—significant improvement in symptoms and post-void residual

Risk of water/glycine toxicity—which causes fluid overload and hyponatremia as a result of the large volumes of irrigation fluid being absorbed

Laser Enucleation

High-power holmium laser used endoscopically to remove the entire transition zone of the prostate by dissecting the pseudocapsule.

Similar efficacy to TURP but it is a technically challenging procedure

Open Prostatectomy

Most invasive option requiring the longest recovery time in hospital, but efficacy is maintained for up to 6 years

Laser Ablation

Laser used to vaporize prostatic tissue

Similar efficacy to TURP, although postoperative storage symptoms may last up to 1 year after.

Urolift, that is, prostatic urethral lift, is a simple procedure where clips are placed in the prostatic urethra, and opening it up has become a widely used treatment.[19] It is less effective in the treatment of LUTS in both the long and short term, but comes with significantly less side effects, particularly less retrograde ejaculation.

Rezum is a relatively new procedure using convective radiofrequency water vapor thermal therapy for LUTS in men with BPH.[20] It appears to be better than a sham procedure in treating LUTS also without the side effect of retrograde ejaculation. However, evidence of its efficacy is limited and there are no data on its role in the prevention of acute urinary retention.

Summary and Future Research

The accuracy of a diagnosis is critical to guiding appropriate intervention for optimal patient outcomes and tools to establish the patient history are essential, in combination with careful physical examination. Sometimes overlooked, the examination of the genital area can be useful in eliminating other causes of bladder symptoms such as the presence of a very tight phimosis.

KEY POINTS

- Important to include physical examination in a thorough work up of patients to diagnose BPH
- There are multiple non-surgical treatments to manage BPH before considering surgery

Future challenges are to improve treatment for patients with BPH. There is a need for surgical procedures that are effective but do not cause retrograde ejaculation, as well as interventions that can be performed under local anesthetic for patients with significant comorbidities. For medical management, the 5-ARIs are ideal for older patients but less so for men for whom libido/sexual issues may be of a concern.

PROSTATE CANCER

Diagnosis and Detection of Localized Prostate Cancer

The increased incidence of the prostate cancer correlates with the introduction of **PSA** testing in the late 1990s. With PSA testing, the lifetime risk of diagnosing prostate cancer in the United States increased from 7.3% to 17%, with a reduction in diagnosis of metastatic disease from 28 to 11 per 100,000 men, and with a concomitant increase in the diagnosis of localized disease.[21]

Two major trials were conducted to determine if PSA-based screening would reduce prostate cancer mortality. The first was the US-based Prostate, Lung, Colorectal and Ovarian (PLCO) trial where 76,693 men underwent annual PSA-based screening for 6 years. The 15-year results indicated that 255 deaths from prostate cancer occurred in the screening arm, and 244 deaths in the control arm, and the differences were not significant.[22] However, the study has limitations as 86% of men in the control arm underwent PSA testing at least once and 46% underwent PSA testing annually. Also, the decision to refer for biopsy and treatment was left up to the individual clinician, and many men with raised PSA were not referred for biopsy or treatment, and hence, no survival advantage could have occurred under those circumstances.

BOX 116.6 Main Benefits and Harms of PSA Testing

Benefits	Limitations
Increased detection of prostate cancer earlier in disease course.	False-positive PSA tests lead to unnecessary biopsies which have potential complications including urinary incontinence, erectile dysfunction, and bowel disturbance.
Reduction in prostate cancer mortality.	The advent of new risk stratification scores may help to avoid unnecessary biopsies following positive PSAs.
	May identify cancers that would not have become clinically relevant in a man's lifetime.

The second trial was the European Randomized Screening trial in Prostate Cancer (ERSPC) which screened 162,387 men, aged 55 to 69 years, from multiple European countries using predominantly 4-year PSA intervals between screens, apart from Sweden that was 2 yearly. The PSA cutoff level was lower at 3 ng/mL, and all participants were mandated to have a biopsy if screening PSA was abnormal. A 16-year follow-up demonstrated a 20% relative risk reduction, with a rate ratio of prostate cancer mortality of 0.80 (95% CI 0.72 to 0.89, $P < 0.001$). The number of men needed to be invited for screening to prevent a prostate cancer death was 570, and the number needed to be diagnosed was 18. The difference in absolute prostate cancer mortality was 0.18% at 16 years.[23] Interestingly, men attending one screening round had a mortality reduction of 25%, but those who attended at least 2 screening rounds had a decrease of 48%, highlighting the need for regular testing. In the Rotterdam cohort the relative risk of metastatic disease and prostate cancer death was 0.46 and 0.48, respectively, in favor of screening, suggesting that in some cohorts the benefits of prostate cancer screening in reducing metastasis and death may be greater.[24]

Nonetheless, **harms of screening** persisted (see Box 116.6), namely, false-positive PSA tests leading to unnecessary biopsies, transrectal biopsies potentially leading to complications such as urosepsis, and treatments leading to morbidity such as urinary incontinence, erectile dysfunction, and bowel disturbances. Risk mitigation strategies were researched to reduce the harms associated with screening, without compromising the benefits. These included improved diagnostics utilizing multiparametric prostate magnetic resonance imaging (mpMRI), altered biopsy methods (transperineal biopsy), and increased reliance of monitoring low-risk prostate cancer (active surveillance [AS]) rather than subjecting patients to definitive therapies of surgery and radiotherapy.

The use of **multiparametric prostate magnetic resonance imaging (mpMRI)** was included in recent updates of the EAU and American Urological Association guidelines, with validated risk stratification using PIRADS (Prostate Imaging-Reporting And Data System) scoring, prior to a patient's first biopsy.[25,26] The mpMRI of the prostate gland allows identification of a focal lesion that could more accurately be targeted at biopsy, as well as the potential of avoiding biopsy in those deemed unlikely to harbor clinically significant disease, defined as Gleason ≥7 or International Society of Urologic Pathologists (ISUP) Grade Group ≥2. A systematic review reported that prebiopsy prostate mpMRI reported as PIRADS 1 or 2, and hence defined as normal, has a negative predictive value (NPV) of 90.8% for ruling out prostate cancer grade group ≥ 2. The NPV for ruling out Gleason Grade ≥ 3 was 97%. This avoids biopsy in 30% of cases and reduces the detection of low-risk prostate cancer that may not require immediate therapy in 18% of men.[27] The PROstate Magnetic resonance Imaging Study (PROMIS) study was a multicenter, paired-cohort, confirmatory study to test the diagnostic accuracy of mpMRI prostate against a standard transrectal ultrasound guided biopsy of the prostate using a reference standard of a transperineal mapping biopsy. Seven hundred forty men were enrolled, with cancer identified in 71% of cases, and clinically significant cancer in 40%. mpMRI prostate was more sensitive (93% vs 48%) but less specific (41% vs 96%) compared to transrectal ultrasound (TRUS). However, the use of mpMRI to triage patients would have allowed 27% of men to avoid a biopsy, while missing only 5% of clinically significant cancers.[28] The other major study was the PRECISION study, where men were assigned to mpMRI prior to biopsy, and compared to the previous paradigm of a systematic TRUS biopsy. In this study, 28% of men avoided a biopsy, and more clinically significant cancer was detected in the mpMRI arm (38% vs 26% $P = 0.005$), with a reduced detection of clinically insignificant disease.[29]

Several authors have considered whether **systematic biopsies** should still be performed in the presence of an mpMRI visible lesion that could be specifically targeted. Miah et al. demonstrated that 43.1% men were diagnosed with clinically significant prostate cancer, with 41.1% able to be diagnosed solely on the target cores alone and only 0.8% on the nontargeted systematic cores exclusively. Like PROMIS the definition of clinically significant disease was Gleason score $\geq 4 + 3 = 7$, or any core ≥6 mm in length.[30] Another study used a definition of clinically significant prostate cancer as Gleason $\geq 3 + 4 = 7$ to detect patients with clinically significant disease and a visible PIRADS 4/5 lesion at mpMRI. They showed 9% of patients would have had been undiagnosed if a systematic biopsy had not been performed, but in patients with Gleason $\geq 4 = 3 = 7$ this was only 1%.[31] Similarly, Hanna et al. demonstrated that 16% of clinically significant prostate cancers would be missed by avoiding the systematic biopsy.[32] The likelihood of missing the diagnosis of a clinically significant cancer decreased with increasing Likert/PIRADS score. The more visible and larger lesions were reliably sampled using target biopsies alone, but systematic biopsies were required to ensure cancers were not missed in the smaller PIRADS/Likert 3 and 4 lesions. To improve the accuracy of biopsies, computer software was developed to fuse the mpMRI images to the ultrasound images seen at the time of biopsy. However, trials failed to show superiority of these computer software platforms over visual co-registration, otherwise known as cognitive fusion. Hamid et al. reported that both techniques diagnosed 90% of clinically significant cancers and 10% were missed by cognitive fusion detected using software assistance and vice versa.[33] Yaxley et al. did not demonstrate superiority of an in-gantry mpMRI guided biopsy to cognitive fusion.[34]

There is emerging interest in performing **transperineal biopsies (TPB)** rather than transrectal biopsies. PROMIS compared TRUS biopsies to mapping transperineal biopsies, and showed that of the men diagnosed with Gleason 6 disease at TRUS, 81% harbored Gleason $3 + 4 = 7$ cancer at TPB and 11% Gleason $4 + 3 = 7$. Reliance on TRUS biopsies, especially in those without a clear mpMRI target, risks misclassifying the patient, leading to undertreatment.[35] Comparison of the results of TRUS to TPB vs prostatectomy specimens also demonstrated the superiority of TPB in predicting final surgical histopathology outcomes.[36] Together with a reduced sepsis rate by avoiding the rectal flora during a transrectal biopsy, TPB is emerging as the preferred method of prostate biopsies in many countries, albeit with a slightly higher rate of temporary urinary retention and erectile dysfunction (24% to 34%), hematuria (20% to 70%), and hematospermia (50% to 90%), which may occur in patients undergoing biopsy regardless of the technique used.[37]

KEY POINTS

- PSA is useful for screening in order to assist in the early detection of prostate cancer but mpMRI should be utilized before consideration is given to a biopsy

BOX 116.7 Localized Prostate Cancer Management

Active Surveillance

Includes

- Regular PSA assessment (3 to 6 monthly)
- Multiparametric MRI (1 to 3 yearly)
- Repeat biopsies (1 to 3 yearly) with treatment reserved for those patients who demonstrate disease progression

For low- or intermediate-risk localized prostate cancer

Radical Prostatectomy (RP)

Removal of prostate with adjoining seminal vesicles, with a vesicourethral anastomosis +/– pelvic lymph node dissection

For low-, intermediate-, or high-risk localized prostate cancer

Radiotherapy

Radical external beam radiotherapy

Low-dose rate or high-dose brachytherapy

For low-, intermediate-, or high-risk localized prostate cancer

Can be administered with or without neoadjuvant/adjuvant androgen deprivation therapy

Androgen Receptor–Signaling Inhibitors (ARSIs) or Chemotherapy with Docetaxel

Can be considered in those with high-risk, localized prostate cancer

Management and Treatment of Localized Prostate Cancer

Based on the risk assessment of the patient following biopsy, treatment recommendations are made (see Box 116.7). Those with **low-volume, low-risk disease** (Gleason score 6, ISUP grade 1) remain at low risk of disease progression, and **AS** is a popular method for managing patients, avoiding overtreatment, and minimizing treatment-related morbidities, first popularized by Klotz et al.[38] The Prostate Testing for Cancer and Treatment (ProtecT) study compared active monitoring, radical prostatectomy (RP), and external beam radiotherapy for the treatment of localized prostate cancer, in 1643 men. There were only 17 prostate cancer–specific deaths in this relatively low-risk cohort, 8 in the active monitoring arm, 5 in the surgery group, and 4 in the radiotherapy group ($P = 0.48$). Metastases did develop more frequently in the active monitoring arm (33, 13, and 16 men, respectively, $P = 0.004$).[39] However, the group demonstrated reduced morbidity from the monitoring approach across the important domains of urinary, bowel, and sexual function.[40] A recent meta-analysis of 26 AS cohorts with relatively short follow-up (3.5 years) demonstrated 0.1% risk of prostate cancer death and metastases, and with 8.8% of men undergoing active treatment per year based on progression on biopsy, PSA levels are based on patient anxiety. The Prostate Cancer Intervention versus Observation Trial (PIVOT), comparing surgery to observation, demonstrated no difference in all-cause mortality after a median of 12.7 years, in men diagnosed with low-risk disease but with greater morbidity in the treatment arm.[41] As such, all studies demonstrated a low risk of prostate cancer death, with improved quality of life for patients with AS compared to definitive therapy. Surgery has higher risks of urinary incontinence and erectile dysfunction, while radiation has higher incidence of urinary and bowel bother, and urethral stricture disease with the incidence of Grade 3 toxicities on the order of 6% to 7% with a rare incidence of serious complications, such as fistulae requiring invasive reconstructive surgery to manage.[42–44]

KEY POINTS

- Prostate cancer can run an indolent course and not all tumors require active therapy. In well selected low risk patients managed with active surveillance, cause specific survivals are 99% at 10 years.

Although **AS protocols vary,** most would include a regular assessment of serum PSA (3 to 6 monthly), multiparametric MRI (1 to 3 yearly), and repeat biopsies (1 to 3 yearly) with treatment reserved for those patients who demonstrate disease progression, which is ~50% at 10 years. Biopsies are currently still required, as mpMRI prostate can miss the occasional high-risk prostate cancer, although whether or not missing a small cancer affects long survival remains unclear. Chu et al. identified that the NPV of mpMRI was 79.5% in patients managed with AS, and as low as 65.5% in those with a normal mpMRI prostate but with a PSA density (serum PSA/prostate volume at mpMRI) > 0.15 ng/mL/cm^3. Therefore, biopsy remains essential in the management of men with AS.[45] However, using a protocol omitting biopsy unless mpMRI identified abnormalities, 71.8% of men remained on AS at 5 years. This rate was lower in men with PIRADS 4 or greater lesions noted on mpMRI or those with secondary Gleason pattern 4 (ISUP ≥2) in their biopsies. There were no deaths from prostate cancer, and only 1.2% of men developed metastatic disease, highlighting the feasibility of this approach.[46]

In men with **intermediate- or high-risk prostate cancer**, treatment is indicated, due to the increased risk of prostate cancer metastases and mortality with observation. The standard whole-gland treatments to consider are **RP as well as radiotherapy (RT)** options such as low-dose rate brachytherapy, high-dose brachytherapy, and external beam radiotherapy with or without the neoadjuvant and adjuvant use of androgen deprivation therapy (ADT). Unfortunately, no appropriately conducted randomized controlled trials (RCTs) have been conducted to establish superiority of one technique over another. A recent review comparing surgery to RT demonstrated the risk of overall survival (hazard ratio [HR] 1.63) and prostate cancer–specific survival (HR 2.08) was higher with surgery. It was supported by a Swedish study demonstrating similar outcomes, but whether these differences reflect selection bias remains unclear and possible.[47] A recent multidisciplinary systematic review of 30 studies comparing RP +/− salvage RT to RT +/− ADT reported 27 studies showing an overall and prostate-specific survival advantage for surgery.[48] The improvement in overall survival was estimated as 10% to 28% and cause-specific survival ranged from 4% to 8%, with greater sexual dysfunction and urinary incontinence in the surgical arm, compared to worsening bowel toxicity after RT.[49] It appears that the contemporary management of higher-risk patients with radiotherapy must include the use of ADT and not just RT alone.[50] Further analysis of 4 RCTs noted an advantage of long-term ADT over short-term ADT with improvements in overall and cause-specific survivals in those patients with higher-risk disease.

In addition, studies demonstrated that the addition of a low-dose **brachytherapy** boost to standard RT + ADT improved the biochemical-free survival from 73% to 83%, with improved overall and cause-specific survivals in nonrandomized studies. However, this combination was associated with worsening morbidity in the Androgen Suppression Combined with Elective Nodal and Dose Escalated Radiation Therapy (ASCENDE-RT) trial with grade 3 genitourinary toxicities of 18.3% compared to 5.2%.[51] Whether this provides equivalent care compared to surgery remains unclear, but a recent study demonstrated a superior overall survival outcome of RP +/− salvage RT compared to EBRT+ADT+BT with HR 1.22.[52] Further advances in radiotherapy techniques include strategies to dose escalate, hypofractionation, and the prophylactic irradiation of pelvic lymph nodes in higher-risk patients

BOX 116.8 Robotic Surgery vs Open Radical Prostatectomy

Small but significant advantage of robotic over open surgery, with regard to erectile dysfunction (68 vs 74%).

No difference identified in:

- Incontinence
- Sexual dysfunction
- Positive surgical margins
- Oncological outcomes

and ongoing RCTs should assist in determining the value and safety of these newer radiation techniques. Local control of the cancer remains crucial in the delivery of radiotherapy for localized prostate cancer because local failure was associated with reduced overall survival (HR 1.7), prostate cancer–specific survival (HR 3.1), and metastasis-free survival (HR 1.92).[53]

RP is surgery that removes the prostate with adjoining seminal vesicles, with a vesicourethral anastomosis +/− pelvic lymph node dissection (PLND). The EAU guidelines recommend an extended PLND in **high- and intermediate-risk prostate cancer**, but the therapeutic benefit of this strategy remains unclear. A recent meta-analysis has demonstrated that while pelvic node dissection improves local staging, there was no difference in cancer-specific or overall mortality comparing PLND vs no PLND. In addition, comparing a standard PLND to an extended PLND demonstrated an improved biochemical relapse free rate in some but not all studies. Furthermore, this did not translate into an overall or cause-specific survival advantage and there was a rise in complications by increasing the rate of pelvic lymphocele formation.[54] Of those who demonstrated pathologically involved pelvic nodes, 10-year biochemical recurrence–free survival was 28% to 56%, and cancer-specific survival was 72% to 98%. As such, pelvic node involvement at surgery does not always translate to a poor outcome for patients and can be managed by observation, salvage radiotherapy, or ADT with some evidence to suggest an improved outcome for salvage RT together with ADT compared to ADT alone or observation.[55,56]

Another area of controversy within Urology is the role of **open versus robotic RP** with the latter now the dominant technique without significant evidence confirming benefit (see Box 116.8). The A prospective, nonrandomized comparative trial, LAParoscopic Prostatectomy Robot Open (LAPPRO) study compared the functional and oncological outcomes between open and robotic RP after 2-year follow-up. At 24 months, there was a small but significant advantage of robotic surgery over open RP, with regard to erectile dysfunction (68 vs 74%), and a small but not statistically significant advantage of open surgery over robotic surgery with regard to incontinence (16 vs 19%) and no oncological differences were identified.[57] In the only RCT comparing the techniques, there was no difference in incontinence rates, sexual dysfunction, or positive surgical margins. The conclusions reached by the authors were encouragement for patients to choose an experienced surgeon they trust, with whom they have a rapport and who has documented satisfactory outcomes, rather than choosing a specific technique.[58]

Biochemical recurrence can occur after either definitive treatment for prostate cancer. **Salvage therapies** would include RT +/− ADT after surgery and RP +/− ADT after radiotherapy. Adding salvage therapies increases patient morbidity, with patients potentially experiencing the side effects of androgen deprivation, but both salvage surgery and radiotherapy increase the risk of urethral stricture disease and urinary incontinence. The effect or size of the biochemical relapse as a risk factor for prostate cancer mortality was highly variable. A recent meta-analysis demonstrated that the effects were more pronounced if patients had a PSA doubling time of < 12 months (especially if < 3 months), a shorter interval to biochemical failure, and increasing Gleason score pathologically. It has been proposed that not all men with biochemical recurrence should be treated equally, as a low-risk patient may not benefit from salvage therapies and those with high-risk disease may fail with distant disease and may need ADT as well as possibly salvage local treatments. Those who have a persistently detectable PSA after surgery (as opposed to an undetectable PSA that subsequently rises) are at a higher risk of metastasis (HR 3.59), death (HR 1.86), and cancer-specific death (HR 3.15).[59] These patients at higher risk appear to benefit from the addition of ADT to salvage radiotherapy, especially at presalvage radiotherapy PSA of ≥0.7 ng/mL, high-grade disease, and positive surgical margins.[60] This was proven by the RTOG 9601 and GETUG 16 studies, while a recent Japanese study confirmed that salvage RT+ ADT prolongs time to treatment failure compared to ADT alone in this setting (HR 0.56).[61] The duration of ADT was examined and is reflective of risk factors, as those at high risk should be on life long or prolonged (3 years) ADT, those with 1 to 2 risk factors required < 12 months of ADT, while those without risk factors did not require ADT.[62]

The **standard of care of managing biochemical recurrence** after definitive treatment for prostate cancer is based on data from trials utilizing standard imaging techniques of nuclear bone scan and computerized tomography (CT) chest abdomen and pelvis that has extremely poor sensitivity especially at low PSA values. Improved imaging may provide the opportunity of personalized care and metastasis directed therapy, potentially avoiding the use of salvage treatments to the bladder neck region or the use of ADT, both of which carry additional toxicities. **Prostate-Specific Membrane Antigen (PSMA)** is a transmembrane protein on the cell surface of prostate cells that is overexpressed in prostate cancer. Both antibodies and small molecules that bind to PSMA were developed and radiolabeled with 68 Ga to allow nuclear **positron emission tomographic imaging (PET).** A recent meta-analysis demonstrated that the likelihood of a positive **PSMA PET scan** was 33% at PSA < 0.2 ng/mL, 45% with PSA 0.2 to 0.49 ng/mL, 59% for PSA 0.5 to 0.99 ng/mL, 75% for PSA 1.0 to 1.99 ng/mL, and 95% for PSA > 2 ng/mL.[63] Interestingly, the distribution of the PET avid lesions was highly variable. Only 28% of lesions were in the prostate bed, but 38% in pelvic lymph nodes, 13% in extra pelvic lymph nodes, 22% in bones, and 5% in distant organs. As such, only the 28% destined to fail in the prostate bed may benefit from salvage radiotherapy to that location, and if treatment were confined to those patients, morbidity could potentially be reduced. Several studies reported on the PSMA PET imaging results compared to histological verification of lesions and on a per-lesion basis; the sensitivity was 75% sensitivity 99%, respectively. However, 68 Ga PSMA PET can miss local recurrences due to the activity of the tracer in the bladder urine, and PSA responses do occur with salvage radiation in patients with a negative PSMA PET in the prostate fossa.[64] Additional reasons could also include a low-grade cancer recurrence and the fact that the spatial resolution of the PET tracer can miss microscopic lesions. However, detecting disease recurrence outside the prostate fossa changed salvage radiotherapy planning in 41% of men with PSA levels 0.2 to 0.59 ng/mL.[65] There are now several published series on metastasis directed therapy, including **stereotactic ablative radiotherapy (SABR)** to involved nodal or bony disease, or less commonly salvage lymph node dissection. While early disease control is promising, the likelihood of PSMA PET of missing microscopic nodal disease would suggest that this would delay rather than avoiding therapy in most patients. However, a meta-analysis of major international trials (Observation vs Stereotactic Ablative Radiation for Oligometastatic Prostate Cancer [ORIOLE]; Pilot Study of patients with Oligometastases from Prostate cancer treated with STereotactic Ablative Radiotherapy [POPSTAR]; Surveillance or metastasis-directed Therapy for OligoMetastatic Prostate cancer recurrence [STOMP]) has shown that local control of disease is reported at 93% to 100%, with low toxicities from SABR with 8% grade 2 toxicities, and only 1% grade 3 toxicity.[66] Studies have also compared **extended nodal radiation (eNRT) therapy** to SABR with fewer recurrences with eNRT, but higher toxicities.[67] Studies have also looked at **salvage lymph node dissection** with 5-year biochemical recurrence–free survivals ranging from 6% to 31%, highlighting that if a node dissection was being considered, a wide dissection would be required due to the high likelihood of more extensive nodal disease than detected on PSMA PET.[68] Unfortunately, the rates of grade 3 complications range from 10% to 20% and can include lymphocele formation, ureteric injury, pelvic abscesses, and venous thromboembolism. Given the lower complication rates of SABR, and the fact that in most cases sLND does not lead to long-term cure, the use of salvage nodal surgery is used with extreme caution and ideally as part of a clinical trial.

The management of localized prostate cancer has always relied on whole-gland therapy, with the understanding that this may represent significant overtreatment in some men, also leading to morbidity and loss of quality of life. An emerging treatment is the use of **focal therapy**, the targeted destruction of prostate cancer within a specific region of the prostate, identifiable on mpMRI prostate and PSMA PET scanning. This would spare the rest of the prostate gland, potentially reducing side effects and morbidity while effectively treating the index tumor, namely, the tumor of the greatest grade and size. In order for focal therapy to be effective, the index tumor needs to be identifiable ideally on both mpMRI prostate and PSMA PET scan, and targeted biopsy of this region confirms cancer with the rest of the prostate demonstrating benign changes, or at worse low-volume, low-grade cancer that could be managed by AS. The treatment must be equally effective as whole-gland therapy, be proven to have less side effects, and potential salvage therapies, for example, surgery or radiotherapy should not be impaired by the focal treatment. At this stage robust long-term data are not available and these treatments should be considered experimental and ideally conducted within a clinical trial. Several treatment techniques have been tried including hemigland or quadrant ablation, or ablation targeted to the lesion with a 5 to 10 mm safety margin. Different energy sources have also been tried including **high-intensity focused ultrasound (HIFU), irreversible electroporation (IRE),** interstitial laser, low-dose rate brachytherapy, photodynamic therapy, and cryotherapy with no energy source being proven to be superior to another.[69] The best studied of these techniques at this time are HIFU and IRE.

HIFU is delivered noninvasively, transrectally, under ultrasound guidance in order to ablate the prostate tissue by both thermal and mechanical effects. A recent systematic review demonstrated that only 8% of patients having repeat biopsies harbored clinically significant disease, subsequently needing additional therapies. Functional outcomes were satisfactory but varied considerably due to differing definitions of erectile dysfunction and incontinence, highlighting the need for international standards for follow-up post treatment and assessment of functional outcomes. A further study reported that 83% of patients had infield negative biopsies with 13% having *de novo* out of field clinically significant disease at 12 months follow-up. Urinary symptoms returned to baseline by 3 to 6 months, and sexual function returned to baseline by 12 months.[70] Several studies showed that salvage RP is safe and feasible after treatment, but oncological follow-up is short and difficult to compare with surgery in treatment naïve patients. In one study there was a 38% positive margin rate, 17.6% required salvage radiotherapy, 20.6% developed biochemical recurrence. 91.2% of patients were continent but there was still a significant decline in the International Index of Erectile function scores post treatment.[71] Another study reported an 83% continence rate and only a 48% progression free survival at 48 months post salvage surgery, identifying that suboptimal outcomes may occur after failed focal HIFU requiring salvage surgery.[72]

Irreversible electroporation (IRE) involves using pulsed electric fields to create destabilization of the cell membrane, causing excessive cell membrane permeability, leading to disruption of osmotic balance within the cell and subsequent cell death, but avoiding harmful thermal effects. Theoretically, damage to surrounding structures such as the external sphincter, rectum, and neurovascular bundles is minimized. A review of 123 patients demonstrated infield recurrences in only 2.7% to 9.8% of patients, failure-free survival of 96.75%, metastasis-free survival of 99%, and overall survival at 100%. 98.8% remained pad free and 76% had no change in erectile function, with only 7% having complete erectile dysfunction. Given these promising short-term oncological and functional outcomes, together with improved imaging techniques, further evaluation of these techniques and developing an RCT comparing focal therapy to whole-gland therapy would be important in the coming years.[73]

Diagnosis and Detection of Advanced Prostate Cancer

Some men develop metastases after failing local treatment with surgery or radiation therapy and disease progression is detected biochemically or radiologically. **Biochemical recurrence** is defined as an elevation in serum PSA. The sensitivity of PSA in this setting is improved because removal of the prostate or radiotherapy to the prostate reduces the amount of noncancer PSA present. If there is no evidence of disease on conventional imaging with CT scan and Tc-99 whole body bone scan (WBBS), this is termed **M0 prostate cancer**, and treatment decisions are based on the PSA level. If disease is present on conventional imaging, it is termed **metastatic prostate cancer.**

Men with a low PSA velocity and long PSA doubling time on average have a delayed onset of symptomatic prostate cancer. In this case the toxicity of treatment must be balanced against the risk posed by prostate cancer. In older men, there is a proportion of men who will never develop symptomatic disease and can avoid any treatment at all. Regular follow-up with PSA testing is required in this setting to ensure that PSA velocity and doubling time do not change and switch the balance in favor of treatment.

Some men will not undergo treatment of localized prostate cancer because of comorbidities or age. These men will be followed with

BOX 116.9 Advanced Prostate Cancer Management

Androgen Deprivation Therapy

Gonadotropin-releasing hormone (GnRH) agonists (goserelin, leuprorelin, diphereline)

GnRH antagonists are also available (degarelix, relugolix)

Most men initially respond to ADT, but inevitably, patients develop castration-resistant prostate cancer (CRPC).

Androgen receptor–signaling inhibitors (ARSIs)

Abiraterone, enzalutamide, apalutamide, and darolutamide

Improve survival in men with CRPC and recently shown to improve survival in high-risk, castrate sensitive prostate cancer (CSPC)

Chemotherapy

Taxane Chemotherapy

Doctetaxel—*Improves overall survival* in CRPC and CSPC

Cabazitaxel—*Used subsequent to docetaxel and ARSIs*

Personalized therapy

Treatment based upon genomic abnormalities within a particular tumor

Poly-ADP ribose polymerase (PARP) inhibitors—*Olaparib*

AKT-signaling inhibitors—*Ipatasertib*

PSA testing and commenced on ADT, based on PSA level, velocity, and doubling time. This group of men will also be designated as having M0 prostate cancer. Metastatic disease at diagnosis ***(de novo metastatic disease)*** occurs in some men and in this situation, it is necessary to treat all sites of disease.

Management and Treatment of Advanced Prostate Cancer

The most important target for treatment of prostate cancer remains testosterone-driven growth of prostate cancer cells. **ADT** has been the cornerstone of treatment of advanced prostate cancer for nearly 80 years.[74] This was initially achieved by a surgical orchidectomy but the advent of 3 or 6-monthly subcutaneous or intramuscular administered gonadotropin-releasing hormone (GnRH) agonists (goserelin, leuprorelin, diphereline) has removed the need for surgery and allowed intermittent therapy for patients who respond well to treatment but are troubled by side effects.

GnRH antagonists are also available (degarelix, relugolix) and have several advantages over **GnRH agonists.** They cause a rapid fall in testosterone rather than the spike in testosterone responsible for painful disease flares seen in patients with bone metastases treated with GnRH agonists. Degarelix is given by monthly injection and has limited long-term use, but relugolix is a newer oral preparation that has a lower rate of major cardiovascular events than leuprorelin (2.9% vs 6.2%) in men with advanced prostate cancer.[75]

Although most men initially respond to ADT, prostate cancer inevitably becomes castration-resistant, requiring additional therapeutic approaches (see Box 116.9). **Chemotherapy** is effective treatment for metastatic castration-resistant prostate cancer (CRPC) and the taxane drug docetaxel provides a significant survival advantage.[76] Treatments are given via intravenous infusion every 3 weeks in combination with 10 mg prednisolone daily and standard side effects include alopecia, marrow toxicity, neuropathy, and paronychia. In addition, high doses of dexamethasone are required prior to treatment to prevent infusion reactions and fluid retention. This can be challenging in patients with diabetes and impaired glucose tolerance. Cabazitaxel is also active when used subsequent to docetaxel and androgen receptor–signaling inhibitors, resulting in disease response in 37% of patients and 4.4 months of disease control. Standard side effects of marrow suppression and diarrhea are commonly observed.[77]

Oral **androgen receptor–signaling inhibitors** are used in the treatment of prostate cancer for decades. First generation agents such as bicalutamide, flutamide, and cyproterone are useful in preventing disease flare which can occur on commencing GnRH agonists. They are used also in castrate-resistant disease where PSA responses are observed, but improvements in survival have not been demonstrated.

More recently, **potent newer generation androgen receptor–signaling inhibitors** have shown survival benefits as well as high rates of PSA response in CRPC. The enhanced potency is believed to block local intratumoral androgen levels that sustain tumor growth in the presence of low systemic levels of androgens. Abiraterone acetate inhibits any androgen biosynthesis when it is metabolized to abiraterone. Abiraterone acts to block CYP17A, an enzyme required for the conversion of pregnenolone and progesterone to testosterone. However, as this drug also blocks cortisol synthesis, it is given in conjunction with corticosteroids, usually in the form of prednisolone at 10 mg/day. If corticosteroids are not given concurrently, some patients will develop hyperaldosteronism. Abiraterone is well tolerated but has been associated with hepatotoxicity, requiring liver function to be monitored in the first couple of months of therapy.

In patients with metastatic CRPC who have received docetaxel chemotherapy, abiraterone with prednisolone improved survival to 14.8 months, compared with 10.9 months in patients who received prednisolone alone.[78]

More potent androgen receptor inhibitors have been developed in the last decade to block androgen receptor–signaling including enzalutamide, apalutamide, and darolutamide. These agents also prevent receptor dimerization, transport to the cell nucleus, and recycling back to the cell surface to allow further signaling. Enzalutamide improved survival of men with CRPC following docetaxel from 13.6 months to 18.4 months compared with placebo.[79] Although the quality of life in the treated men is better, enzalutamide causes fatigue, diarrhea, and hot flushes. There was a small risk of seizures (<1%) that appear to be unrelated to mechanism of action. Hypertension has been reported with longer duration of treatment. Apalutamide is a similar acting agent with a similar side effect profile. Darolutamide differs as it does not cross the blood-brain barrier, resulting in minimal fatigue compared to ADT alone and has not been associated with seizures.

Enzalutamide, apalutamide, and darolutamide have all been evaluated in M0 CRPC. Enzalutamide improved overall survival from 56.3 to 67 months, suggesting a greater benefit in using the drug earlier in disease progression.[80] However, this is offset by increased fatigue, hypertension, and falls. Apalutamide also improved OS with an increase from 73.5% to 82.4% at 24 months and with some increase in the rate of fractures compared with placebo alone.[81] Darolutamide improved OS at 3 years from 77% to 83% but did not cause any significant increase in toxicity compared with ADT alone and actually delayed symptomatic skeletal events with a median follow-up time of 29 months.[82]

Several treatments showed benefit in metastatic disease when commenced within 12 weeks of initiation of ADT. Docetaxel given every 3 weeks for 6 cycles improved median survival from 47.2 to 57.6 months. Most of this benefit was driven by patients with high-volume disease, defined by the investigators as either the presence of visceral metastases or four or more bone metastases with at least one outside the vertebral column and pelvis.[83] Similar benefits were seen with androgen receptor–targeting agents. Enzalutamide when used upfront, significantly improves survival but median survival has not yet been reached (3-year overall survival improved from 72% to 80%). In patients who received upfront docetaxel, no additional improvement is seen with the addition of enzalutamide.[84] Similarly, improved survival is seen with upfront abiraterone with an increase from 36.5 to 53.3 months in patients with high-risk disease defined as two of: High-grade tumor (Gleason score >7); >2 bone lesions; visceral metastases.[85] Upfront docetaxel and abiraterone were tested as part of the large UK-based STAMPEDE trial and showed improvement in survival with both agents in all patient groups, not just high-risk or high-volume patients.[86,87] More recently, apalutamide showed an improvement in survival at 24 months of 82.4% compared with 73.5% with placebo alone with benefit for high- and low-volume disease groups of patients.[81]

Falls and fractures occur more frequently in patients treated with inhibitors of androgen receptor signaling. As it appears that earlier use of these agents improves survival in advanced prostate cancer, it is likely that the duration of treatment will increase and so may the fracture rate. This occurred with enzalutamide, abiraterone, and apalutamide, but the absolute fracture rate was low. Longer follow-up is required to see if the rate of fracture increases and whether this effect will also be seen with darolutamide. The use of bisphosphonates and receptor activator of nuclear factor kappa-B ligand (RANKL) inhibitors reduces the fracture risk when used with abiraterone. Structured exercise programs are also recommended to reduce muscle weakness and prevent osteoporosis.

KEY POINTS

- Before commencing ADT in men with advanced prostate cancer, the risk vs benefit must be weighed in each case
- Androgen signaling plays a critical role, and remains a target for therapies for men with advanced prostate cancer, but eventually androgen blockade is insufficient to eliminate disease

Novel imaging modalities have made the classification of metastatic vs nonmetastatic prostate cancer more difficult. **PSMA** is a highly expressed protein on prostate cancer cells which can be bound by the peptide PSMA-617. PET imaging utilizes the positron emitter Gallium-68 bound to PSMA-617 and is much more sensitive than CT scan and WBBS in detecting metastases in M0 CRPC, detecting disease in 98% of patients and distant disease in 55%.[88] PSMA is also used as a target for radioisotope therapy by binding the ß-emitter Lutetium-177 to PSMA-617. Early results demonstrated a better PSA response to **177-Lu-PSMA** compared with cabazitaxel chemotherapy and with less side effects.[89]

The use of personalized therapy, that is, treatment based upon genomic abnormalities within a particular tumor, shows some promise in prostate cancer. A proportion of men with prostate cancer will carry DNA repair defects such as BRCA1, BRCA2, and ATM mutations. In patients randomized between the PARP inhibitors, olaparib, and enzlalumide or abiraterone, survival was improved from 14.7 months to 19.1 months. Similarly, PTEN loss occurs in about half of prostate cancers and the addition of the AKT-signaling inhibitor ipatasertib to abiraterone delayed disease progression by 2 months. Although the improvements at present are not clinically significant, it is hoped that combination therapy and better identification of target groups may improve outcomes.

SUMMARY AND FUTURE CHALLENGES

Despite advances in the treatment of men with advanced prostate that extend their lifetime, many thousands of patients still die of this disease because it remains incurable. There is increasing agreement that blockade of the androgen receptor and/or androgen biosynthesis is required but is insufficient to eliminate disease. Instead, combination drug therapy is necessary, similar to that proven to be effective in other malignancies such as breast cancer. However, there are many challenges to evaluate combination therapies in men with prostate cancer. Although there is a rich pipeline of therapeutics, it is not feasible to systematically evaluate large numbers of promising drug combinations in patients themselves, given the sheer number of combinations, sequences and timing of drugs. The numbers of patient available to enroll for clinical trial is not unlimited, yet there is redundancy in active trials, with many drugs directed at the same targets. A paucity of preclinical models is another limitation to the process of drug development and a reliance on decades-old cell lines that do not accurately reflect the clinical responses in patients seen in the clinic today. Nevertheless, these barriers need to be overcome, and trials could be designed using precision medicine paradigms where the patients are selected, based on molecular biomarkers that predict response.

THE MENSTRUAL CYCLE: AN INTRODUCTION

The menstrual cycle represents repetitive (cyclic) activity of the hypothalamic-pituitary-ovarian axis that achieves episodic—approximately once-monthly—presentation of a mature oocyte for fertilization. Additionally, coordinated changes in ovarian hormone production prepare the endometrium for possible pregnancy. In the absence of pregnancy, the major clinical manifestation of cyclic hypothalamic-pituitary-ovarian activity is episodic menstrual (vaginal) bleeding related to endometrial shedding.

Menstrual cycles are often anovulatory, and intermenstrual length is often irregular, during the initial postmenarcheal years. Once regular cyclic ovulation is established, however, median (interquartile range) intermenstrual length approximates 28 (26–31), 27 (25–30), and 26 (24–28) days at ages 20, 30, and 40 years, respectively.[1] Intermenstrual length tends to be stereotyped—and thus rather predictable—for individual women with consistent ovulatory cycles. Anovulation becomes more common and intermenstrual length variability increases in the menopausal transition, and menopause represents the permanent cessation of menses related to depletion of ovarian follicles (see Chapter 122)

The menstrual cycle is governed by complex interactions among the hypothalamus, pituitary, and ovary. Simplistically, hypothalamic gonadotropin-releasing hormone (GnRH) stimulates luteinizing hormone (LH) and follicle-stimulating hormone (FSH) production from pituitary gonadotropes, and these gonadotropins direct the major functions of the ovaries: follicular maturation, ovulation, and sex steroid production. In turn, ovarian products—estradiol, progesterone, and inhibins in particular—modulate GnRH pulse generator activity and gonadotropin responses to GnRH. These bidirectional interactions between the hypothalamic-pituitary unit and the ovaries are highly coordinated and sequenced.

By convention, menstrual cycle day numbering begins with the first day of menses (i.e., cycle day 1 is the first day of menses), and the cycle is conceptually divided into two phases. The time period from the onset of menses to the onset of the midcycle gonadotropin surge is called the follicular phase, so named because it is characterized by the growth and maturation of ovarian follicles, a process that culminates in the emergence of a mature follicle prepared for ovulation. The early follicular phase coincides with endometrial shedding (menses), but follicular development is associated with a progressive increase in estradiol production, which thereafter stimulates endometrial proliferation. Follicular phase length is typically 14–21 days, but it can be of variable length, especially during the years following menarche and the years leading up to menopause.

The gonadotropin surge marks the follicular-to-luteal transition, which is also known as “midcycle.” The time period from the gonadotropin surge to the onset of menstrual bleeding is called the luteal phase, so named because the corpus luteum is a prominent ovarian structure during this phase. The ovarian luteal phase coincides with the uterine (endometrial) secretory phase: corpus luteum-derived progesterone directs endometrial changes that optimize endometrial receptivity in the case of fertilization. In the absence of fertilization, however, the corpus luteum regresses 9–11 days after ovulation, and the associated decrease in progesterone production results in endometrial shedding (menses). Typical luteal phase length is 10–16 days and tends to be stereotyped for individuals.

OVERVIEW OF THE HYPOTHALAMIC-PITUITARY-OVARIAN AXIS

KEY POINTS

- Pulsatile GnRH release from the hypothalamus is the final common pathway for the central neuronal control of reproduction.
- GnRH neuron function is regulated by afferent neuron populations including those that secrete kisspeptin, neurokinin B (NKB), and dynorphin; these and other afferents mediate the negative feedback effects of ovarian estradiol and progesterone.
- GnRH signal transduction within pituitary gonadotropes involves complex intracellular pathways that culminate in gonadotropin subunit gene expression, gonadotropin assembly, and gonadotropin release into the systemic circulation.
- Within the physiological range, higher and lower GnRH pulse frequencies favor LH and FSH secretion, respectively.
- At low physiological concentrations, estradiol reduces GnRH pulse amplitude and inhibits pituitary FSH release, while progesterone is the principal negative feedback regulator of GnRH pulse frequency.
- Ovarian-derived inhibins selectively restrain FSH secretion from gonadotropes, while pituitary activins and follistatin selectively augment and reduce, respectively, FSH secretion in an autocrine/paracrine manner.
- At high physiological concentrations, estradiol markedly augments gonadotrope responsiveness to GnRH—a unique long-loop positive feedback mechanism that underlies the midcycle gonadotropin surge.

The GnRH Pulse Generator

GnRH is a decapeptide hormone synthesized in some 7000 specialized hypothalamic neurons whose cell bodies primarily reside in the infundibular nucleus of the mediobasal hypothalamus—human homologue of the arcuate nucleus in lower mammalian species—and to a lesser degree in the preoptic area of the anterior hypothalamus. The principal form of GnRH (pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH2) is a product of the GnRH type I gene (*GNRH1*) located on chromosome 8.

Nascent GnRH neurons originate in the nasal (olfactory) placode and migrate to the hypothalamus during embryological development. This migration is guided by olfactory and vomeronasal neurons: GnRH cells adhere to such axons and are thus guided through the nasal epithelium, across the cribriform plate, and through the forebrain toward the hypothalamus. Upon reaching their hypothalamic destinations, GnRH neurons extend projections to the median eminence, where GnRH is released into the hypophyseal portal vessels for transport to the anterior pituitary (Fig. 117.1). These neuronal processes have recently been called "dendrons" because they exhibit characteristics of both axons and dendrites.

GnRH stimulates synthesis and secretion of both LH and FSH from gonadotrope cells in the anterior pituitary. Appropriate ovarian function—gametogenesis, ovulation, sex steroid production—is absolutely dependent on appropriate gonadotropin signaling, and appropriate gonadotropin secretion is absolutely dependent on pulsatile GnRH release.

Pulsatile GnRH Release. Although GnRH cell bodies are loosely associated anatomically, GnRH neurons are functionally integrated and secrete GnRH in a coordinated and pulsatile (episodic) fashion. GnRH is released at the median eminence into the hypophyseal portal system en route to the anterior pituitary gland. However, GnRH is rapidly degraded and has an approximately 2- to 4-minute half-life in hypophyseal portal blood. Episodic GnRH release into the portal system, along with the very short half-life of GnRH, renders discrete episodes of GnRH stimulation of gonadotropes.

Pulsatile GnRH release is essential for normal LH and FSH secretion. GnRH upregulates its own receptors (self-priming or autopriming) on pituitary gonadotropes, but this effect is most prominent when GnRH pulses occur every 60–90 minutes. Continuous GnRH receptor (*GnRHR*) stimulation leads to markedly reduced gonadotropin secretion (desensitization), as demonstrated in GnRH-deficient rhesus monkeys (Fig. 117.2).[2] Desensitization involves a reduction in *GnRHR* expression

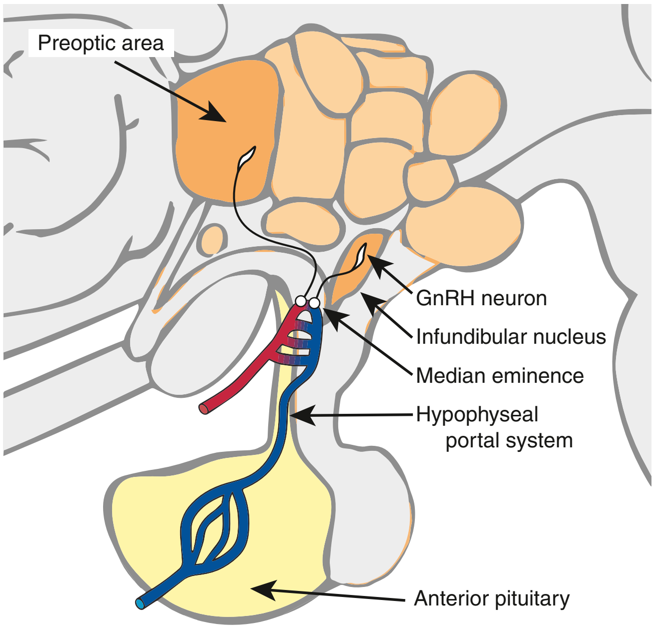

Figure 117.1 **Anatomy of the hypothalamic-pituitary unit (simple schematic).** GnRH neuron cell bodies primarily reside in the infundibular nucleus (mediobasal hypothalamus) and preoptic area. GnRH neuron projections (dendrons) extend to the median eminence, where pulses of GnRH are released into the hypophyseal portal system, through which GnRH is transported to gonadotropes in the anterior pituitary. *GnRH,* Gonadotropin-releasing hormone.

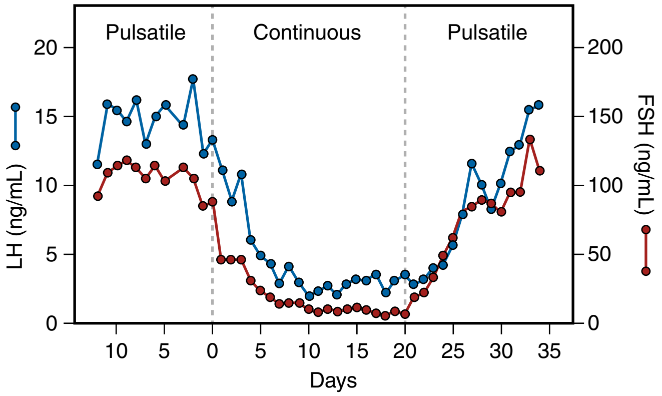

Figure 117.2 **Effects of pulsatile versus continuous GnRH stimulation on gonadotropin secretion.** These data were obtained in gonadectomized but sex steroid-replaced monkeys after arcuate nucleus ablation, which produced GnRH deficiency. Exogenous GnRH administered in hourly pulses (1 μg/minute for 6 minutes per hour) reconstituted gonadotropin secretion. However, continuous GnRH infusion (1 μg/minute) markedly reduced LH and FSH release. Gonadotropin secretion was again restored with hourly GnRH pulses. *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone. (From Belchetz PE, Plant TM, Nakai Y, et al. Hypophysial responses to continuous and intermittent delivery of hypopthalamic gonadotropin-releasing hormone. *Science*. 1978;202:631–633.)

on gonadotropes in addition to the uncoupling of *GnRHR* agonism and gonadotropin synthesis. Notably, this phenomenon can be used to therapeutic advantage with the use of long-acting synthetic GnRH agonists—peptides similar to GnRH but with amino acid substitutions that enhance *GnRHR* binding affinity, reduce proteolytic degradation, or both.

Gonadotropin secretion is sensitive to GnRH pulse frequency and amplitude. In GnRH-deficient rhesus monkeys treated with once-hourly exogenous GnRH pulses, plasma LH and FSH concentrations decreased by approximately 50%–60% over 1–2 weeks when frequency was increased to 2 pulses per hour; and profound gonadotropin suppression occurred with GnRH pulse frequencies of 3–5 pulses per hour (Fig. 117.3).[3] In this same study, a 90% decrease in GnRH dose per pulse yielded unmeasurable gonadotropins within 2–7 days, whereas a 10-fold increase in GnRH dose per pulse resulted in a 34% decrease in FSH but no change in LH concentrations. These results highlight that gonadotropin secretion is dependent on both GnRH pulse frequency and GnRH pulse amplitude.

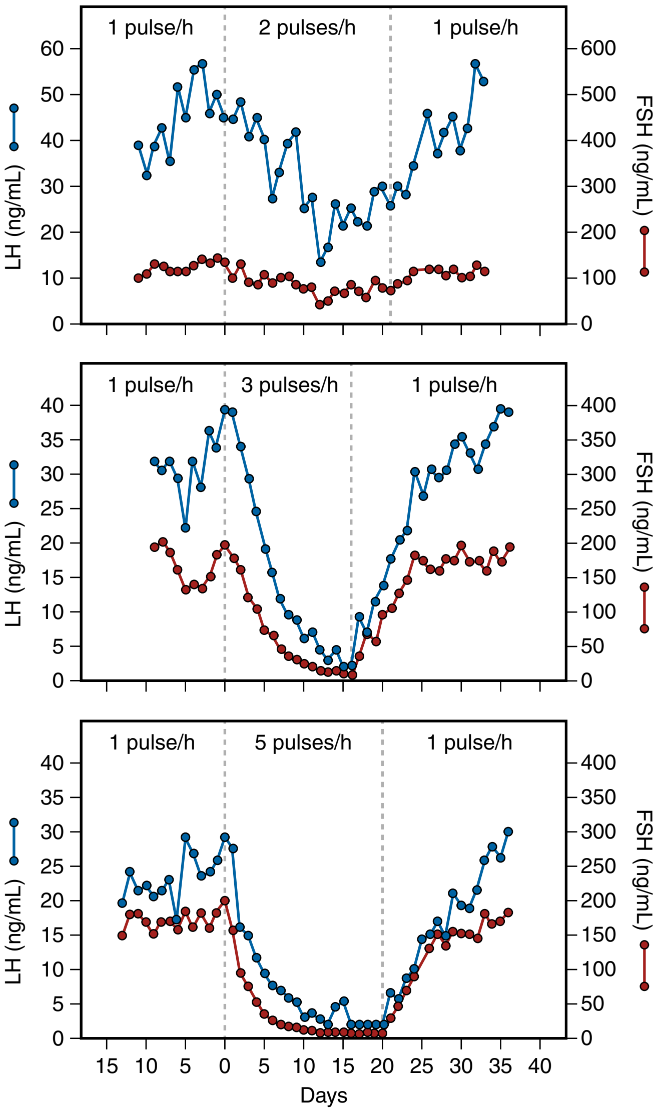

Figure 117.3 Effects of supraphysiological GnRH pulse frequencies on gonadotropin secretion. These data were obtained in gonadectomized but sex steroid-replaced monkeys after arcuate nucleus ablation, which produced GnRH deficiency. Exogenous GnRH administered in hourly pulses (1 μg/minute for 6 minutes per hour) reconstituted gonadotropin secretion. However, circulating LH and FSH release concentrations decreased when exogenous GnRH pulse frequency was increased to 2, 3, or 5 pulses per hour. *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone. (From Wildt L, Hausler A, Marshall G, et al. Frequency and amplitude of gonadotropin-releasing hormone stimulation and gonadotropin secretion in the rhesus monkey. *Endocrinology.* 1981;109:376–385.)

Cyclic Changes in GnRH Pulse Secretion. Animal studies confirm that each GnRH pulse elicits a secretory burst of LH (Fig. 117.4).[4] Thus, in human studies, patterns of pulsatile GnRH secretion may be inferred from LH pulse patterns. The circulating half-life of LH approximates 30–60 minutes, so LH pulses are readily discernable in the peripheral circulation in most physiological situations. GnRH pulses also elicit secretory bursts of free α-subunit, which has a shorter half-life than LH; thus, free α-subunit pulse analysis may be advantageous when GnRH pulse frequency is at its highest (e.g., after menopause). Although GnRH pulses elicit secretory bursts of FSH, such pulses are often obscured by the longer circulating half-life of FSH.

LH (GnRH) pulse frequency varies substantially across the menstrual cycle (Fig. 117.5).[5,6] Available data are consistent with the notion that the GnRH pulse generator has an intrinsic pulse frequency of approximately 1 pulse per hour and that cyclic changes in GnRH pulse frequency primarily reflect the imposition and removal of sex steroid negative feedback. For example, isolated human mediobasal hypothalami secrete GnRH pulses every 60–100 minutes,[7] and GnRH pulse frequency is around once hourly in the near absence of negative feedback (e.g., after menopause).[8,9] In contrast, GnRH pulse frequency is low (1 pulse every 3–5 hours) during the luteal phase, reflecting negative feedback restraint from corpus luteum-derived progesterone.

With the demise of the corpus luteum, falling progesterone concentrations allow 24-hour GnRH pulse frequency to increase to 1 pulse every 90–100 minutes in the early follicular phase. The 24-hour GnRH pulse frequency gradually increases to about 1 pulse every hour by the mid- to late follicular phase. This increase appears to reflect a gradual escape from (luteal) progesterone negative feedback.[10] It also reflects changes in sleep-related LH pulse frequency across the follicular phase. In particular, sleep-related decreases in LH pulse frequency are most prominent in the early follicular phase and less prominent in the later follicular phase.[11,12] A recent study suggested that the degree of sleep-associated frequency slowing in the early follicular phase correlates with the degree of previous progesterone exposure.[13]

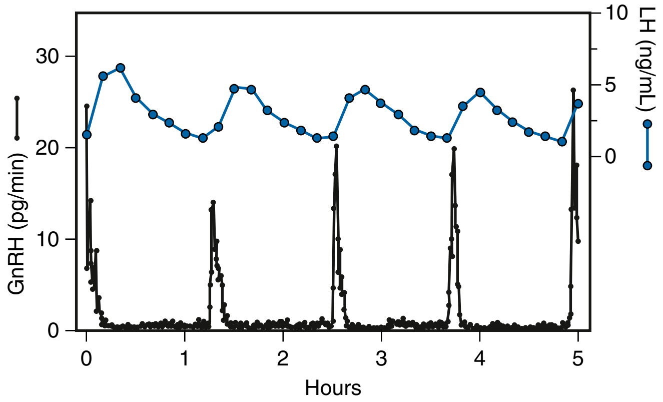

Figure 117.4 GnRH and LH concentration time series in the ewe, obtained via frequent blood sampling from the hypophyseal portal system and jugular vein, respectively. Note the close temporal relationship between GnRH pulses and subsequent LH pulses. *GnRH,* Gonadotropin-releasing hormone; *LH,* luteinizing hormone. (From Moenter SM, Brand RM, Midgley AR, et al. Dynamics of gonadotropin-releasing hormone release during a pulse. *Endocrinology.* 1992;130:503–510.)

(Study A: Reame N, Sauder SE, Kelch RP, et al. Pulsatile gonadotropin secretion during the human menstrual cycle: evidence for altered frequency of gonadotropin-releasing hormone secretion. *J Clin Endocrinol Metab.* 1984;59:328–337. Study B: Filicori M, Santoro N, Merriam GR, et al. Characterization of the physiological pattern of episodic gonadotropin secretion throughout the human menstrual cycle. *J Clin Endocrinol Metab.* 1986;62:1136–1144.)

LH pulse amplitude also changes throughout the menstrual cycle (Fig. 117.5).[5,6] Importantly, LH pulse amplitude reflects both the amount of GnRH released per pulse and gonadotrope responsiveness to GnRH stimulation. Studies in GnRH-deficient subjects treated with exogenous pulsatile GnRH also disclose that GnRH-stimulated LH release varies inversely with the preceding GnRH inter-pulse interval, at least within physiological ranges.[14]

Pulsatile exogenous GnRH restores cycles and fertility in women with isolated GnRH deficiency, and such treatment may employ variable GnRH doses and frequencies to mimic normal physiology.[15] Maintenance of high-frequency exogenous GnRH pulses throughout the luteal phase may impair subsequent follicular development and corpus luteum function,[16,17] suggesting that cyclic changes in GnRH pulse frequency—high physiological pulse frequency in the follicular phase with slowing during the luteal phase—may be an important factor for long-term cyclic ovulation. However, in women with isolated GnRH deficiency, ovulation also occurs with exogenous GnRH administered at a fixed dose and frequency; in such cases, supraphysiological GnRH dosing might potentially compensate for the absence of periodic pulse frequency slowing.

Higher-Order Control of GnRH Secretion. GnRH neuron activity is characterized by episodic increases in action potential firing rates; these increases presumably provoke pulses of GnRH release. However, the fundamental nature of the GnRH pulse generator remains unclear. GnRH neurons intrinsically exhibit episodic bursts of action potential firing, and both immortalized GnRH-secreting neurons and cultured GnRH neurons secrete GnRH in a pulsatile fashion. Coordination of episodic action potential firing and episodic GnRH release could reflect extensive cell-to-cell interconnections. Nonetheless, currently available data suggest that neuronal populations afferent to GnRH neurons—including those that secrete kisspeptin, NKB, and dynorphin—represent critical components of the GnRH pulse generator.

Kisspeptin is the neuropeptide product of the *KISS1* gene and the natural ligand of the seven transmembrane domain, G protein-coupled kisspeptin receptor (KISS1R). Patients and animal models with inactivating *KISS1* or *KISS1R* mutations have pubertal failure and hypogonadotropic hypogonadism. Exogenous kisspeptin administration markedly stimulates LH release, and this is mediated through GnRH neurons. Kisspeptin fibers synapse with GnRH cell bodies and GnRH neuron terminals at the median eminence—both of which express KISS1R—and kisspeptin stimulates GnRH neuron activity and GnRH secretion. Moreover, kisspeptin-stimulated LH release is blocked by GnRH antagonists, and pulsatile GnRH restores reproductive function in patients with loss-of-function inactivating KISS1R mutations.

NKB is a neuropeptide encoded by the tachykinin 3 gene (*TAC3*). NKB exerts its actions primarily through its cognate receptor NK3R (encoded by the *TACR3* gene). Patients with homozygous inactivating mutations of *TAC3* or *TACR3* may demonstrate pubertal failure and hypogonadotropic hypogonadism. Senktide, a selective NK3R agonist, stimulates LH secretion in animals, and this action is blocked by *GnRHR* antagonism. Data suggest that the effects of NKB on GnRH secretion are primarily mediated through kisspeptin release: kisspeptin neurons express NK3R; senktide increases kisspeptin neuronal activity; LH responses to senktide are absent or markedly impaired in the absence of kisspeptin neuron activation; and kisspeptin infusion can restore pulsatile LH secretion in patients with loss-of-function *TAC3* or *TACR3* mutations.

Endogenous opioid peptides also direct GnRH neuronal function, and they play a major role in mediating progesterone negative feedback on GnRH release. For example, hypothalamic portal blood concentrations of β-endorphin are elevated during the luteal phase in monkeys, and opiate receptor antagonists increase LH pulse frequency in luteal phase women and progestin-treated postmenopausal women. Numerous animal studies indicate that dynorphin is a key mediator of progesterone negative feedback on GnRH pulse frequency, reducing GnRH secretion via reduced kisspeptin release.

Interestingly, kisspeptin, NKB, and dynorphin are frequently coexpressed in the same neuron—KNDy neurons (Kisspeptin, NKB, Dynorphin). KNDy neurons form an extensively interconnected network and interact with GnRH neurons in the arcuate (infundibular) nucleus in addition to GnRH fibers in the internal zone of the median eminence. Extensive animal data suggest that KNDy neurons mediate sex steroid negative feedback on GnRH secretion, and many consider the kisspeptin/KNDy neuronal network to be a fundamental component of the GnRH pulse generator (Fig. 117.6).

Many other neuronal populations (e.g., those secreting gamma aminobutyric acid [GABA], glutamate, neuropeptide Y [NPY], corticotropin-releasing hormone [CRH], dopamine) and endocrine signals (e.g., leptin, insulin) appear to influence GnRH secretion. A growing body of evidence also suggests that RFamide-related peptides (mammalian orthologues of gonadotropin-inhibitory hormone) are important regulators of GnRH and gonadotropin secretion.[18]

Anterior Pituitary Gonadotropes and Regulation of Gonadotropin Secretion

Gonadotropes constitute roughly 10% of the anterior pituitary cell population, and a majority of gonadotropes produce both LH and FSH. GnRH binding to the membrane-associated *GnRHR* on gonadotropes initiates a cascade of intracellular events leading to LH and FSH production and release (Fig. 117.7). In turn, LH and FSH act in concert to regulate ovarian function and thus are critical regulators of sexual maturation

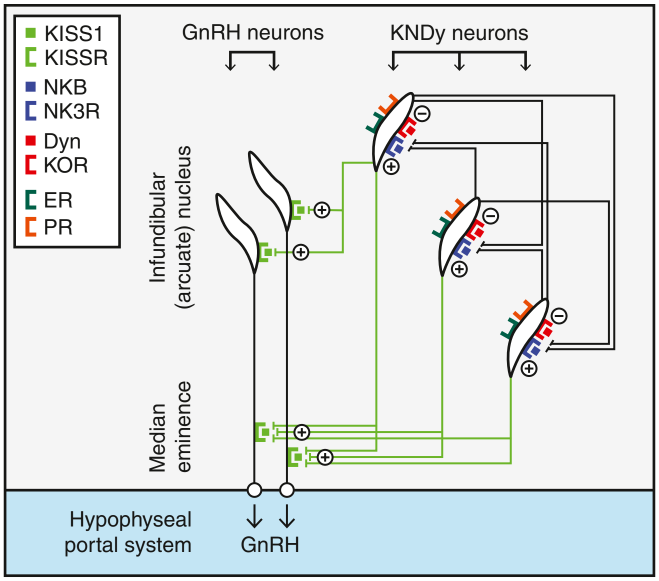

Figure 117.6 **Simplistic model of the infundibular (arcuate) KNDy neuronal network.** KNDy neurons form an interconnected network. NKB release activates KNDy neurons and stimulates kisspeptin release at synapses with GnRH neuron cell bodies and at GnRH dendrons at the median eminence. Conversely, Dyn release inhibits KNDy neurons and suppresses kisspeptin release at synapses with GnRH neuron cell bodies and GnRH dendrons at the median eminence. This schematic does not incorporate the possible roles of NKB and Dyn release directly onto GnRH neurons. *Dyn,* Dynorphin; *ER,* estradiol receptor; *GnRH,* gonadotropin-releasing hormone; *KISS1,* kisspeptin; *KISSR,* kisspeptin receptor; *KNDy,* kisspeptin, neurokinin B, dynorphin; *KOR,* kappa-opioid receptor; *NKB,* neurokinin B; *NK3R,* neurokinin 3 receptor; *PR,* progesterone receptor.

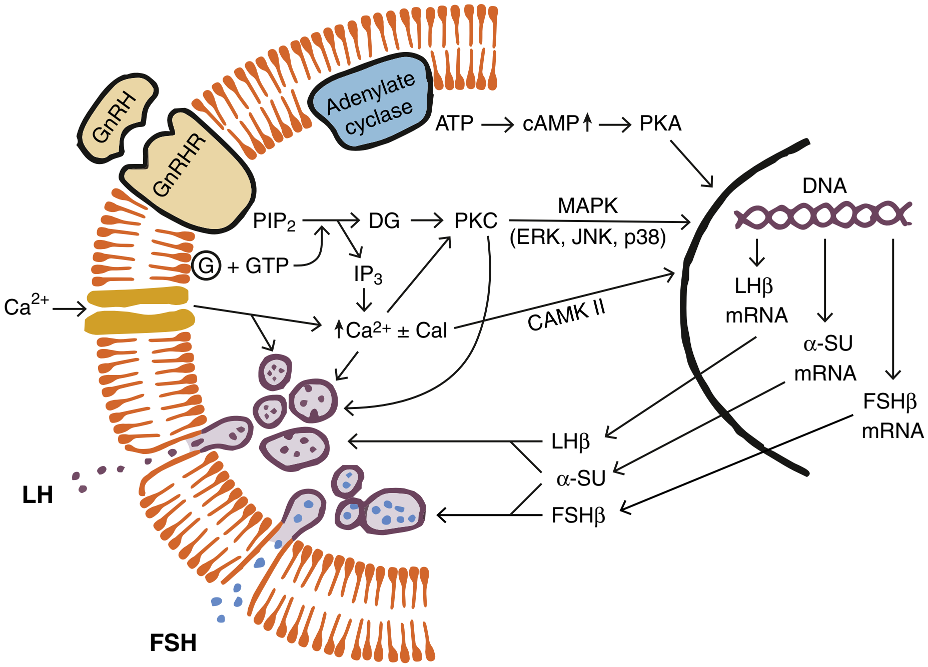

Figure 117.7 **Mechanisms involved in GnRH action on the gonadotrope.** *α-SU,* α-Subunit; *ATP,* adenosine triphosphate; *Ca^{2+},* calcium; *Cal,* calmodulin; *CAMK II,* calcium/calmodulin dependent kinase II; *cAMP,* cyclic adenosine monophosphate; *DG,* diacylglycerol; *ERK,* extracellular signal-regulated kinase; *FSH,* follicle-stimulating hormone; *G,* G protein; *GnRH,* gonadotropin-releasing hormone; *GnRHR,* GnRH receptor; *GTP,* guanosine triphosphate; *IP3,* inositol triphosphate; *JNK,* c-jun N-terminal kinase; *LH,* luteinizing hormone; *MAPK,* mitogen-activated protein kinase; *PIP2,* phosphatidylinositol 4,5-diphosphate; *PKA,* protein kinase A; *PKC,* protein kinase C.

and fertility. Primary roles of LH relate to theca cell steroidogenesis, ovulation, follicular luteinization, and corpus luteum steroidogenesis, while primary functions of FSH relate to follicular development, including dominant follicle recruitment and growth, and induction of granulosa cell aromatase activity (see Chapters 118 and 119).

Mechanisms of GnRH Signal Transduction. The type I *GnRHR* is encoded by the *GNRHR* gene on chromosome 4. Part of the rhodopsin-like G protein-coupled receptor superfamily, the *GnRHR* has a seven-transmembrane-domain structure with both extracellular and intracellular loops. Some of the highly complex intra-gonadotrope mechanisms involved in GnRH action are summarized in Fig. 117.7.[19–21] Briefly, GnRH binding to the *GnRHR* activates guanosine triphosphate (GTP)-associated proteins (e.g., $G\alpha_{q/11}$, $G\alpha_s$), with subsequent phospholipase Cβ hydrolysis of phosphatidylinositol 4,5-diphosphate (PIP_2) to inositol triphosphate (IP_3) and diacylglycerol. IP_3 provokes rapid intracellular calcium release from endoplasmic reticulum, which initiates the first 1–2 minutes of LH pulse release. This is followed by the opening of voltage-gated (L-type) calcium channels within the plasma membrane leading to a more sustained increase in intracellular calcium, supporting the remainder of LH pulse release.

Elevated intracellular calcium and diacylglycerol activate various protein kinase C (PKC) isoforms, which in turn activate a number of mitogen-activated protein kinases (MAPKs) such as extracellular signal-regulated kinase (ERK), c-jun N-terminal kinase (JNK), and p38-α. These MAPKs are involved in stimulating gonadotropin subunit transcription. Activated PKC also contributes to the sustained phase of gonadotropin release. Interestingly, GnRH-related calcium oscillations within the gonadotrope cells also increase gonadotropin subunit mRNA expression, which is at least partly mediated by calcium-/calmodulin-dependent kinase II (CAMK II) and calcineurin. GnRH action also appears to be partly mediated through a pathway involving cyclic adenosine monophosphate (cAMP), protein kinase A (PKA), and cAMP response element binding proteins.

LH is stored in granules, and LH release is closely tied to GnRH pulse stimulation. Although GnRH pulses acutely provoke FSH release as well, FSH exhibits some degree of constitutive secretion. Also of interest, GnRH stimulation increases gonadotrope responsiveness to GnRH stimulation (self-priming or autopriming), which appears to reflect changes in *GnRHR* density on the gonadotrope cell membrane. In rodents, maximum *GnRHR* density is achieved with the high GnRH pulse frequency of 1 pulse every 30 minutes; and *GnRHR* density correlates positively with GnRH secretion, being highest during gonadotropin surges or after castration.

Gonadotropin Structure. Each gonadotropin is a heterodimeric glycoprotein consisting of two different protein subunits, α and β. The 92-amino acid α-subunit, encoded by a single gene (*CGA*) on chromosome 6, is common to LH, FSH, chorionic gonadotropin (CG), and thyroid-stimulating hormone. The β-subunit for LH (LHβ) is a 121-amino acid protein derived from the *LHB* gene on chromosome 19, whereas the β-subunit for FSH (FSHβ) is a 111-amino acid protein derived from the *FSHB* gene on chromosome 11. The unique β-subunits account for the biological specificity of each gonadotropin.

GnRH stimulates LHβ, FSHβ, and α-subunit gene transcription and translation. Disulfide bonds between cysteine residues play important roles in the tertiary structures of each subunit. The α-subunit dimerizes non-covalently with an LHβ or FSHβ subunit to form LH or FSH, respectively. In contrast to the LHβ or FSHβ subunits, α-subunit is synthesized in excess and is independently secreted into the circulation. However, the α- and β-subunits exhibit no known independent biological actions.

Subunits also undergo variable post-translational glycosylation, namely the addition of N-linked oligosaccharide chains to specific asparagine residues. This occurs at positions 52 and 78 of α-subunit, positions 7 and 24 of FSHβ, and position 30 of LHβ. The quantity and types of oligosaccharide additions appear to be involved with gonadotropin assembly, and they influence both gonadotropin bioactivity and circulating half-life. N-linked oligosaccharide chains on FSH and CG tend to end with sialic acid moieties, while N-linked carbohydrate chains on LH tend to end with sulfate moieties. Higher numbers of sialic acid moieties are associated with slower metabolic clearance, while sulfonated N-acetylgalactosamine targets LH for hepatic removal. These factors contribute to the different circulating half-lives for LH and FSH in cycling women: approximately 30–60 minutes for LH and 120–240 minutes for FSH. Interestingly, the ratio of sialic acid to sulfonated N-acetylgalactosamine can vary across the cycle. For example, at midcycle, LH sulfonation is decreased and sialylation slightly increased, which is expected to increase LH half-life, contributing to the preovulatory LH surge.[22,23]

CG is produced by syncytiotrophoblast cells of the developing placenta. The CGβ subunit is a 145-amino acid protein that is 82% homologous with LHβ and includes a unique final C-terminal peptide (amino acid positions 121–145). Both LH and CG activate the LH receptor (LHCG receptor), and CG is critical for the maintenance of corpus luteum function and, thus, maintenance of favorable endometrial conditions during early pregnancy. CG exhibits glycosylation on two asparagine residues (positions 13 and 30) in addition to four mucin-type O-linked glycans at four serine residues (positions 121, 127, 132, and 138). Although CG shares biological activity with LH, higher sialic acid content of CGβ contributes to a much longer circulating half-life.

Feedforward Control of LH and FSH Secretion. A single hormone (GnRH) stimulates the synthesis and secretion of two hormones (LH and FSH) from a single cell type (gonadotrope). Yet circulating LH and FSH concentrations vary differentially across the cycle. For example, the luteal-follicular transition is characterized by a 3-fold increase in FSH, but less than a 2-fold increase in LH.[24] In contrast, FSH decreases while LH tends to increase in the latter half of the follicular phase.

Differential regulation of LH and FSH secretion is partly dictated by GnRH pulse frequency. Specifically, higher physiological GnRH pulse frequencies favor LH synthesis and secretion, whereas low physiological GnRH pulse frequencies favor FSH synthesis and secretion. Studies in GnRH-deficient monkeys disclosed that decreasing the frequency of exogenously administered GnRH pulses from 1 pulse every hour to 1 pulse every 3 hours led to a 50% decrease in plasma LH concentration but a 65% *increase* in plasma FSH concentration (Fig. 117.8).[3] In addition, FSH responses to each GnRH pulse increased 4-fold at this lower frequency, while LH responses increased by approximately 67%.[3] Similar findings have been described in humans. In one study of men with GnRH deficiency, pulsatile GnRH administration restored normal gonadotropin levels, yet FSH progressively increased when pulse frequency was reduced from 1 pulse every hour to 1 pulse every 2 hours to 1 pulse every 3 hours, whereas LH concentrations remained similar across these frequencies.[25] In other studies of men and women with GnRH deficiency, increasing GnRH pulse frequency was associated with increased LH concentrations, but no clear changes in FSH.[26,27]

Animal studies demonstrate that different GnRH pulse frequencies differentially impact LHβ and FSHβ subunit production.[19–21] In rodents, high-frequency GnRH pulse stimulation favors α-subunit and LHβ mRNA expression, whereas low-frequency stimulation favors FSHβ mRNA expression. Different signaling pathways appear to be differentially regulated by high and low GnRH pulse frequencies.

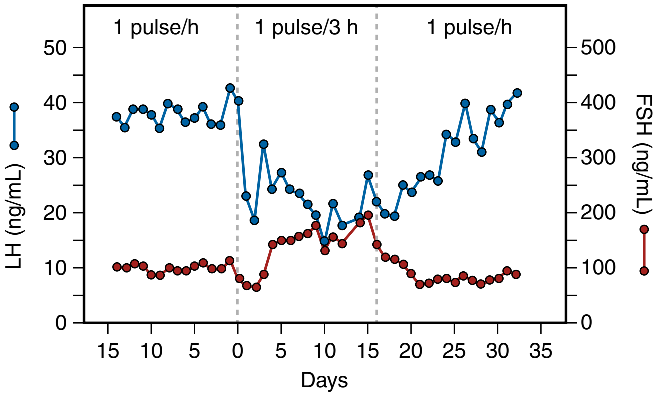

Figure 117.8 Differential effects of GnRH pulse frequency on LH and FSH secretion. These data were obtained in gonadectomized but sex steroid-replaced monkeys after arcuate nucleus ablation, which produced GnRH deficiency. Exogenous GnRH administered in hourly pulses (1 µg/minute for 6 minutes per hour) reconstituted gonadotropin secretion. Changing the frequency of exogenous GnRH pulse administration from a high physiological frequency (hourly) to a relatively low frequency (every 3 hours) resulted in decreased LH but increased FSH concentrations. *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone. (From Wildt L, Hausler A, Marshall G, et al. Frequency and amplitude of gonadotropin-releasing hormone stimulation and gonadotropin secretion in the rhesus monkey. *Endocrinology.* 1981;109:376–385.)

For example, high GnRH pulse frequency increases *GnRHR* density at the cell surface, and higher *GnRHR* density at the gonadotrope cell surface favors LHβ gene expression, whereas lower *GnRHR* density favors FSHβ gene expression. Additional post-receptor mechanisms contribute to this phenomenon as well, including differential GnRH pulse frequency-specific effects on MAPK pathways, the cAMP/PKA pathway, etc. Indeed, different frequencies of experimentally induced intracellular calcium oscillations differentially impact LHβ and FSHβ mRNA expression. In addition, higher GnRH pulse frequencies enhance gonadotrope follistatin production, which leads to a selective reduction in FSHβ. Although different GnRH pulse amplitudes differentially impact LHβ and FSHβ translation, the impact of this phenomenon is modest compared with frequency effects.

Of critical importance, LH and FSH secretion is differentially influenced by ovarian hormone feedback. For example, high physiological concentrations of estradiol markedly increase gonadotropin responses to GnRH, and this effect is more prominent for LH than FSH. In addition, ovarian inhibins and low physiological estradiol concentrations selectively restrain FSH secretion in the later follicular and luteal phases. These feedback effects on gonadotropin secretion are discussed further as follows.

Ovarian Folliculogenesis and Steroidogenesis

The ovarian follicle—an oocyte surrounded by granulosa and theca cells—is the functional unit of the ovary, and circulating gonadotropins direct ovarian function. LH and FSH receptors are seven-transmembrane domain, G protein-coupled receptors with large extracellular domains. FSH receptors localize to granulosa cells: FSH regulates follicular growth and maturation, and it stimulates estradiol production from granulosa cells by enhancing aromatase expression. LH receptors are expressed by theca cells; granulosa cells in large, preovulatory follicles; and steroidogenic cells of the corpus luteum. LH stimulates sex steroid (e.g., androstenedione) production from theca cells during the follicular phase; provokes ovulation at midcycle; and controls sex steroid (e.g., progesterone) production from the corpus luteum during the luteal phase.

Folliculogenesis, ovulation, and luteogenesis are addressed in Chapter 118, and ovarian hormone synthesis is addressed in Chapter 119. However, the following brief overviews are provided for context.

Ovarian Follicular Development. Oogonia begin, but do not complete, the first meiotic division between 8 and 13 weeks of gestation, thus becoming primary oocytes. At approximately 20 weeks of gestation, primary oocytes will be surrounded by pre-granulosa cells to form primordial follicles. The number of oogonia reaches a peak of approximately 6–7 million at 20 weeks of gestation, but ongoing atresia will reduce the number of primordial follicles to roughly 700,000 at birth and 300,000 at puberty.

Primordial follicles are dormant, but can be engaged for further development—a process called follicular activation or initial follicular recruitment. This process, which occurs continuously from the fifth or sixth gestational month until menopause, is primarily governed by local growth factors through complex autocrine and paracrine interactions among the oocyte, follicular cells, and surrounding cells. The endgame of follicular development is ovulation, and the progression from recruited primordial follicle to ovulatory follicle usually takes about a year. However, since only 400–600 follicles will proceed to ovulation in a woman's lifetime, the vast majority of follicles will undergo atresia instead.

When a follicle is initially recruited for further development, the flat pre-follicular cells begin to proliferate and become cuboidal granulosa cells; the oocyte increases in size; and a zona pellucida surrounds the egg. This structure is now called a primary (unilaminar) follicle. A developing follicle becomes a secondary (multilaminar) follicle when granulosa cells replicate, accumulate, and form layers around the oocyte. Around this time, granulosa cells begin to express FSH and estrogen receptors; and some of the ovarian stromal cells surrounding the granulosa cells become theca cells, which develop LH receptors and begin to express the steroidogenic machinery to produce androgens. The transition from primordial to full-grown secondary follicle occurs over about 10 menstrual cycles. While gonadotropins are not absolutely required for preantral follicular development, FSH appears to play a facilitatory role in this regard.

Secondary follicles can respond to the increase in FSH during the luteal-follicular transition, thus beginning the "gonadotropin-dependent phase" of follicular development, although local growth factors still participate in this process. FSH stimulation promotes granulosa cell division, which increases inhibin B production. Granulosa cell FSH receptor and aromatase expression increases, and estrogen also stimulates granulosa cells to divide and to express more FSH receptors. With continued stimulation, fluid appears between granulosa cells and coalesces to form a fluid-filled cavity—the antrum. As follicle size increases further, there is a progressive, gonadotropin-stimulated increase of androgen production (especially androstenedione) from theca cells, with subsequent aromatization to estradiol in granulosa cells.

During the luteal-follicular transition, the increase in FSH secretion elicits growth of a cohort of antral follicles measuring approximately 4–5 mm in diameter—a process that is sometimes called cyclic recruitment—in addition to lead follicle selection and growth. Notably, the lead follicle destined to ovulate can be distinguished in the early follicular phase (e.g., its granulosa cells have higher mitotic rates and produce more estradiol). Through a marked increase in granulosa cell mitosis and antral fluid accumulation, the diameter of the lead follicle reaches approximately 10 mm during the midfollicular phase and thereafter grows approximately 2 mm per day until ovulation. In contrast, granulosa cell proliferation tapers off in the non-selected follicles. Mechanisms underlying monofollicular dominance remain unclear, but this phenomenon partly reflects the ability of estradiol and inhibin

B to restrain FSH secretion, thus reducing a stimulatory growth factor for non-selected follicles. Indeed, exogenous FSH administration to maintain an FSH elevation for 5–6 additional days encourages multifollicular development,[28] while suppression of FSH with exogenous estradiol delays dominant follicle emergence.[29]

Five to six days prior to ovulation, the dominant follicle grows rapidly and moves toward the ovarian surface. Toward the end of this maturation process, estradiol and FSH stimulate the appearance of LH receptors on the granulosa cell layers closest to the basal lamina. LH will act on granulosa cells to begin luteinization and stimulate production of progesterone and prostaglandins, which appear to be important in the ovulatory process. High estradiol concentrations derived from the mature, preovulatory follicle will then elicit a preovulatory gonadotropin surge.

This midcycle gonadotropin surge provokes ovulation—expulsion of the cumulus-oocyte complex—and initiates formation of the corpus luteum. Notably, the mature preovulatory (Graafian) follicle typically measures 20–25 mm in diameter at ovulation, which occurs approximately 24–36 hours after the start of the midcycle gonadotropin surge. Follicle rupture and oocyte release involve factors such as plasminogen activator, inflammatory cells (leukocytes, macrophages), prostaglandins, chemokines, and cytokines. Oocyte meiosis I is resumed in response to the preovulatory gonadotropin surge, and the second meiotic division is arrested at metaphase until fertilization.

After ovulation, the remnant of the mature follicle becomes the corpus luteum. Granulosa cells are transformed into granulosa-lutein cells, which acquire the capacity to synthesize progesterone from cholesterol, but also continue to express aromatase. High luteal progesterone concentrations are important for preparing the endometrium for embryonic implantation and suppressing the GnRH pulse generator. Theca cells from the ovulated follicle are also integrated into the corpus luteum; these theca-lutein cells continue to express the steroidogenic enzymes necessary to produce androgen precursors that are aromatized to estrogens by granulosa-lutein cells. Importantly, LH is required for normal luteal function in primates: corpus luteum life span is shortened in the absence of LH, and corpus luteum life span can be prolonged by exogenous LH or placental chorionic gonadotropin (CG).

In a fertile cycle, trophoblast-derived CG prevents luteolysis and maintains progesterone production, which is critical for the maintenance of pregnancy—especially in the first 7–10 weeks of gestation. In the absence of fertilization, the functional lifespan of the corpus luteum approximates 14 (12–16) days, after which it will undergo luteolysis—a complex and incompletely understood process of regression. Reduced progesterone production during luteolysis partly reflects disruptions in post-receptor LH signaling. In addition, luteal cell apoptosis and autophagy, along with reduced perfusion, lead to tissue involution and formation of a fibrotic corpus albicans. Mechanisms underlying the preprogrammed lifespan of the corpus luteum remain uncertain.

Ovarian Steroidogenesis. The primary theca cell product is the weak androgen androstenedione. The initial step of theca cell steroidogenesis is the shuttling of cholesterol—either imported from circulating low-density lipoprotein-cholesterol particles or synthesized de novo—from outer to inner mitochondrial membranes by steroidogenic acute regulatory protein (StAR). Cholesterol is then converted to pregnenolone by the mitochondrial side-chain cleavage enzyme complex (P450scc). Notably, StAR expression in secondary and antral follicles is largely specific to theca cells, and StAR and P450scc activities are stimulated by LH. Within the smooth endoplasmic reticulum, the P450c17 enzyme converts pregnenolone to 17-hydroxypregnenolone via its 17α-hydroxylase activity, then to dehydroepiandrosterone via its 17,20-lyase activity. (Synthesis of androstenedione appears to proceed primarily along this Δ5 pathway; it is unclear to what degree procession along the Δ4 pathway—conversion of progesterone to 17-hydroxyprogesterone to androstenedione—is operative *in vivo*.) The enzyme 3β-hydroxysteroid dehydrogenase then converts dehydroepiandrosterone to the weak androgen androstenedione, which may be further transformed to the more potent testosterone by 17β-hydroxysteroid dehydrogenase.

The primary secretory products of the different sex steroid-producing cells depend on the particular complement of steroidogenic enzymes expressed in the cells. Theca cells produce androstenedione in response to LH stimulation, but theca cells do not express the aromatase enzyme. While granulosa cells are incapable of making androstenedione from cholesterol, they express aromatase in response to FSH stimulation. Thus, some theca cell-derived androstenedione diffuses into granulosa cells where it is aromatized into estrone, a weak estrogen. Estrone is then transformed to the potent estradiol by 17β-hydroxysteroid dehydrogenase. Therefore, ovarian estradiol synthesis depends on both LH stimulation of theca cells and FSH stimulation of granulosa cells—the "two-cell, two-gonadotropin concept" of estradiol synthesis.[30]

Granulosa-lutein cells of the corpus luteum gain the capacity to synthesize progesterone from cholesterol, and they also continue to express aromatase. Theca-lutein cells incorporated into the corpus luteum continue to express the steroidogenic enzymes necessary to produce androgen precursors, which are aromatized to estrogens by granulosa-lutein cells.

Mechanisms of Ovarian Feedback Control of GnRH and Gonadotropin Secretion

Estrogen Negative Feedback. Estrogens play a critical role in the feedback control of gonadotropin secretion. At low physiological concentrations, estrogens inhibit gonadotropin secretion. This phenomenon largely accounts for the observation that women with natural or surgical menopause, in addition to patients with aromatase deficiency, exhibit marked elevations in LH and FSH.

Estradiol negative feedback primarily reflects hypothalamic actions, although direct effects at the gonadotrope may also pertain. Studies in sheep, monkeys, and postmenopausal women suggest that estrogens selectively restrain GnRH pulse amplitude (Fig. 117.9). For example, in postmenopausal women, estradiol replacement enhances the ability of incomplete *GnRHR* blockade to reduce LH concentrations, implying an estradiol-mediated reduction in GnRH secretion.[31] But while estradiol replacement reduces free α-subunit pulse amplitude, it does not reduce free α-subunit pulse frequency in postmenopausal women.[9] Moreover, functional neuroimaging in postmenopausal women suggests that low-dose estradiol replacement reduces metabolic activity at the hypothalamus, but not at the pituitary.[32] Some animal studies also suggest that estrogens decrease pituitary LH responses to GnRH, at least transiently, but data in women are less clear.[33,34]

Estradiol also inhibits pituitary FSH secretion from gonadotropes. Maintenance of midluteal plasma estradiol concentrations across the luteal-follicular transition delays the increase in circulating FSH.[35,36] In women with GnRH deficiency, exogenous estradiol reduces FSH responses to constant-dose GnRH pulse administration.[33] These studies suggest a direct pituitary effect to reduce FSH release. While estrogen-receptor blockade increases FSH in the luteal and early follicular phases in normally cycling women, it does not increase early follicular phase FSH in GnRH-deficient women receiving fixed-dose GnRH pulses, suggesting that estradiol may also restrain FSH release via a hypothalamic mechanism.[37]

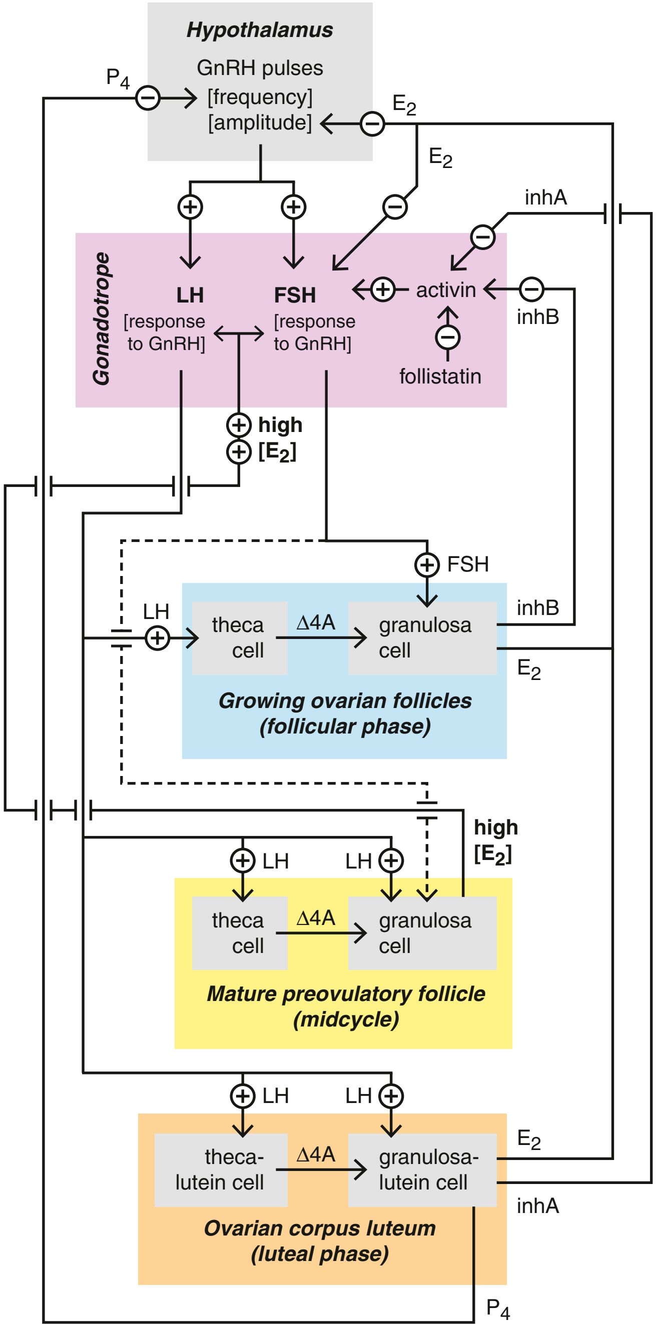

Figure 117.9 Schematic representation of feedforward and feedback relationships governing hypothalamic-pituitary-ovarian function during the menstrual cycle. *Δ4A,* Androstenedione; *E2,* estradiol; *FSH,* follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *inhA,* inhibin A; *inhB,* inhibin B; *LH,* luteinizing hormone; *P4,* progesterone.

Progesterone Negative Feedback. Progesterone appears to be the principal negative feedback regulator of day-to-day GnRH pulse frequency in women. Increased progesterone production in the early luteal phase is associated with a reduction in LH pulse frequency, and decreased progesterone production at the luteal-follicular transition is associated with an increase in LH pulse frequency. GnRH pulse frequency remains low if luteal progesterone and estradiol concentrations are maintained across the luteal-follicular transition,[38] and progesterone administration reduces LH pulse frequency during the follicular phase.[39] In postmenopausal women, progesterone plus low-dose estradiol reduces LH pulse frequency, but estradiol alone does not.[9]

The ability of progesterone to restrain GnRH pulse frequency requires the permissive presence of estradiol, most likely reflecting estrogen-related increases in hypothalamic progesterone receptor expression. In contrast, androgens antagonize the ability of progesterone to suppress GnRH pulse frequency, likely relating to androgen-induced reductions in hypothalamic progesterone receptor expression.

Inhibins, Activins, and Follistatin. FSH secretion, but not LH secretion, is substantially influenced by activins, follistatin, and inhibins. Activins are homodimers of two β-subunits, either βA or βB. Activin B is produced by pituitary cells, and activin receptors are present on gonadotropes. Activin increases FSHβ mRNA expression and stabilizes FSHβ mRNA, thus increasing FSH production. Follistatin, which is produced by gonadotropes and pituitary folliculostellate cells, binds to extracellular activin and reduces its action at the activin receptor; accordingly, follistatin reduces FSH production. Available data suggest that activins and follistatin primarily act in an autocrine/paracrine fashion within the pituitary.

Inhibin is a heterodimer peptide with two isoforms, inhibin A and inhibin B, which contain a common α-subunit disulfide-linked to one of two β-subunits—βA for inhibin A and βB for inhibin B. (Note that these β-subunits are identical to those in activins.) Inhibin B is mainly secreted by ovarian granulosa cells in small antral follicles during the early- and midfollicular phases. Circulating inhibin B concentrations increase in the early follicular phase in response to FSH-driven increases in granulosa cell numbers, but decrease in the latter follicular phase and are low during the luteal phase (Fig. 117.10).[40] Inhibin A is primarily produced by granulosa cells of the dominant follicle and granulosa-lutein cells of the corpus luteum; it therefore increases in the latter follicular phase and peaks in the luteal phase. Both inhibins bind to and interfere with the function of the activin receptor complex, thereby reducing FSH release. Thus, inhibins A and B act in an endocrine fashion to selectively restrain FSH secretion during the mid- to late follicular and luteal phases.

Estrogen and Progesterone Positive Feedback. The influence of estradiol on LH and FSH release is concentration- and time-dependent. High-dose exogenous estradiol has biphasic effects on circulating LH concentrations, with initial suppression over 2–3 days followed by marked augmentation (Fig. 117.11).[41–43] Similarly, high-dose exogenous estradiol initially reduces but later increases LH responses to exogenous GnRH. This latter phenomenon largely accounts for the midcycle (preovulatory) gonadotropin surge.

This positive feedback phenomenon—the only known example of long-loop positive feedback in endocrinology—primarily reflects the effects of high estradiol concentrations, as high-dose exogenous estradiol triggers a gonadotropin surge in the early- and midfollicular phases and in postmenopausal women.[41–43] Positive feedback is at least partly mediated at the pituitary gonadotrope, as gonadotropin responses to exogenous GnRH are increased at midcycle. Numerous mechanisms are involved, including increased *GnRHR* expression, increased gonadotropin subunit expression, and an increase in the number of LH-secreting cells.

In rodents, sheep, and monkeys, the gonadotropin surge is associated with increased GnRH pulse frequency and amplitude—a "GnRH surge." In women, the midcycle gonadotropin surge can be blocked by *GnRHR* antagonists, indicating its GnRH dependence. However, while LH and free α-subunit pulse amplitudes increase at midcycle in women, LH and free α-subunit pulse frequency does not.[44] In addition, a study employing incomplete *GnRHR* antagonism suggested that

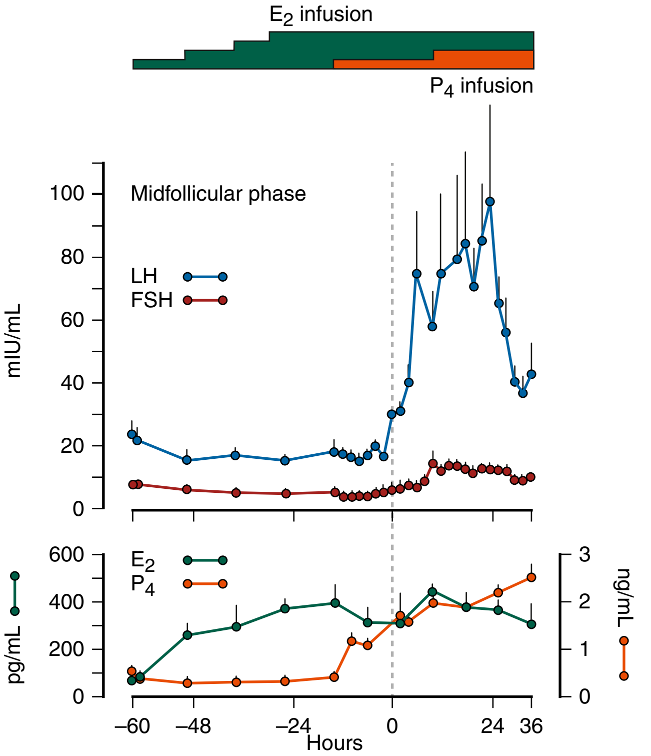

Figure 117.11 **Circulating luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol (E2), and progesterone (P4) concentrations in response to graded doses of estradiol and progesterone administered to normally-cycling women during the midfollicular phase (cycle days 7–9).** Data are represented as mean ± standard error. Conversion of conventional to International System (SI) units: estradiol (pg/mL) multiplied by 3.67 (pmol/L); progesterone (ng/mL) multiplied by 3.18 (nmol/L). (From Liu JH, Yen SS. Induction of midcycle gonadotropin surge by ovarian steroids in women: a critical evaluation. *J Clin Endocrinol Metab.* 1983;57:797–802.)

GnRH release decreases at midcycle in women[45]; and functional neuroimaging suggests that pituitary metabolic activity, but not hypothalamic metabolic activity, increases at midcycle in women.[32] Moreover, in GnRH-deficient monkeys and women, gonadotropin surges occur with fixed-dose pulsatile GnRH therapy. Indeed, apparently-normal gonadotropin surges occurred in women with GnRH deficiency even when GnRH doses were reduced from 75 ng/kg to 25 ng/kg at midcycle.[46] Taken together, these data suggest that the midcycle gonadotropin surge in women primarily—if not exclusively—reflects an increase in gonadotrope responsiveness to GnRH.

The addition of progesterone to estradiol appears to augment GnRH-stimulated gonadotropin release. For example, in GnRH-deficient women treated with fixed-dose GnRH pulses, progesterone enhances pituitary gonadotropin responses to GnRH.[47] Similarly, progesterone-receptor antagonism decreases mean LH, LH amplitude, and LH responses to exogenous GnRH administered during the luteal phase.[48,49] Notably, progesterone also has an indirect effect to increase LH pulse amplitude, related to the inverse relationship between GnRH pulse frequency and LH pulse amplitude.

Uterine Events During the Menstrual Cycle

Cyclic changes of the endometrium are geared toward preparation for embryo implantation in the event of fertilization.[50] The follicular phase corresponds to menses and the proliferative phase of the uterine cycle: after menses, estradiol from developing ovarian follicles stimulates growth of the endometrial functional layer, prompting the growth of endometrial glands and an increase in the stromal extracellular matrix. The luteal phase corresponds to the secretory phase of the uterine cycle. Corpus luteum-derived progesterone inhibits estradiol-induced mitosis and induces differentiation into the secretory endometrium: endometrial glands become coiled, they secrete glycogen and other substances needed for implantation, and spiral arteries develop.

In a fertile cycle, implantation begins approximately 6–7 days after fertilization (7–10 days after ovulation). An approximately 3-day window surrounding the peak of luteal progesterone and estradiol production represents the "implantation window"—the time when the secretory endometrium is optimal for implantation. Trophoblast-derived CG maintains function of the corpus luteum and thus endometrial decidualization, which is critical for maintenance of pregnancy. If implantation does not occur, however, the corpus luteum regresses, and the withdrawal of progesterone support initiates a cascade of events that culminate in menstruation, or shedding of the functional portion of the uterine lining. The beginning of this process is characterized by contraction of uterine spiral arteries and arterioles, leukocyte infiltration, and degradation of the endometrial stroma. By the vasoconstriction model of menstruation, menses result from anoxia and reperfusion injury after uterine spiral artery and arteriole constriction and relaxation, respectively, whereas the inflammation hypothesis of menstruation holds that menses primarily reflect the inflammatory response induced by progesterone withdrawal. It is likely that a combination of vasoconstriction and inflammation contribute to menstruation. Menstrual flow, which typically lasts 4–6 days, primarily consists of endometrial debris and blood. A basal layer of endometrium remains intact for regeneration in response to follicular estrogen production.

INTEGRATED PHYSIOLOGY OF THE MENSTRUAL CYCLE

KEY POINTS

- Cyclical ovulation involves complex, coordinated, sequenced, and bidirectional interactions between the hypothalamic-pituitary unit and the ovary.
- During the follicular phase, FSH and LH act in concert to stimulate ovarian follicular development, selection of a dominant follicle, and an increase in estradiol production.
- In the midfollicular phase, ovarian estradiol stimulates endometrial proliferation, while both estradiol and inhibin B selectively restrain FSH release, discouraging the development of multiple dominant follicles.
- At midcycle, high concentrations of estradiol and a modest rise in progesterone—both derived from the mature preovulatory follicle—markedly augment pituitary LH and FSH responses to GnRH, inducing the midcycle gonadotropin surge, which in turn provokes ovulation.
- The remnant of the dominant follicle becomes a corpus luteum and secretes progesterone, estradiol, and inhibin A; these hormones suppress GnRH pulse frequency, inhibit FSH release, and prepare the endometrium for possible pregnancy.
- In a non-fertile cycle, the corpus luteum regresses, and circulating progesterone, estradiol, and inhibin A concentration levels fall; the loss of progesterone support leads to endometrial shedding (menstruation), and an increase in GnRH pulse frequency drives a monotropic rise in plasma FSH levels, which stimulates the next wave of follicular recruitment and selection of a dominant follicle.

Luteal-Follicular Transition

In a non-fertile cycle, the corpus luteum regresses toward the end of the luteal phase. Plasma concentrations of progesterone, estradiol, and inhibin A—products of the corpus luteum—decrease during the last 4–5 days of the luteal phase (Fig. 117.12). In addition to provoking endometrial shedding (menstruation), the decrease in progesterone and estradiol allows GnRH pulse frequency to increase from about 1 pulse every 3–5 hours to 1 pulse every 90–100 minutes in the early follicular phase (Fig. 117.13).[51] In one careful study, GnRH pulse frequency increased 4.5-fold (from 3 to 13.5 pulses per 24 hours), mean LH concentrations increased 67%, and mean FSH concentrations increased 3.5-fold across the luteal-follicular transition (Fig. 117.14).[24]

The marked increase in FSH across the luteal-follicular transition appears to reflect increased GnRH pulse frequency in the setting of decreasing estradiol and inhibin A concentrations—hormones that inhibited pituitary FSH release during much of the luteal phase. Studies in GnRH-deficient women receiving pulsatile exogenous GnRH indicate that the transition from a low physiological GnRH pulse frequency (every 240 minutes) to a higher physiological GnRH pulse frequency (every 90 minutes) is required for the normal intercycle rise in FSH.[52] The preferential increase in circulating FSH concentrations compared with LH likely reflects the longer circulating half-life of FSH as well. Importantly, the marked increase in FSH initiates dominant follicle selection and the next wave of cyclic follicular recruitment.

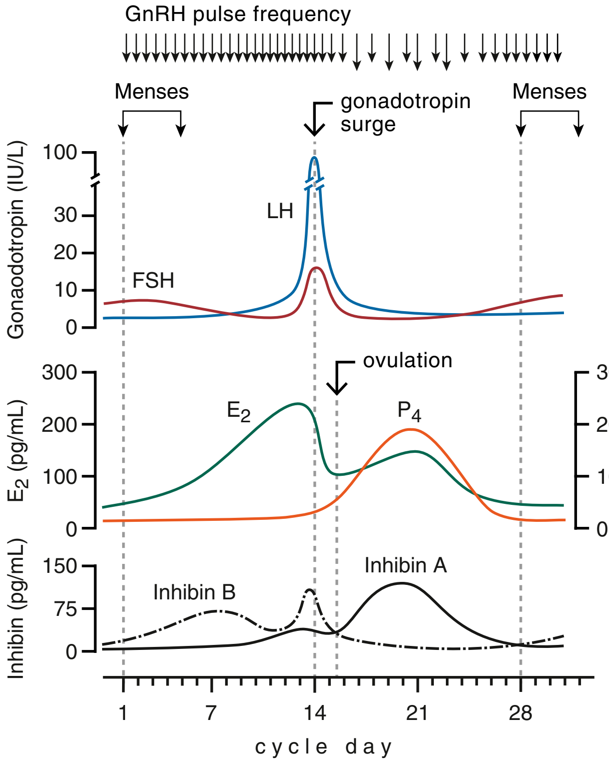

Figure 117.12 **Schematic representation of circulating concentrations of luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol (E2), progesterone (P4), and inhibins A and B across an ovulatory menstrual cycle.** Arrows at the top of the diagram indicate relative changes in pulsatile gonadotropin-releasing hormone (GnRH) secretion. Follicular Phase

Early Follicular Phase. The early follicular phase is characterized by relatively high plasma FSH concentrations and follicular growth. FSH stimulates growth of a cohort of antral follicles by activating granulosa cell proliferation and estradiol secretion, and FSH animates lead follicle growth and the establishment of dominance. Sleep-related slowing of GnRH pulse frequency is very prominent in the early follicular phase, which may support the robust FSH secretion characteristic of this portion of the cycle.[11] FSH-stimulated granulosa cell proliferation also leads to an increase in inhibin B production.

By definition, the initial days of the menstrual cycle are marked by menstrual bleeding. After completion of menstruation, a basal layer of endometrium remains. Thereafter, estradiol production from developing ovarian follicles stimulates endometrial proliferation.

Midfollicular Phase. FSH continues to stimulate the growth of recruited follicles in the first part of the follicular phase. However, only one follicle typically establishes dominance—at approximately 10 mm diameter—and progresses further towards full maturity and ovulation. Mechanisms accounting for the emergence of a single dominant follicle across the follicular phase are unclear, but estradiol and inhibin B appear to play important roles by reducing FSH secretion across the follicular phase. As described previously, inhibin B and estradiol from growing follicles suppress FSH release via a direct and selective action on the gonadotropes: this midfollicular reduction in circulating

Hypothalamic gonadotropin-releasing hormone secretion and follicle-stimulating hormone dynamics during the luteal-follicular transition. *J Clin Endocrinol Metab.* 1992;74:600–607.)

FSH concentrations reduces the growth stimulus for non-dominant follicles. Additional mechanisms likely pertain to regression of non-selected follicles.

LH pulse frequency increases to approximately 1 pulse every 60 minutes by the midfollicular phase—presumably reflecting a gradual release from progesterone negative feedback—while increasing estradiol from the dominant follicle restrains LH (GnRH) pulse amplitude. However, in contrast to the decrease in FSH concentrations, average LH concentrations increase across the follicular phase, perhaps in part reflecting the increase in GnRH pulse frequency.

Increasing estradiol concentrations in the midfollicular phase stimulate endometrial proliferation and development of endometrial glands. This process will continue into the late follicular phase.

Late Follicular Phase. In the latter part of the follicular phase, the dominant follicle grows at a rate of approximately 2 mm daily—related to continued granulosa cell proliferation and antral fluid accumulation. The dominant follicle typically reaches a diameter of 20–25 mm (range, 18–30 mm) at the time of ovulation. Although inhibin B levels decline in the later follicular phase, the growing dominant follicle produces increasing amounts of estradiol and inhibin A, both of which selectively restrain FSH release.

Toward the end of the follicular phase, estradiol and FSH stimulate the appearance of LH receptors on the granulosa cell layers closest to the basal lamina. Granulosa cells in the dominant follicle begin to luteinize and produce progesterone, plasma concentrations of which increase to approximately 1.0–1.5 ng/mL (~3.2–4.8 nmol/L) on the day of gonadotropin surge generation. Plasma estradiol concentration peaks at approximately 200–400 pg/mL (~730–1470 pmol/L) on the day before gonadotropin surge initiation.[42,53] The sustained increase in circulating estradiol concentrations provokes a marked increase in gonadotrope responsivity to GnRH, and the gonadotropin surge is initiated: in essence, the mature follicle signals readiness for ovulation by entraining the gonadotropin surge, thus coordinating the ovulatory stimulus with full dominant follicle maturation.

Midcycle Gonadotropin Surge and Ovulation

LH and FSH concentrations increase approximately 10- and 4-fold, respectively, at midcycle (Fig. 117.15).[53] This preovulatory gonadotropin surge relates to a marked increase in gonadotrope responsiveness to GnRH, which primarily reflects the estradiol positive feedback phenomenon.[41,54–56] Other factors may also be required for normal gonadotropin surges at midcycle, and candidate contributors include progesterone, inhibin A, neuropeptide, galanin, and kisspeptin, among others. For example, circulating progesterone concentrations begin to increase approximately 12 hours before gonadotropin surge generation (Fig. 117.15)[41,53]; progesterone appears to augment estradiol positive feedback at midcycle[41,55]; progesterone-receptor antagonism delays gonadotropin surge generation[57]; and some studies suggest that progesterone is important for normal surge timing, surge duration, and/or the FSH surge.[41,42,55,56]

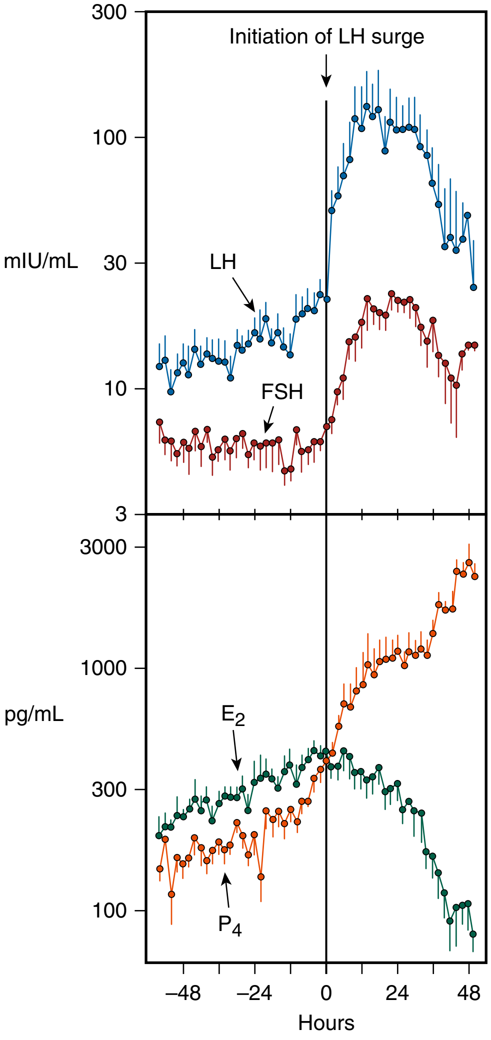

Figure 117.15 **Luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol (E2), and progesterone (P4) concentrations at midcycle, aligned to gonadotropin surge initiation.** Data are shown as mean ± standard error and displayed on a logarithmic scale. Conversion of conventional to International System (SI) units: estradiol (pg/mL) multiplied by 3.67 (pmol/L); progesterone (pg/mL) multiplied by 0.00318 (nmol/L). (From Hoff JD, Quigley ME, Yen SS. Hormonal dynamics at midcycle: a reevaluation. *J Clin Endocrinol Metab.* 1983;57:792–796.)

By acting on newly acquired LH receptors expressed by the outer granulosa cells, the LH surge triggers ovulation—rupture of the mature follicle with release of the ovum and surrounding granulosa cells (cumulus-oocyte complex) into the peritoneal space en route to the fallopian tubes. Ovulation occurs approximately 24–36 hours after the start of the surge. The LH surge also triggers resumption of meiosis I and luteinization of the follicular remnant (i.e., formation of the corpus luteum). The preovulatory FSH surge may play a role in the recruitment of follicles that will develop in subsequent cycles. The midcycle gonadotropin surge lasts approximately 48 hours,[53] but mechanisms underlying surge termination remain unclear.

Notably, there appear to be substantial species differences in the mechanisms underlying gonadotropin surge generation.[58] In rodents, GnRH and gonadotropin surges depend on estradiol-induced activation of kisspeptin neurons in the anteroventral periventricular nucleus (AVPV) of the preoptic area. In primates, however, kisspeptin neurons primarily reside in the infundibular (arcuate) nucleus, and gonadotropin surges occur in female monkeys after surgical separation of the mediobasal hypothalamus from the remainder of the brain. While kisspeptin neurons have been identified in the preoptic area in primates, functional analogues to rodent AVPV kisspeptin neurons have not been identified. Also, while LH surges in female rodents are temporally confined to the late afternoon—believed to reflect a circadian signal that is relayed only in the presence of preovulatory estradiol concentrations—gonadotropin surges do not appear to be constrained to a specific time of day in primates.

Luteal Phase

Serum estradiol concentration falls precipitously around the time of the gonadotropin surge, reflecting functional changes in the newly luteinized follicle. In contrast, progesterone concentrations continue to rise, reflecting LH-induced luteinization of granulosa cells shifting steroidogenesis toward progesterone secretion. During the luteal phase, the corpus luteum is the dominant structure in the ovary, and progesterone is the dominant steroid produced by the corpus luteum.

FSH and LH levels decrease rapidly and remain relatively low during much of the luteal phase. LH pulse frequency progressively decreases across the luteal phase, achieving a nadir frequency of approximately 1 pulse every 3–5 hours (or slower) at the mid- to late luteal stage. Low luteal GnRH pulse frequency reflects negative feedback by high levels of progesterone and estradiol, products of the corpus luteum. While high-amplitude LH pulses occur at regular intervals in the early luteal phase, LH pulse frequency and amplitude exhibit more variability in the mid- and late luteal phases.[59]

While progesterone secretion does not initially exhibit periodicity, prominent LH-induced pulses of progesterone secretion—coinciding with LH pulses—are evident in the mid- and late luteal phases.[59] The corpus luteum also produces estradiol, a number of other steroids (e.g., 17-hydroxyprogesterone, estrone), and inhibin A. Inhibin A and estradiol suppress FSH release from gonadotropes, helping to ensure that the antral follicle growth does not proceed prematurely.

Ovarian secretion of the above products increases in the 7–8 days after ovulation, and both progesterone and estradiol levels peak in the midluteal phase; this is when the secretory endometrium is most hospitable to implantation of the fertilized ovum—the “implantation window.” Continued progesterone secretion is a critical requirement for maintenance of pregnancy. If oocyte fertilization occurs, the resulting trophoblast produces CG, which activates LH receptors and maintains corpus luteum function. If fertilization does not occur, however, the corpus luteum eventually regresses. As corpus luteum function wanes, circulating progesterone, estradiol, and inhibin A concentrations fall. The release from negative feedback permits an increase in GnRH pulse frequency and FSH release, which initiates the next wave of follicular recruitment and dominant follicle selection. The reduction in circulating progesterone concentrations also initiates a cascade of events leading to endometrial shedding (menses).

NEUROENDOCRINE MECHANISMS OF ANOVULATION

KEY POINTS

- Anovulation is relatively common in recently-menarcheal girls and in the years leading up to menopause.
- Physiological anovulation occurs during pregnancy, lactation, and in the setting of inadequate energy availability.
- Numerous genetic defects can cause isolated hypogonadotropic hypogonadism (IHH) with accompanying pubertal failure and infertility.
- In functional hypothalamic amenorrhea (FHA), decreased energy availability, stress, and other factors lead to central inhibition of GnRH pulse frequency and hypogonadotropic hypogonadism.
- Hyperprolactinemia acts in a dose-dependent fashion to suppress GnRH pulse frequency, which can lead to gonadotropin deficiency.
- Polycystic ovary syndrome (PCOS) is associated with a number of neuroendocrine abnormalities that contribute to ovulatory dysfunction: relative resistance of the GnRH pulse generator to progesterone and estradiol negative feedback, persistently high GnRH pulse frequency, relatively high LH concentrations, and relatively low FSH concentrations.

Anovulation most commonly manifests as a disruption in expected menstrual patterns. Failure to achieve menarche by age 15 years, or by 3 years after thelarche, represents primary amenorrhea. In the absence of pregnancy, secondary (postmenarcheal) amenorrhea is defined by the absence of menstrual bleeding for at least 3 months. Although normal intermenstrual length is considered to be 21–35 days, oligomenorrhea is often defined as an intermenstrual length greater than 45 days or, alternatively, fewer than 9 menses per year.

Anovulation may relate to defects at any of the three levels of the hypothalamic-pituitary-ovarian axis. Anovulation may also relate to normal physiological processes (e.g., pregnancy, lactation) or reflect mechanisms that maintain whole-body homeostasis (e.g., in the setting of inadequate energy availability). Anovulation is also common in recently-menarcheal girls (see Chapter 102) and in the years leading up to menopause (see Chapter 122).

Physiological Anovulation

Peripubertal (Maturational) Anovulation. During childhood, LH (GnRH) pulse frequency and amplitude are low, and gonadotropin concentrations are inadequate to stimulate ovarian follicular development or substantial ovarian sex steroid production. Puberty is heralded by sleep-associated increases in both LH (GnRH) pulse frequency and amplitude. The resulting increases in circulating gonadotropin concentrations begin to stimulate ovarian follicular development and sex steroid production, especially estradiol, which largely accounts for the physical changes of early puberty (e.g., thelarche).

Adult patterns of gonadotropin secretion are established over time, and menstrual irregularity and anovulation are relatively common in recently-postmenarcheal adolescent girls. Available data suggests that the establishment of the complex cyclic relationships among the hypothalamus, pituitary, and ovary is contingent on maturation of both the hypothalamic-pituitary unit and the ovaries. For example, cyclic hormone activity with small amplitude LH surges have been demonstrated prior to menarche, with more prominent cyclic changes in LH and progesterone being observed across pubertal maturation.[60] In keeping with these findings, transdermal estradiol administration can provoke an approximately 5-fold increase in urinary LH in premenarcheal, early to mid-pubertal girls (Tanner II-III, ages 9–12 years).[61] While this proportional increase was similar to that in adult women, the absolute urinary LH peak was approximately one-quarter of that in adult women. Nonetheless, these data suggest early functioning of the estrogen positive feedback mechanism underlying gonadotropin surge generation, and these investigators hypothesized that ovarian factors play an important role in physiological peripubertal anovulation.

A recent detailed study compared cycles in healthy Tanner V girls (0.4–3.5 years postmenarche) with ovulatory cycles in adults.[62] Ovulatory adolescent cycles were associated with lower LH and FSH levels in the early follicular and luteal phases; lower estradiol concentrations in the early follicular, late follicular, preovulatory, and luteal phases; and a suggestion of lower luteal progesterone concentrations. After adjusting for lower preovulatory estradiol levels, the magnitude of the midcycle LH peak was similar to that in adult cycles, which may imply maturity of the estrogen positive feedback mechanism in such cycles. Ovulatory adolescent cycles were associated with lower early follicular phase inhibin B concentrations, even after statistically adjusting for lower FSH concentrations, in addition to lower mid- to late follicular estradiol concentrations, even after statistically adjusting for lower FSH and smaller follicle sizes: these findings may suggest ovarian immaturity. In adolescent ovulatory cycles with short luteal phases, LH, FSH, estradiol, and progesterone levels were low during the luteal phase. The magnitude of the midcycle LH peak was also reduced, even after adjusting for preovulatory estradiol concentrations, suggesting immature positive feedback as a possible mechanism for luteal insufficiency. Girls with anovulatory cycles demonstrated variable patterns: some demonstrated minimal follicle growth, whereas others demonstrated preovulatory follicles without ovulation (at times despite a robust midcycle LH peak), either with or without follicle luteinization. Anovulatory adolescent cycles were marked by lower LH and FSH in the early follicular, midcycle, and luteal phases; and the midcycle LH peak was attenuated even after statistically adjusting for estradiol levels. Anovulatory cycles also demonstrated reduced inhibin B concentrations in the early follicular phase, even after statistically adjusting for lower FSH, suggesting ovarian immaturity.

In summary, adult patterns of cyclic hypothalamic-pituitary-ovarian activity are established over time. Early cycles may be characterized by longer follicular phases, relatively slow follicle growth, delayed dominant follicle emergence, failure to achieve a preovulatory follicle, failure to achieve ovulation despite a midcycle LH surge, and/or ovulation with short luteal phases. It is tempting to speculate that the likelihood of more-mature cycle patterns increases as peripubertal girls mature—anovulatory cycles without follicle luteinization, anovulatory cycles with follicle luteinization, ovulatory cycles with luteal insufficiency, and normal ovulatory cycles[63]—but this notion requires further study. The endocrinology of sexual maturation and puberty is addressed in more detail in Chapter 102.

Pregnancy and Lactation. Pregnancy is the most common cause of amenorrhea. Markedly elevated placental sex steroid concentrations and significant hyperprolactinemia profoundly suppress GnRH and gonadotropin secretion, thus halting follicular development during pregnancy. The endocrinology of pregnancy and parturition is addressed in more detail in Chapter 129.

In mothers who do not breastfeed, ovulation typically resumes over the 8 weeks following delivery. In lactating mothers, however, GnRH secretion remains suppressed, and pregnancy is very uncommon in fully breastfeeding, amenorrheic women.[64,65] This presumably represents an advantageous physiological adaptation since short intervals between births can negatively impact infant well-being. Pulsatile exogenous GnRH can restore ovarian function in amenorrheic lactating women, suggesting that suppressed GnRH secretion is the primary cause of lactational amenorrhea.[66]

Hyperprolactinemia suppresses GnRH pulsatility, yet circulating prolactin concentrations gradually decrease towards normal despite continued breastfeeding. Animal studies suggest that lactation is associated with increased orexigenic neural system activity (e.g., NPY) and reduced anorexigenic neural system activity, and these alterations may suppress GnRH neuronal activity.[67] Indeed, the very high energy requirements of lactation likely impair GnRH secretion in many of the same ways described below in the context of reduced energy availability. In addition, the suckling stimulus likely inhibits the hypothalamic-pituitary-ovarian axis through additional neural mechanisms, and the intensity of suckling appears to be an important determinant of contraceptive effectiveness in women.

Selected Causes of Pathological Anovulation

The World Health Organization (WHO) has categorized anovulation into three primary classes. Although this classification system is not often used in the clinical setting, it represents a useful conceptual framework. Hypogonadotropic hypogonadal anovulation (WHO class 1) is characterized by estrogen deficiency and low or inappropriately normal serum LH and FSH concentrations. At its foundation, this relates to inadequate gonadotropin secretion for maintenance of cyclic ovulation, as may occur with isolated GnRH deficiency, FHA, and structural hypothalamic-pituitary damage (e.g., related to tumors, surgery, radiation, or pituitary infarction [Sheehan's syndrome]). Although hyperprolactinemic anovulation constitutes a separate category according to the WHO schema, its pathophysiology primarily relates to hypogonadotropic hypogonadism. The most common cause of normogonadotropic normoestrogenic anovulation (WHO class 2) is PCOS, although congenital adrenal hyperplasia is another important example. Women with PCOS are estrogen sufficient and typically have serum gonadotropin concentrations within the reference range, although as a group these patients demonstrate relative LH excess and relative FSH deficiency. Hypergonadotropic hypoestrogenic anovulation (WHO class 3) most commonly relates to a marked reduction in ovarian follicles (primary ovarian insufficiency). Such women are estrogen deficient and have elevated plasma LH and FSH concentrations due to the loss of central negative feedback by estrogens and inhibins.

Isolated Hypogonadotropic Hypogonadism. IHH typically refers to inadequate GnRH secretion or action related to one or more genetic defects. Patients with genetic defects that severely impair GnRH secretion or action demonstrate pubertal failure, hypogonadotropic hypogonadism, and infertility.[68]

The first discovered cause of Kallmann syndrome—a congenital disorder characterized by GnRH deficiency and abnormal sense of smell (anosmia or hyposmia)—was deletion of *ANOS1* (formerly *KAL1*), which encodes a secreted matrix glycoprotein (anosmin-1) believed to be critical for olfactory system development. Loss-of-function *ANOS1* mutations lead to abnormal olfactory system development, which interrupts the guidance infrastructure for migrating GnRH neurons. Accordingly, GnRH neurons fail to reach the hypothalamus appropriately. This syndrome exemplifies the importance of the olfactory guidance system as nascent GnRH neurons migrate from the nasal (olfactory) placode to the hypothalamus during embryological development.

Additional genes associated with Kallmann syndrome include those for *SEMA3A* (semaphorin 3A) and *SOX10* (SRY-box 10), among others. Numerous genes have been associated with both Kallmann syndrome and normosmic IHH, including *PROK2* (prokineticin 2), *PROKR2* (prokineticin 2 receptor), *FGF8* (fibroblast growth factor-8), *FGFR1* (fibroblast growth factor receptor 1), *CHD7* (chromodomain helicase DNA binding protein 7), and *NSMF* (N-methyl-D-aspartate [NMDA] receptor synaptonuclear signaling and neuronal migration factor), among others. Normosmic IHH may also be related to mutations of *GNRH1*, *GNRHR*, *KISS1*, *KISS1R*, *TAC3*, and *TAC3R*. Inheritance patterns are variable depending on the genetic defect(s), although some cases appear to be sporadic. Moreover, penetrance and manifestations can be variable among affected members of the same family, in part related to oligogenic IHH gene mutations.

In most cases of IHH—with notable exceptions including *GNRHR* mutations—pubertal changes can be induced by pulsatile exogenous GnRH therapy.[15,69] However, treatment more commonly involves sex steroid (estradiol) administration to induce and maintain secondary sex characteristics, with progesterone eventually added to prevent endometrial hyperplasia. In most patients, ovulation and fertility can be achieved with exogenous gonadotropin therapy or, much less commonly, pulsatile GnRH therapy.

Functional Hypothalamic Amenorrhea. Since pregnancy and lactation are metabolically demanding, reproductive function may be suppressed when energy availability is reduced (nutritional infertility). This may occur with absolute reductions in calorie intake, insufficient calorie intake vis-à-vis energy demands (e.g., exercise), or both. Stress may also impair reproductive function, presumably because the presence of stressors can herald an inauspicious environment for childbearing.

FHA represents the reversible suppression of hypothalamic-pituitary function that may accompany reduced body weight, disordered eating (e.g., restrictive eating patterns), excessive exercise, psychological stress, or a combination of these factors. These relationships are mediated by neural systems located in the hypothalamus that impair GnRH and gonadotropin secretion. The primacy of dysfunctional GnRH secretion is supported by studies demonstrating that pulsatile exogenous GnRH restores cyclic ovulation and fertility in women with FHA.[15] Women with FHA demonstrate variable patterns of LH pulse secretion, including absent pulses, low frequency and amplitude, low frequency only, low amplitude only, and (apparently) normal frequency and amplitude.[15,70,71] Some women with FHA demonstrate variable patterns over time (Fig. 117.16).[15,70,71] Many such patients exhibit a GnRH pulse frequency approximating 1 pulse every 3–4 hours, similar to that observed in the luteal phase. Regardless of the particular secretory patterns in women with FHA, GnRH and gonadotropin secretion is inadequate for normal follicular development, estrogen production, and ovulation. For example, while hourly GnRH pulses restore ovulatory function in GnRH-deficient monkeys, a long-term GnRH pulse frequency of 1 pulse every 2 hours was associated with reduced LH concentrations, limited follicular development, and anovulatory cycles; and a long-term pulse frequency of 1 pulse every 3 hours largely abolished follicular development.[72]

The observation that FHA can follow significant weight loss contributed to the "critical fatness hypothesis," which holds that FHA largely reflects insufficient body fat stores. However, subsequent studies suggested that reduced energy availability—rather than reduced fat stores per se—is a primary cause of impaired reproductive neuroendocrine function in these women. For example, calorie restriction can impair menstrual cyclicity before weight loss is evident, and amenorrhea can persist after weight restoration in those with a history

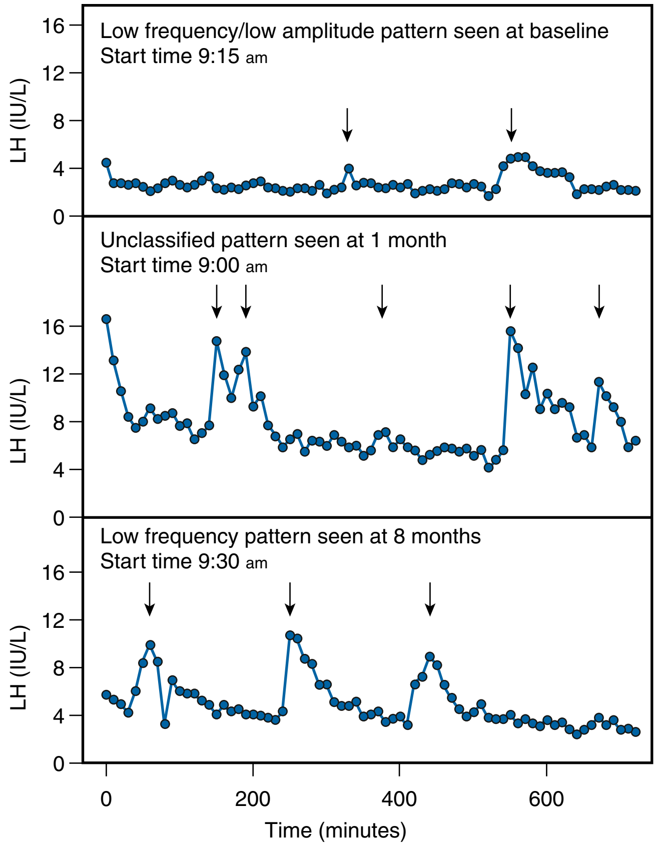

Figure 117.16 Three luteinizing hormone (LH) concentration time series in a single woman with functional hypothalamic amenorrhea studied longitudinally. This patient demonstrated three different LH pulse patterns at three different time points. Arrows indicate significant LH pulses. (From Perkins RB, Hall JE, Martin KA. Neuroendocrine abnormalities in hypothalamic amenorrhea: spectrum, stability, and response to neurotransmitter modulation. *J Clin Endocrinol Metab.* 1999;84:1905–1911.)

of eating disorders.[73] Studies in women and monkeys suggest that reproductive neuroendocrine dysfunction may not occur until energy availability is reduced by at least 30%, and altered LH pulsatility occurs within 5 days of controlled reductions of energy availability.[74,75] While some have suggested that excessive exercise per se may impair GnRH pulsatility, enhancing calorie intake to maintain adequate energy availability can prevent LH secretory abnormalities despite significant exercise loads.[76,77]

The neurobiological mechanisms underlying FHA are complex and incompletely understood. Decreased energy availability provokes numerous hormonal changes including reduced leptin, insulin, insulin-like growth hormone-1, and thyroid hormone concentrations; increased growth hormone and ghrelin concentrations; and activation of the hypothalamic-pituitary-adrenal axis.[78] Of interest, leptin plays a critical permissive role in reproductive function, and recombinant human leptin administration may rapidly (within 2 weeks) increase LH pulsatility in women with FHA, followed by increases in dominant follicle number, ovarian volume, and estradiol concentrations, with ovulation in a subset.[79]

A number of neuropeptides appear to mediate reproductive impairments in the setting of reduced energy availability, including kisspeptin, NPY, galanin-like peptide, beta-endorphin, CRH, ghrelin, and polypeptide YY. Such effects are at least partly mediated by kisspeptin neurons.[80,81] For example, leptin-deficient (ob/ob) mice demonstrate reduced hypothalamic *Kiss1* expression, which is partially reversed with leptin administration. Increased opioid tone also appears to contribute to low GnRH pulse frequency in FHA, as it can be rapidly reversed with opiate receptor blockade (naloxone).[82]

Stress can also contribute to the pathophysiology of FHA. Women with FHA may be more likely to exhibit perfectionism and difficulty coping with stressors; and amenorrheic athletes and women with anorexia nervosa have evidence of hypothalamic-pituitary-adrenal axis activation including elevated serum cortisol concentrations and blunted cortisol responses to exogenous CRH.[78] Mechanisms underlying the suppression of reproductive function during stress are highly complex; and while suppression of GnRH secretion is a major component, direct pituitary and gonadal effects may occur as well. A number of mediators have been implicated in stress-related inhibition of GnRH secretion, including CRH, urocortins (CRH-like peptides), adrenocorticotropic hormone (ACTH), arginine vasopressin (AVP), endogenous opioid peptides, and cortisol, in addition to noradrenergic, GABAergic, and serotoninergic neural pathways.

Women exhibit variable reproductive sensitivity to reduced energy availability and other forms of stress: some are more “stress sensitive,” whereas others are more “stress resilient.” Mechanisms for such variability remain incompletely defined, but one study suggested that mutations in some IHH-associated genes (e.g., *ANOS1*, *FGFR1*, *PROKR2*, and *GNRHR*) are more likely in women with FHA, suggesting that underlying genetic (and perhaps epigenetic) architecture plays an important role.[83]

Mainstays of FHA management include behavioral approaches to restoring sufficient energy availability (e.g., increased calorie intake, decreased physical activity) along with psychological support (e.g., cognitive behavioral therapy).[84] Ovarian hormone replacement—particularly transdermal estradiol with cyclic progestin—can also be used as needed. When pursued, pharmacological ovulation induction will generally require exogenous gonadotropins or pulsatile GnRH therapy.

Hyperprolactinemic Anovulation. Elevated circulating prolactin concentrations are commonly associated with ovulatory dysfunction. The causes of hyperprolactinemia are numerous and include pregnancy, lactation, and prolactin-secreting pituitary adenomas (prolactinoma). Moreover, since prolactin production and release from pituitary lactotrophs is tonically suppressed by hypophysiotropic dopamine, hyperprolactinemia may result from impaired hypothalamic dopamine secretion, interruption of hypothalamic dopamine transport to lactotrophs, or impaired action at lactotroph dopamine D2 receptors (e.g., some medications).

Hyperprolactinemia is associated with low-frequency, irregular LH pulse patterns, which are insufficient to maintain normal gonadotropin secretion.[85,86] Significant hyperprolactinemia can cause secondary hypogonadism with low or inappropriately normal serum gonadotropin concentrations, impaired follicular maturation, and failure to ovulate. The degree of menstrual cycle dysfunction generally correlates with the degree of hyperprolactinemia. As a general rule, mild hyperprolactinemia (2- to 3-fold elevated) can impair luteal progesterone secretion and reduce fertility, but may not disrupt menstrual cyclicity, while higher prolactin concentrations (2- to 5-fold elevated) tend to be associated with ovulatory dysfunction and either oligomenorrhea or amenorrhea. Women with severe hyperprolactinemia (more than 4- to 5-fold elevated) typically exhibit conspicuous secondary hypogonadism marked by estrogen deficiency and amenorrhea. It seems highly likely that different individuals exhibit hypothalamic-pituitary-ovarian dysfunction at different prolactin thresholds.

Prolactin-mediated GnRH suppression appears to involve hypothalamic opioids, as pulsatile LH (GnRH) secretion is improved with

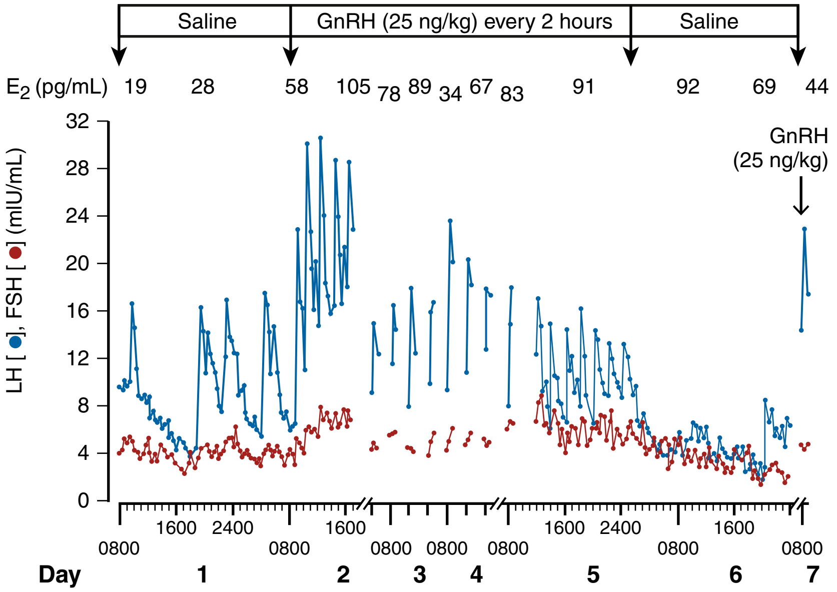

Figure 117.17 LH and FSH concentration time series in a woman with hyperprolactinemia (average serum prolactin 134 ng/mL [5.8 nmol/L]). LH pulse frequency and estradiol concentrations were low during saline infusion. Exogenous low-dose GnRH pulses administered every 2 hours for the following 4 days (days 2–5) led to an approximately 3-fold increase in serum estradiol (E_2) concentrations (circa 30 to 90 pg/mL). Conversion of conventional to International System (SI) units: estradiol (pg/mL) multiplied by 3.67 (pmol/L). *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone. (From Sauder SE, Frager M, Case GD, et al. Abnormal patterns of pulsatile luteinizing hormone secretion in women with hyperprolactinemia and amenorrhea: responses to bromocriptine. *J Clin Endocrinol Metab.* 1984;59:941–948.)

naloxone (opiate receptor antagonist) despite continued hyperprolactinemia.[87] Impaired GnRH secretion also appears to reflect suppression of kisspeptin neuron function. For example, exogenous prolactin decreases kisspeptin expression in the arcuate nucleus in mice, but prolactin does not suppress pulsatile LH secretion in mice lacking prolactin receptors in arcuate nucleus kisspeptin neurons.[88] Moreover, exogenous kisspeptin restores gonadotropin secretion, ovulation rates, and estrus cyclicity in mice subjected to experimental hyperprolactinemia[89]; and exogenous kisspeptin may at least partially restore gonadotropin and estradiol secretion in women with hyperprolactinemia.[90]

Pulsatile GnRH treatment reverses hyperprolactinemia-related hypogonadotropic hypogonadism (Fig. 117.17)[85] and infertility, suggesting that impaired GnRH secretion is the primary cause of hyperprolactinemia-associated anovulation. However, the first-line medical approach to hyperprolactinemia-related ovulatory dysfunction is dopamine agonist therapy (e.g., cabergoline, bromocriptine), which suppresses prolactin secretion and thus restores cyclic ovulation.

Polycystic Ovary Syndrome. PCOS is a complex and heterogeneous disorder characterized by androgen excess, anovulation, and polycystic ovarian morphology (see Chapter 124). Although the precise causes of PCOS remain enigmatic, important factors contributing to PCOS pathophysiology include (potentially inherent) abnormalities of ovarian steroidogenesis, the effects of insulin resistance and compensatory hyperinsulinemia, and neuroendocrine dysfunction. Disordered gonadotropin secretion in PCOS contributes to both dysregulated steroidogenesis (hyperandrogenemia) and abnormal follicular dynamics (e.g., enhanced androgen-stimulated follicular activation but later follicular arrest).

Ovarian hyperandrogenemia in PCOS is LH dependent, as long-acting GnRH agonists markedly reduce androgen production in women with PCOS. Moreover, women and adolescents with PCOS exhibit persistently high GnRH pulse frequency, increased LH pulse amplitude, exaggerated LH responses to exogenous GnRH, relative LH excess, and relative FSH deficiency. In one study, after excluding women with PCOS who had recently ovulated, 75% exhibited elevated serum LH and 94% had elevated LH-to-FSH ratio.[91] LH concentrations tend to be lower in those with concomitant obesity, but LH (GnRH) pulse frequency is high in PCOS regardless of obesity status (Fig. 117.18).[92] Also of interest, a number of gonadotropin-related genes including *FSHB*, *FSHR* (FSH receptor), *LHB*, and *LHCGR* (LHCG receptor) have been implicated in the etiology of PCOS.[93,94]

High- and low-frequency GnRH pulses favor LH or FSH production, respectively; accordingly, elevated GnRH pulse frequencies contribute to relative excess and deficiency of LH and FSH, respectively, observed in PCOS. High GnRH pulse frequency in PCOS partly reflects relative resistance to progesterone and estradiol negative feedback, and this feedback defect can be reversed with androgen receptor blockade (Fig. 117.19).[95] Additional basic science observations suggest that hyperandrogenemia plays a central role in the neuroendocrine dysfunction of PCOS.[96] For example, dihydrotestosterone (DHT) increases GnRH neuron firing rates in murine brain slices. Prenatally androgenized (PNA) animals, which exhibit both endogenous ovarian hyperandrogenism and ovulatory dysfunction, exhibit high GnRH neuron firing frequency, increased LH secretion, and central resistance to the feedback effects of sex steroids. Similarly, in female rhesus monkeys, mild experimental hyperandrogenemia beginning at 1 year of age (prepubertal) increased LH pulse frequency 2.6-fold at 5 years of age.

Animal studies suggest that elevated GnRH pulsatility in PCOS is at least partly mediated by afferent neurons.[96] For example, some studies suggest that PNA rodents exhibit increased kisspeptin and NKB expression in the arcuate nucleus. The roles of kisspeptin and KNDy neurons in women with PCOS remain unclear. Of interest, however, neurokinin-3 receptor antagonism appears to reduce LH pulse frequency and serum LH concentrations in women with PCOS.[97]

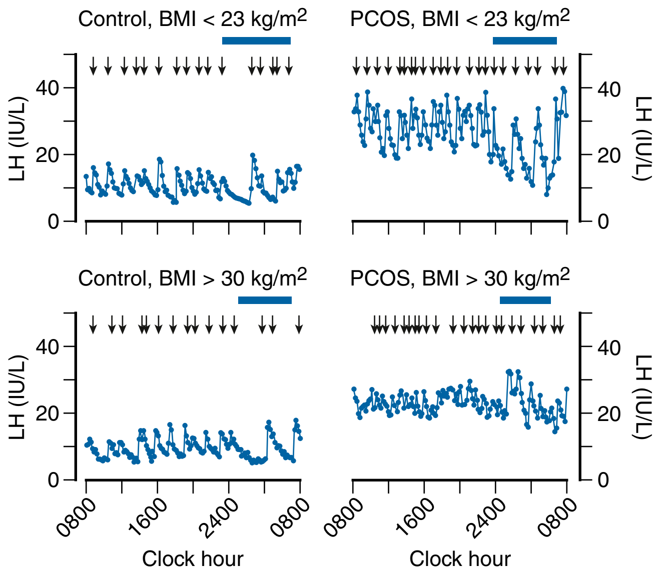

Figure 117.18 **LH concentration time series in women with and without PCOS and with or without obesity.** Arrows indicate significant LH pulses, and horizontal bars at the top of the panels indicate sleep periods. In this study, lean women with PCOS demonstrated 38% higher LH pulse frequency and 2.7-fold higher LH pulse amplitude compared to lean controls, rendering 3-fold elevated mean LH levels. As a group, women with PCOS and obesity demonstrated 50% higher LH pulse frequency, but no significant difference in LH pulse amplitude, rendering 1.9-fold elevated mean LH levels compared to controls with obesity. *BMI,* Body mass index. *LH,* luteinizing hormone; *PCOS,* polycystic ovary syndrome. (From Morales AJ, Laughlin GA, Butzow T, et al. Insulin, somatotropic, and luteinizing hormone axes in lean and obese women with polycystic ovary syndrome: common and distinct features. *J Clin Endocrinol Metab.* 1996;81:2854–2864.)

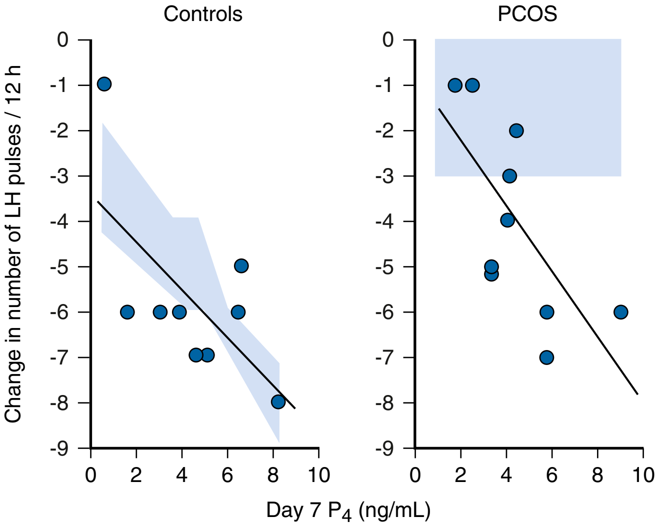

Figure 117.19 **Impact of androgen-receptor blockade (flutamide) on progesterone dose-LH pulse frequency response relationships in normally cycling women and women with PCOS.** In this study, GnRH pulse generator sensitivity to progesterone (P_4) negative feedback is assessed as the change in LH pulse frequency occurring with 7 days of exogenous estradiol and progesterone administration. The shaded areas indicate the range of responses in the absence of flutamide pretreatment, while data points represent subjects who were studied after 4 weeks of flutamide pretreatment. These data indicate that, in women with PCOS, flutamide pretreatment normalized the ability of progesterone to suppress LH (GnRH) pulse frequency. Conversion of conventional to International System (SI) units: progesterone (ng/mL) multiplied by 3.18 (nmol/L). *LH,* Luteinizing hormone; *PCOS,* polycystic ovary syndrome (From Eagleson CA, Gingrich MB, Pastor CL, et al. Polycystic ovarian syndrome: evidence that flutamide restores sensitivity of the gonadotropin-releasing hormone pulse generator to inhibition by estradiol and progesterone. *J Clin Endocrinol Metab.* 2000;85:4047–4052.)

GABAergic neurons also substantially impact GnRH neuron activity and appear to partly mediate effects of progesterone and DHT on GnRH neuronal function.[96] For example, PNA mice exhibit increased excitatory GABAergic drive onto GnRH neurons—a phenomenon that can be reversed with post-pubertal androgen receptor blockade.[98,99] Moreover, long-term, selective activation of arcuate nucleus GABAergic neuron terminals—which densely contact GnRH neurons—leads to PCOS-like features such as abnormal estrous cyclicity, hyperandrogenemia, and a trend toward increased LH pulse frequency.[100] Although the role of GABAergic neurons in the neuroendocrine dysfunction of PCOS remains unclear, cerebrospinal fluid GABA concentrations may be elevated in women with PCOS; and the use of valproate, which increases GABAergic tone, has been associated with PCOS.[96]

Recent interest has also focused on the potential role of anti-Müllerian hormone (AMH) in the neuroendocrine dysfunction of PCOS. Serum concentrations of AMH—derived from granulosa cells in pre- and small antral ovarian follicles (2–9 mm)—are 2- to 4-fold elevated in PCOS, and AMH directly stimulates GnRH neuron activity in mice.[101] In addition, when pregnant mice are exposed to experimental AMH excess, their female progeny demonstrate increased GABAergic appositions onto GnRH neurons, increased GnRH neuron firing rate, high LH pulse frequency, and circulating LH excess.[102] These findings were prevented by maternal co-treatment with a GnRH antagonist, suggesting that the fetal effects were mediated by abnormal maternal GnRH secretion.

No current treatments directly address the underlying pathophysiology in PCOS, and treatments are largely symptomatic. Combined hormonal (estrogen-progestin) oral contraceptives are generally considered the first-line pharmacological approach to hyperandrogenism and oligo-/amenorrhea in PCOS. The synthetic estrogen and progestin suppress GnRH and gonadotropin secretion, thus reducing ovarian androgen production; the synthetic estrogen also increases plasma sex hormone-binding globulin concentrations, which reduces androgen bioavailability. Anovulation in PCOS is associated with unopposed estrogen stimulation of the endometrium, which can lead to endometrial hyperplasia and increase the risk for endometrial carcinoma. These risks can be mitigated with exogenous progestin therapy. Lifestyle and weight optimization are foundational components of the overall treatment approach to PCOS, including for those with infertility. When needed, ovulation induction with an aromatase inhibitor is typically the first-line pharmacological approach to anovulatory infertility in PCOS, although more advanced treatments (e.g., exogenous gonadotropin therapy) are sometimes required.

CONCLUSION

The menstrual cycle is characterized by highly complex cyclic interactions among the hypothalamus, pituitary, ovaries, and endometrium. The fundamental teleology of the menstrual cycle relates to episodic presentation of a mature oocyte for fertilization in addition to preparation for early pregnancy. In short, the incompletely understood cyclic interactions described in this chapter undergird fertility in women and, thus, the very survival of the human species. Although it is tempting to speculate that most of the endocrine physiology of the menstrual cycle has been reasonably well described, it seems presumptuous to assume too much in this regard. With regard to neuroendocrine control of the cycle, much recent research attention has focused on the roles of neuronal populations afferent to GnRH neurons (e.g., kisspeptin neurons). Ovulatory dysfunction is a major cause of female-factor infertility, and accompanying physiological states (e.g., estrogen deficiency) may lead to negative long-term health consequences for women. As such, much research attention has rightly focused on the mechanisms underlying ovulatory disorders such as FHA and PCOS.

Folliculogenesis, Ovulation, and Luteogenesis

Marco Conti and Paolo Rinaudo

OUTLINE

Ovary Anatomy and Histology, 1971
Folliculogenesis, 1971
  Preantral Follicles, 1972
  Antral or Graafian Follicles, 1976
Ovulation, 1981
  Oocyte Maturation Following the LH Surge, 1981
Luteogenesis, 1982
  Luteinization, 1983
  Luteolysis, 1984
Conclusion, 1984

The human ovary has two primary functions during the reproductive years: (1) to produce every 28 days a single Graafian follicle that secretes estradiol (E_2) and ovulates a mature oocyte at about midpoint in the menstrual cycle; and (2) to produce an endocrine structure called the *corpus luteum* that secretes large amounts of E_2 and progesterone (P_4), which act on the uterine endometrium to prepare it for implantation of an embryo and sustain a conceptus in early gestation. A major feature of this ovarian activity is its cyclic nature, which is reflected in the growth and development of the dominant follicle and corpus luteum, respectively. These cyclic changes are regulated predominantly by changing concentrations of the anterior pituitary hormones, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The objective of this chapter is to review the structural and functional changes that occur in the human ovary to evoke a menstrual cycle, namely, folliculogenesis, ovulation, and luteogenesis. Although outside the scope of this chapter, it should be noted that ovarian endocrine secretions have major systemic effects on body homeostasis.

KEY POINTS

- Less than 0.1% of follicles ovulate over a woman's reproductive lifespan.
- Follicle development is a highly coordinated process involving intraovarian factors and hormonal stimulation.
- The completion of oocyte maturation requires epidermal growth factors (EGFs) as well as other local factors.
- Follicle rupture and ovulation are induced by local growth factor, P_4, and prostaglandin production.

OVARY ANATOMY AND HISTOLOGY

In normal adult women, the ovaries are oval-shaped organs, each measuring 2.5 to 5.0 cm in length, 1.5 to 3.0 cm in width, and 0.6 to 1.5 cm in thickness. The ovaries are covered by a sheet of squamous or cuboidal epithelium, the ovarian surface epithelium (also called the *germinal epithelium)*, which rests on a basement membrane. The ovarian surface epithelium is of mesodermal origin and may give rise to surface epithelial-stromal tumors. Beneath the surface epithelium is a layer of dense connective tissue termed the *tunica albuginea*. The proximal edge of the ovary, the hilum, is attached to the broad ligament by the mesovarium and to the vasculature.

The ovary is organized into two principal regions: a central region called the medulla and a peripheral region called the cortex (Fig. 118.1). Embedded in the stroma of the medulla is a mass of blood vessels and associated nerves, which radiate toward the cortex. In the hilum are nests of Leydig-like cells, called *hilus cells,* which secrete testosterone in response to LH stimulation.[1]

The cortex is a dynamic structure with follicles and corpora lutea (see Fig. 118.1). These histologic units exhibit a specialized architecture that reflects their stage of growth and development. The pool of follicles is divided into two major classes: growing and non-growing. Most (90% to 95%) follicles are non-growing or "primordial." Once a primordial follicle is recruited to grow, its size, structure, and position in the cortex change dramatically. During this process, the follicle transitions through three developmental stages: primary, secondary, and tertiary or Graafian stages (see Fig. 118.1). Selection of the single dominant follicle destined to ovulate occurs during the Graafian stage, and those follicles that are not selected degenerate by a process called *atresia*. After ovulation of the large dominant follicle, the follicle wall transforms into a corpus luteum through a process called *luteinization*. The corpus luteum, in the absence of pregnancy, ultimately degenerates by a process called *luteolysis*.

KEY POINTS

- While the exact length of time needed for a primordial follicle to reach the ovulatory stage is unknown, it is accepted that it is at least several months long.
- Preantral follicles are gonadotropin-responsive, whereas antral follicles require gonadotropins for their growth.
- The phosphatidylinositol-3-kinase /AKT/mTOR and Hippo pathways are critical regulators of follicular growth.

FOLLICULOGENESIS

The ability of a primordial follicle to develop into an ovulatory follicle is at the very foundation of menstrual cyclicity and ovarian hormone

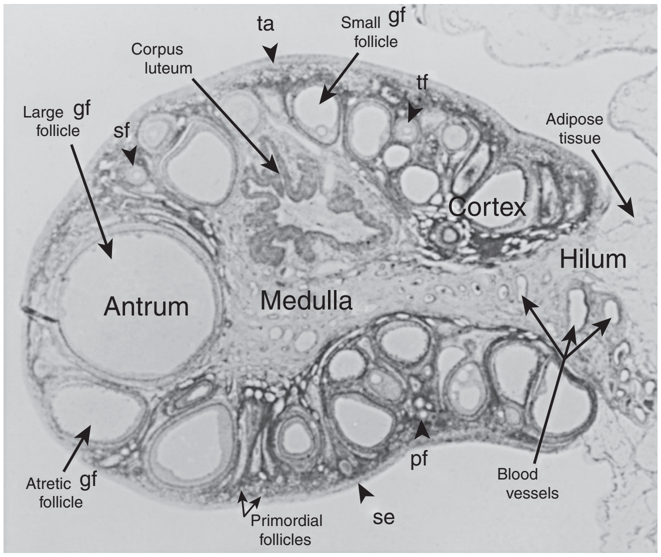

Figure 118.1 Photomicrograph of an adult primate ovary showing the follicular and luteal units in the cortex and large blood vessels and nerves in the medulla. *Gf,* Graafian follicle; *pf,* primary follicle; *se,* serous or surface epithelium; *sf,* secondary follicle; *ta,* tunica albugínea; *tf,* tertiary follicle. (Modified from Bloom W, Fawcett DW, eds. *A textbook of histology.* Philadelphia: WB Saunders; 1975:860.)

production. As a follicle grows and develops, important changes occur within the three major cell populations: oocytes, granulosa cells, and theca cells (TCs). These cellular changes include proliferation, differentiation, growth, and apoptosis. Two major classes of regulatory molecules control these cellular activities, namely, hormones and growth factors. Folliculogenesis can be divided into two phases: preantral growth and antral growth. The interval from recruitment of a primordial follicle to the completion of its growth into a secondary follicle is referred to as the *preantral* phase. While primordial follicles are not sensitive to gonadotropins, primary and secondary follicles show progressively increased responsiveness to gonadotropins.

In the antral phase, a fluid-filled cavity or "antrum" develops within the now *tertiary* or *Graafian follicle*, which is dependent on gonadotropins for growth. Graafian follicles grow progressively larger, mainly by accumulating increasing amounts of fluid in the antrum; usually only one follicle (the *dominant follicle*) will be larger than the remaining ones. The fully developed Graafian follicle is termed the *preovulatory follicle.*

Preantral Follicles

The development of a preantral follicle is characterized by three major events: (1) recruitment of a primordial follicle into the growing pool; (2) growth and differentiation of the oocyte; and (3) acquisition of FSH and LH receptors in the granulosa cells and TCs, respectively.

Primordial Follicle. The primordial follicles comprise a pool of nongrowing follicles from which all preovulatory follicles are ultimately derived. A primordial follicle consists of a small (≈15 μm diameter) oocyte arrested in the dictyotene stage of meiosis, a single layer of flat, squamous pregranulosa cells, and a thin basal lamina that encircles both cell types (Fig. 118.2). Primordial follicles are localized in the ovarian cortex. No blood vascular system is directly associated with the primordial follicles[2]; however, evidence in the rhesus monkey suggests that they may be innervated, most notably by vasoactive intestinal peptide nerves.[3] Although dormant, primordial follicles express genes required to maintain quiescence, until they are recruited into the growing pool.[4]

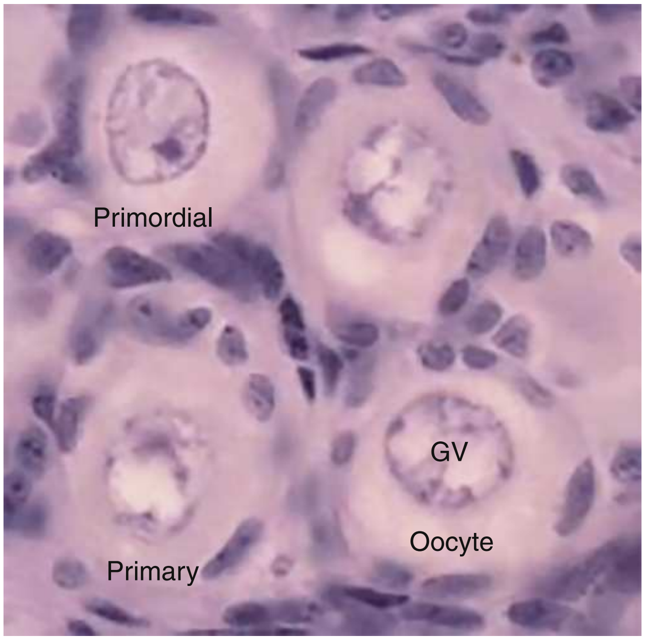

Figure 118.2 Photomicrograph of a portion of the cortex of the ovary. Primordial (non-growing) follicles consist of a small oocyte arrested in diplotene of meiosis I surrounded by a single layer of squamous granulosa cells. A primary follicle contains a growing oocyte and a single layer of cuboidal granulosa cells. Secondary follicles contain a nearly full-grown diplotene oocyte with an intact germinal vesicle or nucleus, a thin zona pellucida, and two or more layers of cuboidal granulosa cells. *GV,* germinal vesicle.

In humans, primordial follicles are formed in the fetal ovaries between the sixth and ninth month of gestation (Fig. 118.3).[5] At this time, all viable female germ cells have committed to meiosis. As a result, by the end of gestation there is no further production of new oocytes. This dogma has been challenged with the isolation of putative "oocyte stem cells" from mouse and human ovary.[6,7] However, this possibility is contradicted by several recent publications and remains highly controversial.[8,9] Consequently, it is most likely that all oocytes in a woman's ovaries are present at birth. Once the primordial follicles are formed, some are recruited to grow. As a woman ages, the process of recruitment continues on a regular basis until the total primordial follicle pool is exhausted. This event, the menopause, occurs in most women at approximately 51 years of age. An important concept is that the time course of loss of primordial follicles or ovarian reserve (OR) follows a simple power curve and can be monitored by measuring anti-Müllerian hormone (AMH) levels or by counting the number of antral follicles of size 2–10 mm visualized by transvaginal ultrasonography (this count is called the "antral follicular count") (Fig. 118.4). Although the mechanisms regulating this accelerated loss are unknown, this phenomenon is of clinical importance because it is associated with a significant decrease in fecundity.[10]

Certainly, one of the foremost questions in reproductive biology concerns the basis of initial primordial follicle growth and maturation. Structurally, the process of primordial-to-primary follicle transition begins with a change in shape in the granulosa cells from a squamous to a cuboidal shape, which, in turn, is accompanied by or associated with a commitment of the granulosa to divide, albeit very slowly.[11] That the first visible signs of primordial follicle growth occur in the granulosa cells fits the prediction that granulosa cells may play a key role in the process.

Figure 118.3 The development of ovarian reserve. Primordial germ cells migrate to the genital ridge 3–5 weeks post conception (wpc). By 5–16 wpc and up to 17–20 wpc, following rapid proliferation, germ cell nests are visible. At this point, germ cells nest break down, some germs cells undergo apoptosis, whereas others are surrounded by pre-granulosa cells, forming primordial follicles. Oocytes in the primordial follicles start meiosis and remain arrested at prophase I. Starting at 23–26 wpc, the first wave of primordial follicle activation commences and at birth (37–40 wpc), a small proportion of preantral and antral follicles are present. Before puberty, activated follicles can only grow until the early antral stage. At puberty, the cyclical changes in gonadotrophin levels allow progression beyond the early antral stage and ovulation may occur. (From Ford EA, Beckett EL, Roman SD, et al. Advances in human primordial follicle activation and premature ovarian insufficiency. *Reproduction*. 2020;159:R15–R29.)

Primary Follicle. A primary follicle consists of a growing oocyte, a single layer of cuboidal granulosa cells, and a basal lamina (see Figs. 118.2 and 118.5). In the primary follicle, several important events occur, including expression of FSH receptors by the granulosa cells, formation of gap junctions between the oocyte and granulosa cells, dramatic oocyte growth, and zona pellucida (ZP) deposition by the oocyte.

The expression of FSH receptor in the granulosa cells[12] opens the possibility that the follicle may become responsive to gonadotropin, even at this early stage. Thus, although preantral follicle growth can occur in the absence of FSH, granulosa cells of this immature structure may be gonadotropin-responsive.

A second key event that occurs in the primary follicle (Fig. 118.6) is the development of gap junctions between the granulosa cells and the oocyte.[13] Gap junctions comprise a family of proteins termed *connexins (Cx)*.[14] Functionally, they allow for transfer between cells of low-molecular-weight molecules, including the second messengers cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), calcium, nutrients, and ATP.[13–15] Gap junctions between granulosa cells are expressed at the earliest stages of primary follicle development and are mainly composed of Cx43.[13] Gap junctions between the oocyte and surrounding granulosa cells comprise Cx37.[16] It is important to note that Cx37-deficient female mice (Cx37 knockouts) lack Graafian follicles, fail to ovulate, and develop numerous abnormal corpora lutea.[16] Thus, physiologically important interactions between oocytes and granulosa cells via Cx37 channels are obligatory for normal folliculogenesis and fertility in mice.

A third event is the growth and differentiation of the oocyte in the primary follicle (see Figs. 118.2 and 118.5). Studies in rodents have demonstrated that the granulosa cells are essential to oocyte growth and development.[17,18] It seems likely that Cx37 connections between the granulosa and the oocyte allow for the exchange of nutrient and regulatory molecules that are required for proper oocyte function. Specifically, they evoke changes in oocyte metabolism that influence gene expression. One example is a marked increase in ZP gene expression. As the oocyte grows, it synthesizes and secretes an extracellular matrix, ZP, which in time encapsulates the egg (see Figs. 118.2, 118.5, and 118.6). The importance of ZP is demonstrated by the fact that it contains the species-specific receptor for capacitated sperm and provides a block to polyspermy.[19] The ZP in humans consists of four glycoproteins, ZP-1, ZP-2, ZP-3, and ZP4, whereas three ZP proteins are present in the mouse.[20] In mice, ZP-3 was thought to be particularly important in sperm binding through its carbohydrate moiety.[21] However, more recent data indicate that ZP-2 may be the primary zona ligand for spermatozoa.[22] Clinically, considerable interest has been devoted in the development of immunocontraceptive vaccines based on the ZP-3 antigen.[23,24]

Secondary Follicle. The secondary follicle consists of a larger oocyte (80 μm) surrounded by a complete ZP, two to eight layers of cuboidal or columnar granulosa cells, and a presumptive theca layer immediately peripheral to the basal lamina (see Figs. 118.2 and 118.5). The acquisition of a theca layer is a major new feature of developing secondary follicles. The presumptive theca consists of several layers of elongated fibroblast-like cells that run radially around the entire follicle (see Fig. 118.2). Theca development is accompanied by angiogenesis. Consequently, the secondary follicle is exposed to important hormones such as FSH, LH, and insulin present in the circulation. Mechanisms underlying theca formation and angiogenesis during secondary follicle development are not clear.[1] However, because theca

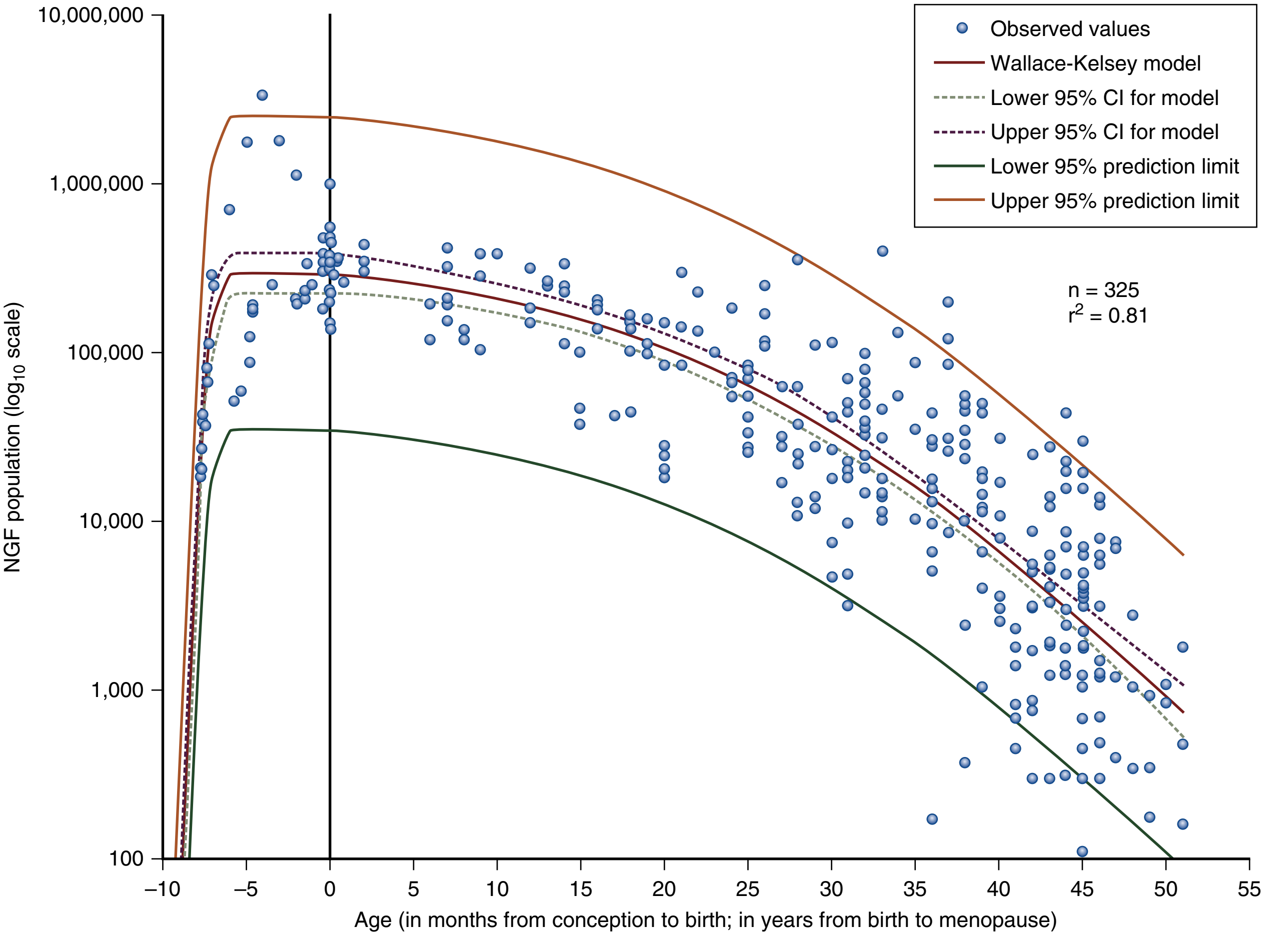

Figure 118.4 **Morphometric analysis of normal human ovaries showing the age-related decrease in the total number of primordial follicles (NGF) within both ovaries from birth to the menopause.** As a consequence of recruitment, the number of NGFs decreases progressively from approximately 1 million at birth to about 25,000 at 37 years of age. Note that the rate of loss of primordial follicles accelerates approximately 2-fold at 37.5 ± 1.2 years, with the number being reduced to about 1000 at approximately 51 years of age. (From Wallace WH, Kelsey TW. Human ovarian reserve from conception to the menopause. *Plos One.* 2010;5:e8772.)

formation requires the presence of follicles, it is believed that granulosa cells, or possibly the oocyte itself, produce factors that direct this process. Among those peptides under consideration are Kit ligand (KL), growth differentiation factor-9 (GDF-9), insulin, insulin-like growth factor-1 (IGF-1) and/or IGF-2, and activin.[25–27] In addition to these growth factors, ample evidence indicates that LH is responsible for early TC differentiation.[1,28,29] The degree to which LH influences TC growth is uncertain.

Role of Growth Factors in Folliculogenesis. Although it is clear that the ovarian cycle is governed by the combinational and sequential actions of key circulating hormones, including FSH, LH, P_4, androgens, E_2, and insulin, large-scale cellular and mutational analyses have led to the identification of local signaling pathways that can modulate the effects of circulating hormones.[30] These local ligands, termed *growth factors*, are capable of interacting with receptors to activate signal transduction pathways that affect multifunctional responses, including cell proliferation, differentiation, and apoptosis. The most intensely and best studied ovarian growth factors include IGF,[31,32] transforming growth factor-β (TGF-β),[30,33] transforming growth factor-α (TGF-α), EGF and related growth factors,[34] fibroblast growth factor (FGF), and cytokines. Thus, the processes of folliculogenesis, ovulation, and luteogenesis require a precise spatial and temporal pattern of expression of different growth factors. In particular, the expression patterns of these growth factors form a controlling network that ensures the proper sequence and timing of developmental events triggered by key hormones such as FSH and LH and play a critical role in the bidirectional interactions between oocytes and somatic cells.

Accordingly, it is recognized that the function of bone morphogenetic proteins (BMPs) is integral to follicular development.[35] For example, BMP-15 and GDF-9 are oocyte-derived growth factors that act to control the ovulation quota[36] by regulating mitosis and the supporting activities of FSH and LH. Therefore, BMPs appear to be obligatory factors that control the hormone-dependent ovarian cycle. In the same vein, EGF-like growth factors are essential for oocyte maturation and ovulation. It is almost certain that growth factors play critical roles in directing the proliferation, differentiation, and death of cells in the human ovary; indeed, evidence suggests aberrant GDF-9 expression in oocytes of women with polycystic ovary syndrome (PCOS).[37] Understanding how specific growth factor signaling pathways lead to activation of particular effector genes could have far-reaching implications for understanding ovarian physiology, infertility, and pathophysiology, including cancer.

follicle recruitment remain unclear.[38] While initiation of follicle growth can be regulated by negative and positive growth factors,[39,40] primordial follicle development is likely under constitutive repressive control. In fact, when the ovarian cortex is placed into culture, precocious activation of primordial follicles occurs.[41] Genetic evidence in rodents indicates that Notch and Wnt signaling are critical for the formation and maintenance of the primordial follicle.[42,43] Similarly, mice bearing mutations in the transcription factors Nobox, Sohlh1, or Sohlh2 or the Cdk inhibitor CDKN1B show defects in the primordial to primary follicle transition.[44,45] Importantly, genetic models provided evidence that phosphoinositide 3-kinase (PI3K)/AKT/mTOR/FOXO pathway is involved in the primordial to primary follicle transition (Fig. 118.7). Mice with loss of function of FOXO3,[46] PTEN,[47] or Tsc1 and Tsc2[48] genes in primordial oocytes display massive activation of all dormant follicles and, eventually, depletion of the follicular reserve. Indeed, pharmacological manipulation of this pathway in the "*in vitro* activation" technology may be a strategy to promote primordial follicle recruitment and may be used clinically to induce *in vitro* maturation of primordial follicles in patients with premature ovarian insufficiency.[38]

Cell-to-cell communication and ovulation: a study of the cumulus-oocyte complex. *J Cell Biol.* 1978;78:58–75.)

KL is one of the key factors involved in initiating follicle activation.[27] In addition, insulin,[49,22] testosterone,[50] BMP-7 and BMP-15,[51,52] GDF-9,[53] and restricted food intake have been shown to stimulate follicle development.[54] For example, in the rat ovary, BMP-7 activates advancement of primordial follicle growth.[52] In sheep, but not mice, BMP-15 has an essential role in promoting the primary to secondary follicle transition during early folliculogenesis, while restraining the transition of follicles to the dominant preovulatory stage.[51,55] Absence of this oocyte-derived peptide as in homozygous carriers of the ovine Inverdale and Hanna *BMP-15* mutations results in infertility with streak ovaries and a block at the primary stage of folliculogenesis.[51] Similarly, targeted deletion of GDF-9 in the oocyte precludes the development of ovarian follicles past the primary stage in mice.[53] Preliminary evidence in women with premature ovarian failure showing mutations in *BMP-15* and *GDF-9* further support these findings.[56–58]

Conversely, evidence in laboratory animals suggests that follicle maturation is inhibited by EGF[54] and AMH (Müllerian-inhibiting substance[59]). In AMH-null mice, the numbers of preantral and small antral follicles were greater in ovaries of 25-day-old and 4-month-old females compared with wild-type females. Moreover, in 4-month-old AMH-null females, smaller numbers of primordial follicles were present, and in 13-month-old animals, essentially no primordial follicles were observed.[60] These findings reflect a generalized progression of follicle growth in the absence of AMH. Importantly, these early stages of follicular development appear to be exquisitely sensitive to environmental endocrine disruptors.[61]

Regulation of Further Follicular Development. Other factors play important roles in follicular development, including FSH, the Hippo pathways, and possibly androgens. As mentioned above, during

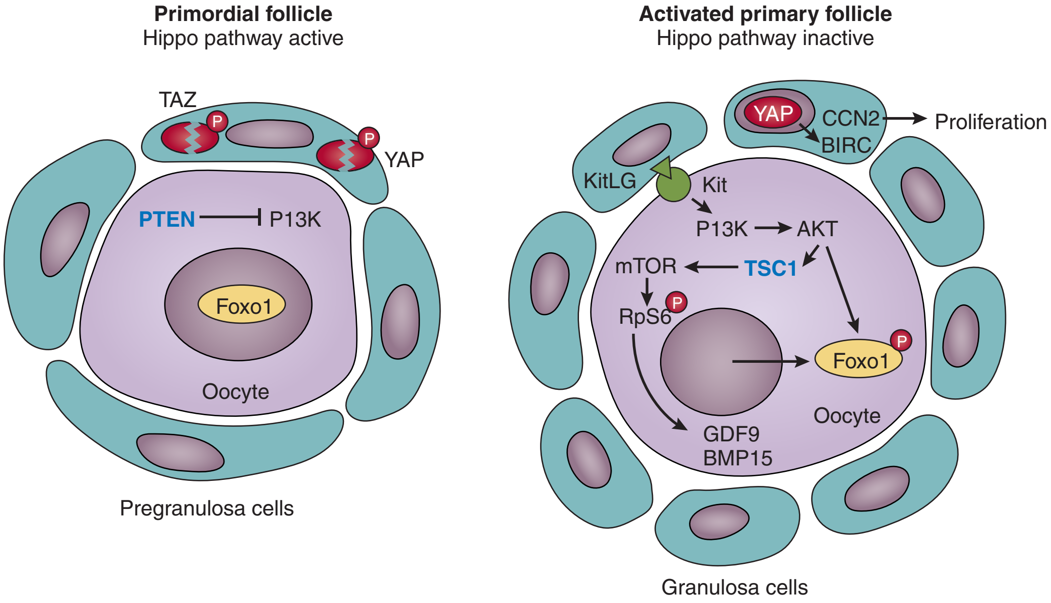

Figure 118.7 Regulation of primordial follicle growth. Genetic and pharmacological models indicate that activation of primordial follicles growth require activation of the Pi3k AKT mTOR FOXO pathway in the oocyte. While the exact nature of ligands involved in the activation is unknown, KIT ligand plays an important role. In addition, disruption of the Hippo pathway in granulosa cells, for example, following ovarian cortex fragmentation, results in proliferation and growth of granulosa cells. PTEN, TSC1, and FOXO are in blue color to indicate that genetic knockout models of these genes show activation of primordial follicle growth.

differentiation of the primary follicle, the gene that encodes the FSH receptor is activated in granulosa cells[12]; this, in turn, is followed by acquisition of cell-surface FSH receptors that can be visualized using ^{125}I-labeled FSH autoradiography.[62] This establishes the follicle potential to be stimulated by FSH-signaling pathways. Although the process of FSH receptor expression is poorly understood in women, evidence in rodents indicates that activin produced by the granulosa cells increases FSH receptor expression by autocrine mechanisms.[63] While follicles at this stage are not dependent on FSH for growth, they may be responsive to it.

The Hippo pathway is a key player in regulating preantral follicular development. Specifically, preantral and antral follicle development is restrained by the inhibitory Hippo signaling pathway, and disruption of this pathway by ovarian fragmentation has resulted in follicular development[64] (Fig 118.7).

Pharmacological and genetic models suggest that androgens may affect preantral follicular development. Administration of androgen[50] or knockout of granulosa-specific androgen receptor[65] results in changes in antral follicle number. Although the weak androgen dehydroepiandrosterone (DHEA) is often prescribed to women with low OR, evidence suggesting benefit is promising but still is inconclusive.[66]

Antral or Graafian Follicles

KEY POINTS

- Coordinated gonadotropin regulation of TCs and granulosa cells defines antral follicle development.
- As in other developmental processes, follicle development and final stages of maturation preceding follicle ruptures are under the control of circulating gonadotropins but also locally released bioactive molecules including growth factors, steroid hormones, cytokines, and other mediators.
- These regulators activate or repress the function of different layers of follicular cells. Moreover, they control the physical coupling of somatic cells with the oocytes and the flow of metabolic and signaling molecules.

During the late stages of growth of the secondary follicle, a clear fluid begins to accumulate between some granulosa cells. The fluid is a transudate of serum components and the secretion of TCs and granulosa cells. When the follicle reaches approximately 400 µm in diameter, the fluid coalesces into a crescent-shaped space called the *antrum*.[67] By definition, the follicle is now a *tertiary* or *Graafian follicle* (see Figs. 118.5 and 118.8). This process, termed *cavitation* or *beginning of antrum formation*, results in remodeling granulosa cells to form a miniature Graafian follicle (see Fig. 118.8). Cavitation is gonadotropin-independent. Precisely how the antrum forms is unknown, but direct evidence of a role for activin has been provided.[68]

TC differentiation is an additional important step that, while started at the secondary follicle stage, continues during cavitation. During cavitation, a subpopulation of cells that surround the growing follicle becomes epithelial-like and acquires ultrastructural and functional characteristics of active steroid-secreting cells.[1] As these changes occur, the cells, now called *theca interstitial cells*, express LH receptors.[1] At the periphery of the *theca interna* is a layer of concentrically arranged fusiform cells that have the ultrastructural and functional characteristics of smooth muscle cells.[69] They constitute the theca externa of the tertiary follicle (see Fig. 118.8).

By the time of cavitation, the oocyte has attained its full size (≈120 µm in diameter) and appears fully developed structurally (see Fig. 118.8). Therefore, the oocyte does not grow further despite the fact that the Graafian follicle as a whole might continue to enlarge to a diameter of 20 mm or more.[70]

Classification of Graafian Follicles. Graafian follicles can be defined structurally as a heterogeneous family of relatively large follicles (400 µm to >20 mm at ovulation or 50-fold increase in diameter) that display an antrum containing follicular fluid, or *liquor folliculi*. The antrum is a characteristic structural feature of all Graafian follicles. As such, the term *antral follicle* is synonymous with the Graafian follicle.

In a broad sense, Graafian follicles can be divided into two major groups: healthy and atretic. The main difference between these is whether or not apoptosis, or programmed cell death, is occurring in the granulosa cells. All Graafian follicles (healthy or atretic) follow a progressive and divergent trajectory during their development. The healthy Graafian follicle becomes progressively larger and more differentiated with time until it reaches the preovulatory stage. The mechanism by which a healthy Graafian follicle is formed depends on pituitary gonadotropins and involves the differential and temporal pattern of expression of specific genes that lead to follicle cell cytodifferentiation and proliferation.[71] In a similar manner, atretic or non-dominant Graafian follicles undergo a temporal pattern of gene expression, which, in turn, results in cessation of growth and activation of apoptosis.

The size of a Graafian follicle is determined largely by the size of the antrum, which, in turn, is determined by the volume of follicular fluid. An atretic follicle rarely reaches a size greater than 10 mm.[69]

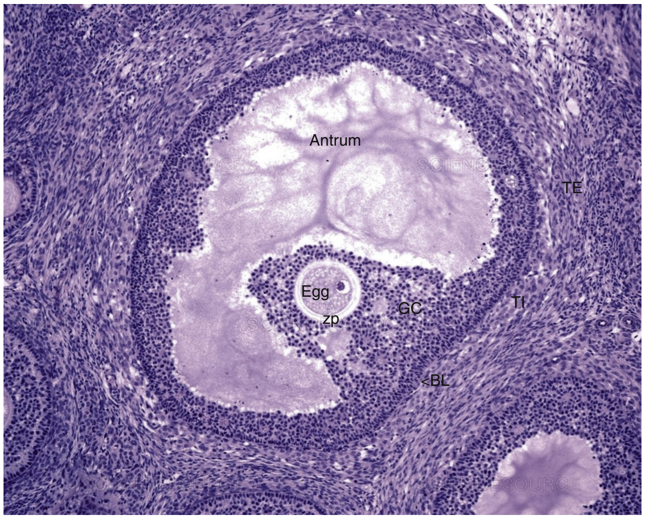

Figure 118.8 **Photomicrograph of a tertiary follicle approximately 400 μm in diameter at the time of cavitation or early antrum formation.** It comprises a fully growing dictyate oocyte (egg) surrounded by a thick zona pellucida; an antrum containing follicular fluid; multiple layers of granulosa cells organized morphologically into recognizable zones; a basal lamina; a theca interna; and a theca externa. *BL,* Basal lamina; *GC,* granulosa cells; *TE,* theca externa; *TI,* theca interna; *zp,* zona pellucida. (From Bloom W, Fawcett DW, eds. *A textbook of histology.* Philadelphia: Saunders; 1975:869.)

Structure of the Graafian Follicle. A healthy Graafian follicle is a multilayered spherical unit that comprises sheets of precisely positioned cells (Figs. 118.8–118.10). The theca externa is innervated by autonomic nerves that play an active role in their contraction.[69] The full functional significance of the theca externa is not known, but regulated contractions of these cells have been implicated in both ovulation and atresia.[69] For example, a role for local release of endothelin-2 by the theca externa in vasoconstriction and ovulation has been reported.[72,73]

The number of differentiated theca interstitial cells that constitute the *theca interna* increases progressively, and their endocrine function is reflected in the large capillary plexus. It is not uncommon to have five to eight layers of theca interstitial cells in a Graafian follicle.[1]

Internal to the theca is a basal lamina that functions as a barrier to vascular tissue. Encircled by the basal lamina are multiple layers of granulosa cells that appear heterogeneous by virtue of their position within the follicle wall (see Figs. 118.9 and 118.10). The position and morphology of the granulosa cells identify at least three different domains: (1) an outer or mural domain (also called membrane) that comprises a pseudostratified epithelium, with cells that make contact with the basal lamina; (2) an inner, periantral or luminal domain lining the antrum; (3) the cumulus domain, which surrounds the oocyte and makes contact with the mural and periantral cells; (see Figs. 118.9 and Fig. 118.10). Electron microscopic reconstruction of granulosa cells has confirmed that granulosa cells have complex elongated shapes with long protrusions that allow inner cells to make contact with the basal lamina.[74] By virtue of their position, the granulosa cells assume different phenotypes, express different genes, and have different functions in response to FSH stimulation.[35,75] For example, the cumulus, and periantral granulosa cells (but not the mural cells) continue to divide throughout Graafian follicle development. By contrast, the cells in the mural domain stop dividing and become highly responsive to FSH and LH (see Fig. 118.9). Although all granulosa cells layers contain similar amount of FSH receptors, cumulus cells express low levels of LH receptors and steroidogenic enzymes. These divergent phenotypes and functions of granulosa cells are generated by two opposing gradients of diffusible signals, one emanating from the theca layers of the follicle and/or the vasculature and the opposing one by the oocyte through secretion of diffusible bioactive molecules.[35,75] In particular, it is well established that oocyte-secreted GDF-9 and BMP-15 play an important role in inducing the unique phenotypic properties of the surrounding cumulus cells.

Chronology of Follicle Development. Folliculogenesis in women is a very lengthy process whose exact duration is uncertain.[11,76,77] In normal cycling women, the dominant follicle that will ovulate originates from a primordial follicle that was recruited several months earlier

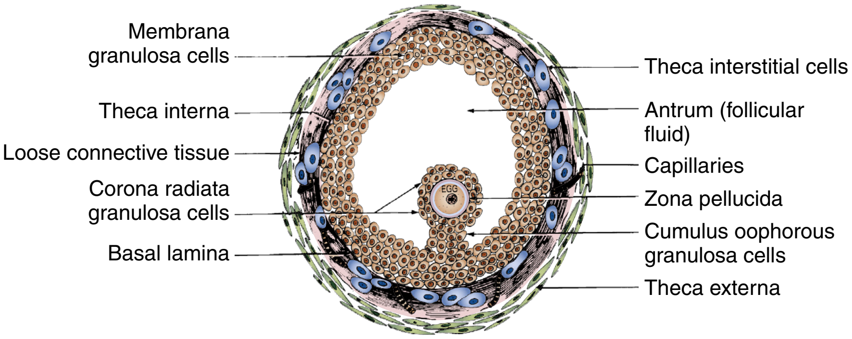

Figure 118.9 **Diagram of the cross-sectional appearance of a typical healthy Graafian follicle showing the organization of its various cell types.** (From Erickson GF. Primary cultures of ovarian cells in serum-free medium as models of hormone-dependent differentiation. *Mol Cell Endocrinol.* 1983;29:21–49.)

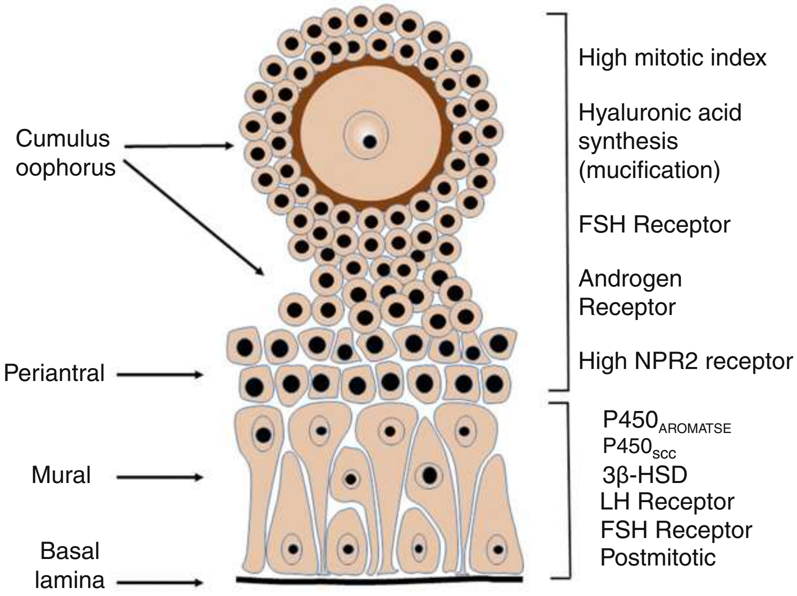

Figure 118.10 **Diagram of the structure-function heterogeneity of the granulosa cells in a healthy Graafian follicle.** By virtue of their position in the follicle wall, the granulosa cells become different from one another, and this is reflected in different patterns of proliferation and differentiation. *FSH,* Follicle-stimulating hormone; *LH,* luteinizing hormone. (Modified from Erickson GF. The graafian follicle: a functional definition. In: Adashi EY, ed. *Ovulation: evolving scientific and clinical concepts.* New York: Springer-Verlag; 2000.)

(Fig. 118.11). While the primordial to primary and secondary follicle transition proceeds very slowly—the growth of a secondary follicle to ovulation is well described and takes approximately 85 days (see Fig. 118.11). The final phase of growth (*selection* of dominant follicle) takes approximately 10 days, The slow nature of the development of preantral follicles results from the long doubling time (≈250 hours) of granulosa cell replication. The rate of follicle growth increases dramatically when follicular fluid begins to accumulate and the healthy Graafian follicle passes through the gonadotropin-dependent or antral phase.

Recruitment and Selection of the Dominant Follicle. Selection of the dominant follicle is a critical event in the ovarian cycle. In normal women, it appears that the dominant follicle is selected from a cohort of small Graafian follicles (4.7 ± 0.7 mm) that are recruited during the late luteal phase of the antecedent cycle (see Fig. 118.11).[11,76,77] On the basis of ultrasound observation, it has been proposed that two or three major waves of follicular recruitment emerge during every menstrual cycle.[78] In addition, minor waves of antral follicle may also be present. The dominant follicle will emerge from one of these waves. With the emergence of the dominant follicle, the remaining cohort of recruited follicles begins to degenerate and undergo atresia. While atresia can occur at any stage, it is most frequent in small and medium Graafian follicles (see Fig. 118.11).

Function of Granulosa Cells of the Dominant Follicle. As described above, the granulosa cells of a dominant follicle are characterized by a sharp increase (~2-fold) in the rate of mitosis.[11,76,77] Indeed, the first visible sign of follicular selection is that granulosa cell division continues at a rapid rate in the chosen follicle, whereas the mitotic rate becomes low in subordinate, non-dominant follicles.[11,76] Because this distinction becomes apparent in the late luteal phase of the cycle antecedent to ovulation, it is argued that selection takes place at this stage (Fig. 118.12). The dominant follicle grows rapidly, reaching an average size of 6.9 ± 0.5 mm at days 1 to 5, 13.7 ± 1.2 mm at days 6 to 10, and 18.8 ± 0.5 mm at days 11 to 14 of the cycle.

A fundamental question is how selection of the dominant follicle occurs. Responsiveness to FSH and the estrogen-FSH feedback in the pituitary are likely critical to establish dominance. According to the FSH threshold/window/gate hypothesis, the increase in plasma FSH occurring at the end of the luteal phase of the preceding cycle is obligatory for, and serves as the basis of, dominant follicle selection.[79] In women, plasma FSH begins to rise at about the same time that plasma P_4 and E_2 levels fall to baseline levels at the end of the luteal phase (Fig. 118.13), concomitantly with decreases in inhibin A emanating from the corpus luteum (see Fig. 118.13). The inverse relationship between plasma FSH and inhibin A (a known inhibitor of pituitary FSH secretion) suggests an endocrine role for inhibin A in regulation of the late luteal FSH rise. By contrast, inhibin B increases before menses coincident with the FSH rise. It is possible that elevated inhibin B levels emanating from the growing follicles play a role in suppressing the FSH rise during the follicular phase (see Fig. 118.13). Given the estrogen (and/or inhibin) feedback in the pituitary, the ensuing decrease in FSH below a threshold at the appropriate time prevents development of subordinate follicles. Continuous growth of a dominant follicle on a background of diminishing FSH may be due to the increased sensitivity to LH.

One effect of the late-luteal FSH rise is a progressive increase in the concentration of FSH in follicular fluid of the dominant follicle. It is noteworthy that FSH levels become low or non-detectable in follicular fluid of non-dominant follicles.[80,81] How a dominant follicle sequesters FSH is not known, even though high concentrations of FSH receptor may play a role. Nonetheless, when the concentration of FSH in the microenvironment reaches threshold levels, dominance is established, and the chosen follicle becomes committed to developing along the ovulatory pathway. In the absence of threshold levels of FSH, the mitotic rate falls to low levels, and non-dominant cohort of follicles proceed along the atretic pathway. Treating women with exogenous FSH stimulates mitosis of granulosa cells in non-dominant follicles,[76] rescuing non-dominant follicles from atresia. This explains how exogenous FSH provokes multiple ovulatory follicles in women undergoing ovulation induction without depleting OR.

Figure 118.11 **The chronology of folliculogenesis in normal human ovaries.** The steps from primordial follicle recruitment, dominant follicle selection, and ovulation can be seen flanked by a timeline. The follicles are labeled to indicate developmental stage, size, and the percentage in atresia. (From Gougeon A. Dynamics of follicular growth in the human: a model from preliminary results. *Hum Reprod.* 1986;1:81–87.)

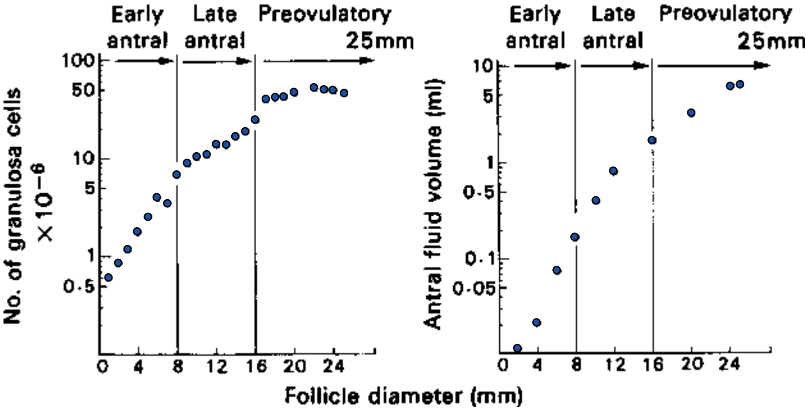

Figure 118.12 **Changes in the number of granulosa cells *(left panel)* and the volume of follicular fluid (right panel) during the growth (diameter) of a healthy (dominant) human Graafian follicle.** (From McNatty KP. Hormonal correlates of follicular development in the human ovary. *Aust J Biol Sci.* 1981;34:249–268.)

As development of the dominant follicle proceeds, granulosa and TCs show a high continual proliferative capacity (see Fig. 118.12).[11,76] In addition to FSH, FGF and EGF are potent stimulators of mitosis by mechanisms independent of FSH.[82] While the numbers of both theca interna and theca externa cells increase concurrently with granulosa cells,[83] mechanisms that regulate their proliferation are virtually unknown.

An important event in the selection of the dominant follicle is the ability of FSH to elicit massive increases in P450arom gene expression in the granulosa cells. Expression of this steroidogenic enzyme results in progressive increases in production of E_2, which, in turn, promotes endometrial growth and the preovulatory surge of LH at midcycle.

The production of E_2 in the follicle requires the coordinated function of theca and granulosa cells, as well as LH and FSH. These integrated functions are collectively summarized in the two-cell, two-gonadotropin model.[69] The theca interstitial cells produce androstenedione (aromatase substrate) in response to LH stimulation.[69] When LH interacts with its transmembrane receptor, the binding event is transduced into an intracellular signal by means of G proteins. The LH-activated receptor is coupled to the trimeric (α, β, γ subunits) stimulatory guanylyl nucleotide binding protein (Gs) adenylate cyclase, cAMP, protein kinase A (PKA) signal transduction pathway, which, in turn, recoupled to the differential activation of genes encoding steroidogenic enzymes. These regulatory proteins include steroidogenic acute regulatory protein (StAR), cytochrome P450 side-chain cleavage (P450c22), 3β-hydroxysteroid dehydrogenase (3β-HSD), and P450 17α-hydroxylase and 17,20-lyase (P450c17). The end result is the production of androstenedione, which accumulates at very high concentrations in the follicular fluid. It is noteworthy that the androstenedione synthetic activity of the theca interstitial cells can be markedly stimulated and enhanced by other regulatory agents, including insulin, IGF-1, low-density lipoprotein (LDL), and high-density lipoprotein (HDL).[1,69] Although the functional significance of these regulatory molecules is poorly understood, it is notable that hyperinsulinemia in women with PCOS is marked by hyperandrogenism and infertility.[84] Thus, although LH is clearly the most important stimulator of follicular androstenedione production, other proteins can affect changes in theca androgen production.

Although detected in some cells outside of the ovary, the granulosa cells are the major site of expression of FSH receptors. Similar to the LH mode

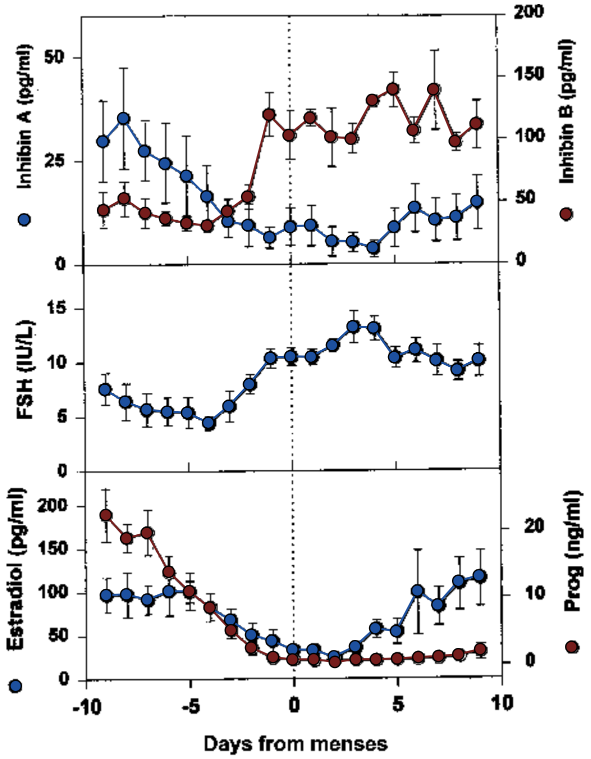

Figure 118.13 **The rise in plasma follicle-stimulating hormone (FSH) as it occurs in normally cycling women during the luteal-follicular transition.** Data are mean ± standard error of the mean (SEM) of daily FSH, estradiol, progesterone, inhibin A, and inhibin B levels in plasma of five normal cycling women. Data are centered to the day of menses. (From Welt CK, Martin KA, Taylor AE, et al. Frequency modulation of follicle-stimulating hormone [FSH] during the luteal-follicular transition: evidence for FSH control of inhibin B in normal women. *J Clin Endocrinol Metab.* 1997;82:2645–2652; © 1997, The Endocrine Society.)

of action, FSH binds to a cell-surface transmembrane receptor, which activates a stimulatory G protein, the adenylate cyclase, cAMP production, and the PKA signaling pathway.[85] Aside from cAMP, recent data show that several additional signaling pathways mediate the FSH effects on granulosa cells via activation of other G proteins.[86] Activation of these multiple FSH-dependent signaling mechanisms (Fig. 118.14) leads to the expression of a large array of genes including those that control the potential for E_2 production, namely, expression of the P450 aromatase *(P450arom87)* and the type 1 17α-hydroxysteroid dehydrogenase *(17α-HSD)* genes.[88,89] By virtue of the expression of these key steroidogenic enzymes, the granulosa cells have the capacity to convert androstenedione to testosterone, which then is aromatized to E_2 by *P450arom.* The temporal pattern and level of expression of *P450arom* enzyme determine the time course and the amount of E_2 produced by the dominant follicle during the follicular phase.

FSH induces additional receptors that are critical for follicle development and ovulation. In particular, FSH induces expression of LH receptors in granulosa cells. As with P450arom, only mural granulosa cells in the dominant follicle express the LH receptor gene; however, in contrast to the relatively early expression of P450arom in granulosa, LH receptors are not expressed until late in the follicular phase of the cycle.[62,90] LH receptors provide the granulosa cells in the dominant follicle with the capacity to respond to the midcycle surge of LH and for the follicle to undergo ovulation. Furthermore, LH signaling plays a fundamental role in granulosa cells by inducing expression of P_4 receptors.[87,91] Importantly, P_4 receptors play an obligatory role in the physiological process of ovulation.[91] Finally, FSH induces the expression of the natriuretic peptide receptor 2 (NPR2) and of the cognate ligand natriuretic peptide precursor type C (NPPC, also known as C-type natriuretic peptide [CNP]).[92] This ligand/receptor pair is responsible for the accumulation of cGMP in the follicle required to maintain oocyte meiotic arrest therein (see Fig. 118.15).[93]

Oocyte Meiotic Arrest in the Antral Follicle. In a fully developed Graafian follicle, the oocyte has acquired competence to undergo meiotic maturation. However, it is held in a meiotic arrest at the dictyate stage by signals originating from the granulosa cells. Seminal work in rodents and humans has demonstrated that removal of the oocyte from the follicular environment causes meiotic resumption, suggesting the presence of meiotic inhibitory factors in the follicular environment.[94,95] Although a low-molecular-weight oocyte maturation inhibitor had been isolated from the follicular fluid and granulosa cell extracts,[96] the nature of these factors has remained controversial for several decades. However, recent observations in rodents indicate that an interplay of two cyclic nucleotides, cAMP, and cGMP, as well as the cyclic nucleotide phosphodiesterase (PDE3A) expressed in the mature oocyte, comprise the primary mechanism to maintain meiotic arrest (see Fig. 118.15).[97,98] PDE3A degrades both cyclic nucleotides, with cGMP functioning as an inhibitor of the enzyme activity.[99] The current model posits that FSH and E_2 induce synthesis of CNP in granulosa cells. CNP interacts and activates the cognate NPR2 receptor on the same granulosa cells, resulting in accumulation of cGMP.[93] In turn, cGMP diffuses via gap junctions into oocytes where it inhibits oocyte PDE3A activity. The net result is cAMP levels prevent reentry into the meiotic cell cycle[97,98] (see Fig. 118.15). This regulatory loop is functional in all species studied, including humans.

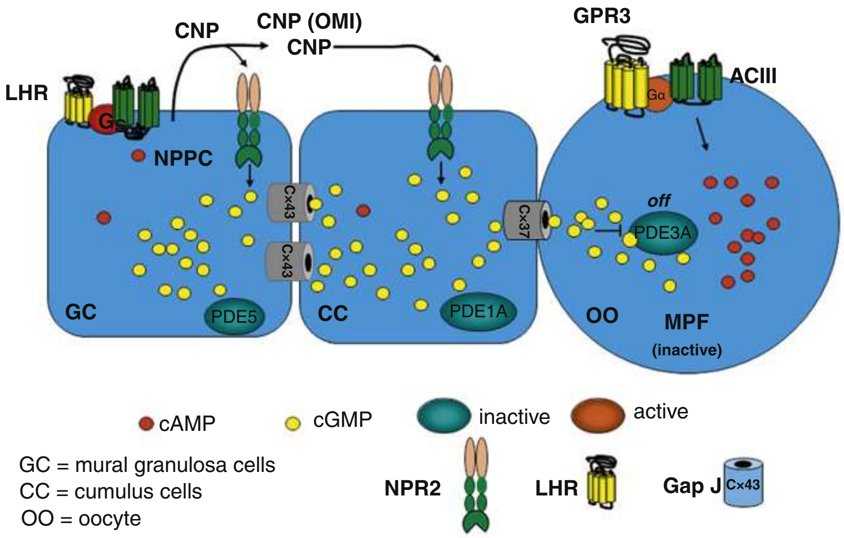

Figure 118.15 **Mechanisms maintaining oocyte meiotic arrest in the antral follicle. Schematic representation of a granulosa cell (GC), a cumulus cell (CC), and an oocyte (OO).** Communication among cells is mediated by connexins (Cx43 and Cx37). Mural granulosa cells produce the NPPC precursor which is then proteolitically processed and secreted as active C natriuretic peptide (CNP). CNP activates the cognate receptor NPR2 activating production of cGMP (yellow symbols). Cyclic GMP diffuses through gap junctions to the oocyte where it inhibits the activity of the oocyte phosphodiesterase PDE3A. In the oocyte, cAMP produced by the GPR3 receptor coupled to adenylyl cyclase ACIII prevents MPF activation and meiotic progression

Atresia. Of the nearly 1 million (400,000 to 2 million) or so primordial follicles present in the ovaries at birth (see Fig. 118.3), about 400 will be ovulated during the reproductive life span. Thus, 99.9% of oocytes are eliminated by apoptosis, which is governed by activation of a genetically controlled cell suicide program.[100] Studies over the past decade have highlighted pathways for directing the expression of proteins involved in promoting and suppressing apoptosis in the ovary.[101,102] The current challenges are to identify how specific atretogenic ligands promote apoptosis and to explain how these interactions are integrated into the overall pattern of folliculogenesis during the cycle. Notably, the ability of high concentrations of FSH to inhibit apoptosis in rodent granulosa cells[103] supports the concept that apoptosis in non-dominant follicles may be causally connected to subthreshold levels of FSH in the microenvironment. Implicit therein is the concept that FSH not only exerts an inductive effect on granulosa cell proliferation and differentiation but also acts as a survival factor through its ability to inhibit the activation of apoptosis. Understanding the nature of FSH signaling pathways that control granulosa apoptosis and follicle atresia is a major goal of reproductive research.

OVULATION

KEY POINTS

- Events associated with ovulation are similar to an inflammatory response.
- Even though LH and FSH share similar mechanisms of action, ovulation is mainly triggered by the gonadotropin LH.
- Intracellular regulation of cyclic nucleotide signaling is only one of the many pathways regulated by gonadotropins.
- This initial signal branches into regulation of a myriad of additional pathways with different biological outcomes.
- Temporal and spatial propagation of these pathways are additional dimensions required to maintain the phenotypic properties of granulosa cells within the follicle.

Thirty-six hours following the LH surge (on or about the 15th day of a 28-day cycle), the preovulatory follicle breaches the surface of the ovary and releases the egg/cumulus complex through a process termed *ovulation* (Fig. 118.16). Normal ovulation requires the coordinated actions of LH, FSH, and P_4, as well coordinates changes in the somatic and germ cell compartments, driven by release of local factors. Given the properties of the signals exchanged during ovulation, this process shares many similarities with an inflammatory response.

Oocyte Maturation Following the LH Surge

At the time of ovulation, oocytes undergo resumption of meiosis. At meiotic reentry, the oocyte dissolves the nuclear membrane (germinal vesicle break down) and extrudes the first polar body; it then arrests in metaphase II. The meiotic process proceeds no farther. The second meiotic division will be completed only when the ovulated egg is fertilized. This critically important transition into the cycle is triggered by the preovulatory surge of LH (Fig. 118.17). The completion of meiosis is termed nuclear maturation and is required to generate a haploid oocyte or "mature egg." A decrease in cGMP diffusing from the somatic compartment is regarded as the primary signal for meiotic reentry: the decrease in cGMP causes an activation of PDE3A and a decrease in cAMP in the oocyte.[99] This in turn causes activation of the meiotic cell cycle machinery.

In addition to nuclear maturation, a second set of less-well characterized changes occurs in the cytoplasm of the oocyte. These complex changes are called "cytoplasmic maturation," which endows the oocyte with the competence to support embryonic development. It is associated with changes in organelle distribution within the oocyte, alteration in membrane and cytoskeleton, and by a complex regulation of gene expression without *de novo* mRNA synthesis. However, selective translation and repression/destabilization of subsets of maternal mRNA will result in oocyte acquisition of developmental competence.[104]

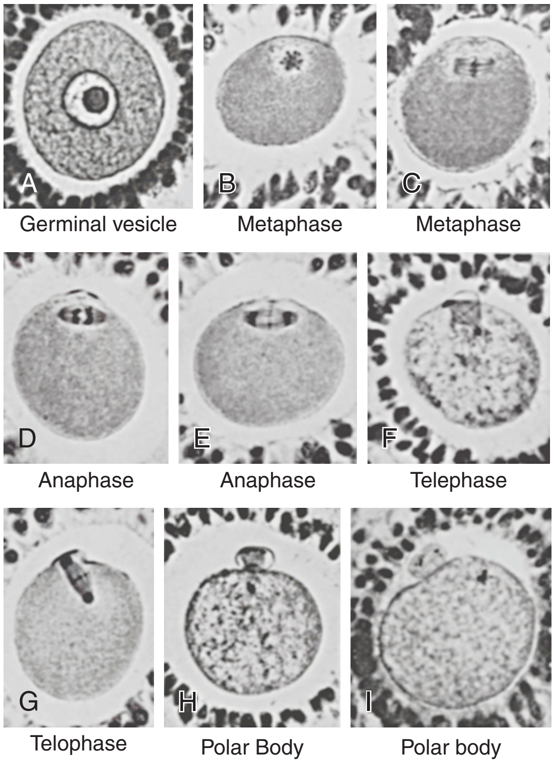

Figure 118.17 Photomicrograph showing the stages of meiotic maturation of the oocyte following resumption of meiosis in the dominant follicle. (From Witschi E. *Development of vertebrates*. Philadelphia: Saunders; 1956.)

Events Triggered by LH in the Somatic Compartment of the Follicle.

The LH surge induces major changes in all granulosa cell compartments of the follicle via modulation of gene expression, steroidogenesis, secretion, and cell-cell communication. Recent observations provide an explanation of how the LH signal propagates from the mural granulosa cells (rich in LH receptors) to the cumulus cells (with LH receptor almost undetectable). In all species studied, the LH surge causes transient increases in the expression of EGF-like growth factors (amphiregulin, epiregulin, betacellulin, and neuregulin) in mural granulosa cells[105] (Fig. 118.18). These growth factors interact with their cognate receptors (EGF receptors) present in all granulosa cells of the follicle, although highly enriched in cumulus cells. In mural granulosa cells, EGF-like growth factors function as autocrine factors amplifying signals originating from the LH receptors. On the other hand, they serve as paracrine factors for the cells that do not express LH receptors. In this case, as in cumulus cells, they function to propagate the LH signal toward the center of the follicle. As the net result of the combined LH/growth factor action, decreased cGMP in the follicle and decreased GAP junction permeability cause a decrease in cGMP in the oocyte and meiotic cell cycle reentry.

Concomitantly with oocyte reentry into the cell cycle, the cumulus granulosa cells undergo a series of structural and functional changes called *mucification* (see Fig. 118.10). In response to the preovulatory LH surge, the cumulus cells secrete large quantities of a glycoproteic mucous substance (primarily hyaluronic acid) into the extracellular space. This accumulation results in the dispersal of cumulus cells and causes the egg/cumulus complex to expand 3- to 5-fold.[86,106] The process of mucification is critical for the transport and fertilization of the egg within the fallopian tube. Mucification is stimulated by the release of multiple factors, including the EGF-like growth factors and prostaglandins. The actual release of the egg/cumulus complex is intimately coupled to the production of proteases[107] that degrade the ovarian tissues in a small, highly localized area called the macula pellucida or stigma. Animal studies have demonstrated that LH-stimulated P_4 and prostaglandin production by the follicle wall play an obligatory role in the expression of the proteolytic activities that occur during ovulation. Indeed, female mice lacking either the P_4 receptor[108] or the prostaglandin synthase gene (cyclooxygenase [COX-2],[109] the first rate-limiting enzyme in the biosynthesis of prostaglandins),[110] fail to ovulate and are infertile. Similarly, histological studies of rodents treated with indomethacin (an inhibitor of prostaglandin production) show that LH-induced prostaglandins synthesis is critical for stigma formation.

The LH surge also induces major changes in gene expression in TCs in preparation for ovulation. These will direct changes in the vasculature and *de novo* angiogenesis in preparation for vasculature invasion of the granulosa cell layer. Recruitment of immune cells at this stage is also essential for ovulation and vasculogenesis.

On the basis of the above changes, the following model for follicle rupture has been proposed (Fig. 118.19): the midcycle LH surge stimulates production of P_4; the P_4 ligand interacts with its receptor in the follicle cells, which, in turn, induce prostaglandin synthase and prostaglandin production. Prostaglandins interact with specific receptors in the surface epithelial cells of the presumptive stigma; prostaglandin receptor signaling causes release of lysosomal (proteolytic) enzymes that degrade the underlying tissue, ultimately resulting in stigma formation and follicle rupture.

LUTEOGENESIS

KEY POINTS

- The development of a transient endocrine structure, the corpus luteum, follows ovulation.
- Coordinated production of estrogen and P_4 by the corpus luteum controls the cyclic changes of the reproductive tract and the pituitary.

After ovulation, the follicle transforms into a novel endocrine organ, the corpus luteum (see Figs. 118.16 and 118.20). The theca interna cells and granulosa cells become the theca lutein and granulosa lutein cells, respectively. The corpus luteum becomes richly vascularized and serves as the site of P_4 and E_2 production during the luteal phase of the cycle. Major changes that occur during the life and death of the

Figure 118.18 **Mechanisms of LH-induced oocyte maturation.** In this scheme, symbols are as in Fig. 118.15. LH interaction with the cognate receptor on mural granulosa cells activates adenylyl cyclase to produce cAMP. cAMP accumulation induces the synthesis of EGF-like growth factors (Areg, Ereg). These growth factors act in an autocrine fashion by activating the EGF receptor. As a consequence of the LH stimulation of cAMP activation of EGF receptors causes the inactivation NPR2 and phosphorylation and closure of GAP junctions. As a consequence, cGMP decrease throughout the follicle. In the oocyte, inhibition of PDE3A is relieved and cAMP is degraded leading to activation of MPF and induction of meiotic maturation. *Areg,* amphiregulin; *CC,* cumulus cells; *Cx43,* connexin 43; *Ereg,* epiregulin; *GC,* granulosa cells; *GPR3,* G protein–coupled receptor 3; *MPF,* metaphase-promoting factor; *NPPC,* natriuretic peptide precursor C; *NPR2,* natriuretic peptide receptor 2; *Oo,* oocyte; *PDE3A,* phosphodiesterase type 3A; *PDE5,* phosphodiesterase type 5.

Figure 118.19 **A model illustrating the cellular activities involved in gonadotropin (follicle-stimulating hormone [FSH] and luteinizing hormone [LH])-induced ovulation.** (From Erickson GF. The ovary: basic principles and concepts. In: Felig P, Baxter JD, Frohman LA, eds. *Endocrinology and metabolism,* 3rd ed. New York: McGraw Hill; 1995:973–1015.)

corpus luteum constitute the processes called *luteogenesis* and *luteolysis*, respectively. Luteinization begins shortly after the preovulatory LH surge, and full expression of the differentiated state of the lutein cells begins by the end of 1 week (day 21 or 22 of a 28-day menstrual cycle). If the egg is not fertilized, the corpus luteum undergoes apoptosis,[111] leading to luteolysis. The process of luteogenesis is reflected in the production of P_4, E_2, and inhibin A during the luteal phase of the cycle.

Luteinization

LH is a central regulator of luteinization. In response to the preovulatory LH surge, genes that encode StAR, P450c22, 3β-HSD, and P450arom are expressed at high levels in the granulosa lutein cells, leading to the production of large amounts of P_4 and E_2. Although mean plasma LH levels are low during the luteal phase, small amounts of LH are critical for proper corpus luteum function.[112] It should be mentioned that luteinization is almost certainly more complex and most certainly involves other regulatory molecules, including LDL,[113] blood cells, cytokines, and angiogenic factors.[114] If fertilization and embryo implantation occur, the corpus luteum enlarges further to become the corpus luteum of pregnancy, in response to hCG produced by the blastocyst. The corpus luteum of pregnancy persists for about 6 weeks, after which it declines in size and function, as the placenta replaces the corpus luteum and produces steroid hormones for pregnancy maintenance.

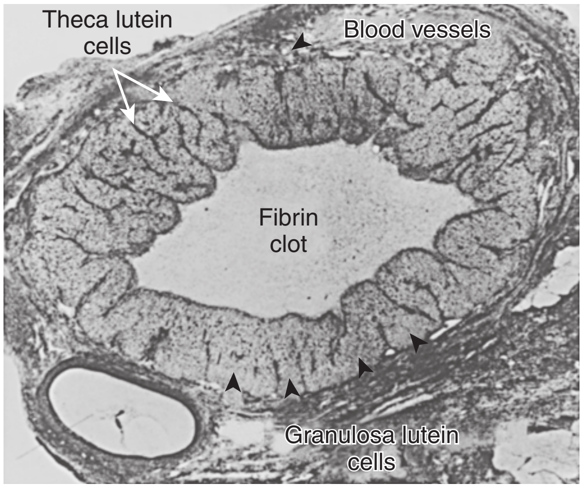

Figure 118.20 Photomicrograph of section of a corpus luteum from the human ovary. (From Bloom W, Fawcett DW, eds. *A textbook of histology*. Philadelphia: Saunders; 1975:875.)

Luteolysis

Luteolysis, or corpus luteum demise, is accompanied by progressive expression of apoptosis in the lutein and vascular cells. During this process, P_4 and E_2 production by the corpus luteum decreases markedly. Despite its great significance to female fertility, the physiological mechanism that governs luteolysis in humans remains unknown. It is possible that prostaglandin $F_2\alpha$ is involved, but its importance in women has yet to be proved.

CONCLUSION

The developmental programs of folliculogenesis, ovulation, and luteogenesis form the basis of the ovarian cycle, which, in turn, generates menstrual cyclicity and female fertility. These programs depend on coordinated regulation of a large array of cellular functions, including mitosis, meiosis, cellular differentiation, growth, and apoptosis. In addition to gonadotropins, recent studies have established the exciting new concept that growth factor-signaling pathways play an obligatory role in specifying ovarian cell fates through local autocrine/paracrine mechanisms. The emerging model is that ovarian growth factors are the controlling modulators that ensure the proper level, timing, and spatial pattern of the developmental programs evoked by hormones, offering a new model for understanding and treating fertility and infertility in women.

Conclusion, 1999

Ovarian hormones can be divided into two categories according to their chemical nature: (1) lipids, including steroids and eicosanoids, and (2) peptide hormones. These hormones act locally within the ovary and adjacent structures and systemically. In the ovary, germ cell growth and maturation and most hormone synthesis take place in the follicle or its derivative, the corpus luteum. The follicle consists of an outer layer of theca cells encircling the inner layers of granulosa cells, which, in turn, surround the oocyte. The androgen-producing theca cells and the estrogen-producing granulosa cells respond to the pituitary gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), respectively. During the final stages of follicle maturation, LH receptors are also expressed on granulosa cells, and the preovulatory LH surge acts on both granulosa and theca cells of the preovulatory (Graafian) follicle, inducing ovulation and transformation of the follicle into a corpus luteum. Circulating and locally produced peptide growth factors, cytokines, and growth factor–binding proteins, as well as the sex steroids produced by the ovarian cells themselves, amplify or attenuate the actions of gonadotropins. Together, they participate in the intricate dialog between the oocyte, granulosa cells, theca cells, vasculature, immune cells, and adjacent stroma to coordinate growth and maturation of the follicle and oocyte, as well as the function of the corpus luteum (see Chapter 120).

Prior to puberty, the human ovary is relatively quiescent in terms of steroidogenesis despite the presence of significant levels of circulating gonadotropins during fetal life and early infancy. The factors that restrain ovarian sex steroid secretion during these times include the relative absence of expression of LH receptors and the low level of expression of key steroidogenic enzyme genes. Gonadarche, the first evidence of substantial ovarian function in response to rising pituitary gonadotropin secretion at puberty, heralds the transition into the reproductive years. During the normal reproductive stage of life, some 400 to 500 follicles will complete the full developmental cycle. Generally, one follicle in a cohort of growing follicles will be selected to ovulate in each cycle. The remainder of the cohort is lost to atresia via autophagy and apoptosis. Under the influence of gonadotropins, the follicle selected to ovulate produces increasing amounts of estradiol through the aromatization of thecal androgen precursors, which ultimately triggers the preovulatory LH surge, ovulation and the transformation of the follicle into a corpus luteum. The corpus luteum in turn produces large quantities of progesterone, and also secretes estrogens. After the depletion of follicles with menopause, the ovarian capacity to cyclically synthesize estradiol and progesterone is lost. However, residual hilar and subsets of stromal cells maintain some capacity for limited steroidogenesis.

OVARIAN STEROID HORMONE BIOSYNTHESIS

The human ovary produces three main classes of steroid hormones: estrogens, androgens, and progestins. Enzymes involved in steroid biosynthesis and metabolism can be classified into two broad groups, the cytochrome P450s and the oxidoreductases. Cytochrome P450s are heme-containing proteins, named for their characteristic light absorption maximum at 450 nm in the presence of carbon monoxide. The second main group of steroid-metabolizing enzymes, oxidoreductases, can be further divided into two families based on their structure and function, namely, short-chain dehydrogenases/reductases (SDR) and aldo-keto reductase (AKR) families.[1] SDR include 3β-hydroxysteroid dehydrogenase (3β-HSD) types I and II and most of the known 17β-HSDs. Of the AKR family, 17β-HSD type V *(AKR1C3)*, is expressed in the ovary, and is thought to be essential for androgen production.

The rate of production of steroid hormones is determined largely by the delivery of cholesterol to the first enzyme in the steroidogenic

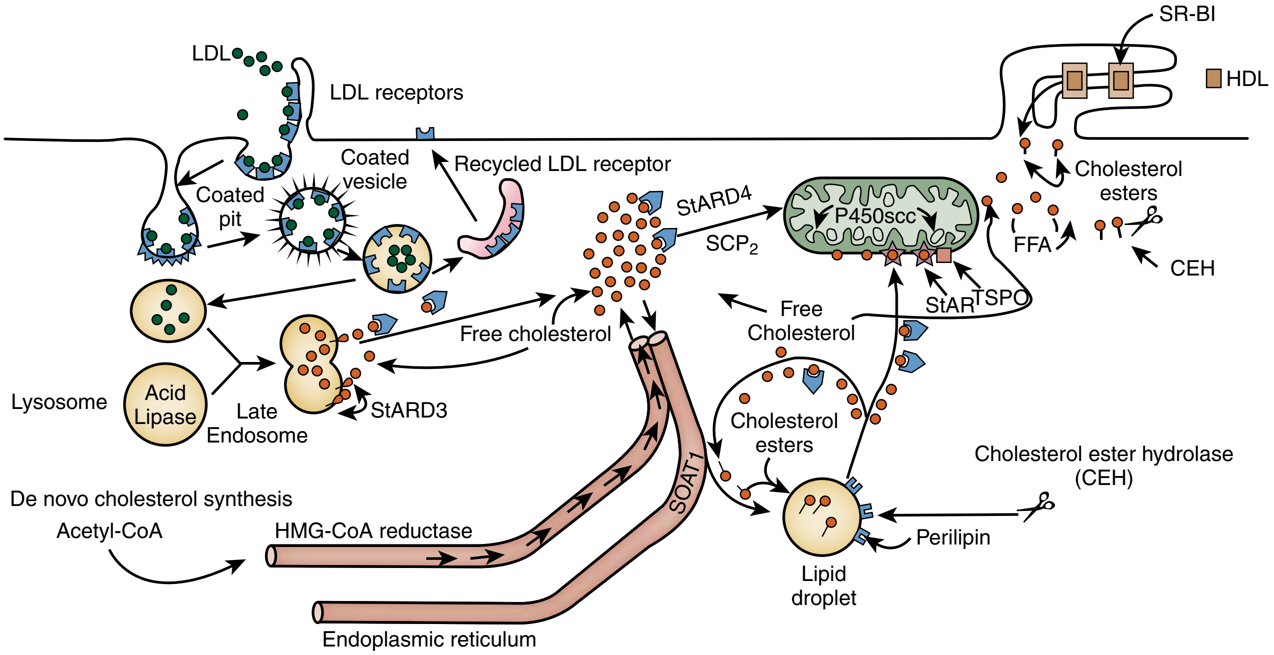

Figure 119.1 The Acquisition, Storage, and Trafficking of Cholesterol in Steroidogenic Cells. *FFA,* free fatty acid; *HMG-CoA,* 3-hydroxy-3-methylglutaryl-coenzyme A; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein; *StARD3,* steroidogenic acute regulatory protein–related lipid transfer domain 3; *P450scc,* cholesterol side chain-cleavage enzyme; *SCP2*, sterol carrier protein 2; *StAR,* steroidogenic acute regulatory protein; *StARD4,* START domain protein 4; *SOAT1,* sterol-O-acyltransferase-1; *TSPO,* translocator protein/peripheral benzodiazepine receptor.

pathway, cytochrome P450 side chain-cleavage enzyme (P450scc encoded by *CYP11A1*), and also by the levels and activities of this and other enzymes that catalyze subsequent biosynthetic steps.[2] Gonadotropins acutely increase ovarian steroid synthesis by stimulating cholesterol transport to P450scc and, in the longer term, control the content of the steroidogenic machinery, mainly by stimulating transcription of the genes encoding steroidogenic enzymes. These acute and long-term changes are primarily, but not exclusively, initiated by a cyclic adenosine monophosphate (cAMP)/protein kinase A (PKA)–mediated signaling system in thecal and luteal cells. FSH regulates the expression of steroidogenic enzymes in granulosa cells, including aromatase, mainly via a cAMP/PKA signaling system, although other signaling pathways may contribute (e.g., Akt/protein kinase B [PKB]).

Acquisition of Cholesterol

Ovarian cells, like other steroidogenic cells, acquire cholesterol either by *de novo* synthesis or by the uptake of lipoprotein-carried cholesterol. Trophic hormones stimulating steroidogenesis generally increase both cholesterol synthesis and lipoprotein uptake. Lipoprotein-associated cholesterol and cholesterol esters enter steroidogenic cells by two receptor-mediated pathways: the low-density lipoprotein (LDL) and the high-density lipoprotein (HDL) pathways (Fig. 119.1). Human steroidogenic cells are enriched with LDL receptors that mediate endocytotic lipoprotein uptake. The endocytosed lipoproteins are delivered to the lysosomal compartment where the apolipoproteins are degraded and the cholesterol esters are hydrolyzed by lysosomal acid lipase. The free cholesterol is then released from the lysosomes through the action of Niemann-Pick C proteins, NPC2 and NPC1. Stimulation of steroidogenic cells by trophic hormones increases the number of LDL receptors, and also accelerates the rate of LDL internalization and degradation. The uptake of HDL cholesterol involves a different process. HDL particles bind to scavenger receptors (e.g., SR-BI), with broad ligand specificity, recognizing HDL apolipoproteins as well as lipids. HDL cholesterol esters are selectively internalized, leaving the apolipoproteins on the cell surface. Evidence indicates that the internalized HDL cholesterol esters are not cleaved by lysosomal acid lipase, but via the action of cytosolic cholesterol ester hydrolase (CEH) or carboxyl ester lipase.[2,3]

Steroidogenic cells producing large quantities of hormone (e.g., luteal cells) accumulate the majority of their cholesterol from circulating lipoproteins. The access of lipoproteins to certain ovarian cells may therefore affect their ability to synthesize hormones. A partial blood-follicle barrier excludes high-molecular-weight substances from the follicular antrum, preventing LDL from reaching granulosa cells until after breakdown of the follicular basement membrane in the ovulatory process, which subsequently allows luteal cells access to LDL.

A characteristic feature of steroidogenic cells is the presence of numerous cytoplasmic lipid droplets containing cholesterol esters. Sterol esters in these droplets are synthesized by sterol-O-acyltransferase type 1 (SOAT1), also known as *acyl coenzyme A: cholesterol acyltransferase* (ACAT1), an endoplasmic reticulum enzyme.[4] The esters generated by SOAT1 accumulate within the endoplasmic reticulum membranes and subsequently bud off as lipid droplets. The sterol esters in lipid droplets are hydrolyzed by the soluble CEHs (see Fig. 119.1). Gonadotropin stimulation of cAMP-dependent protein kinases activates certain CEHs by phosphorylation of serine residues, which promotes the association of the enzyme with perilipins, proteins that coat lipid droplets and normally restrain mobilization of sterol esters. But when phosphorylated by cAMP-activated protein kinases, perilipins facilitate the action of hormone-activated esterases, resulting in hydrolysis of the lipid droplet sterol esters.[5] The size and the number of lipid droplets change as the ester pool expands or contracts. Cellular cholesterol ester storage is dependent on the *de novo* synthesis or accumulation of cholesterol on the one hand and cholesterol depletion through steroidogenic activity of the cell on the other. Trophic stimulation promotes cholesterol ester hydrolysis and diverts

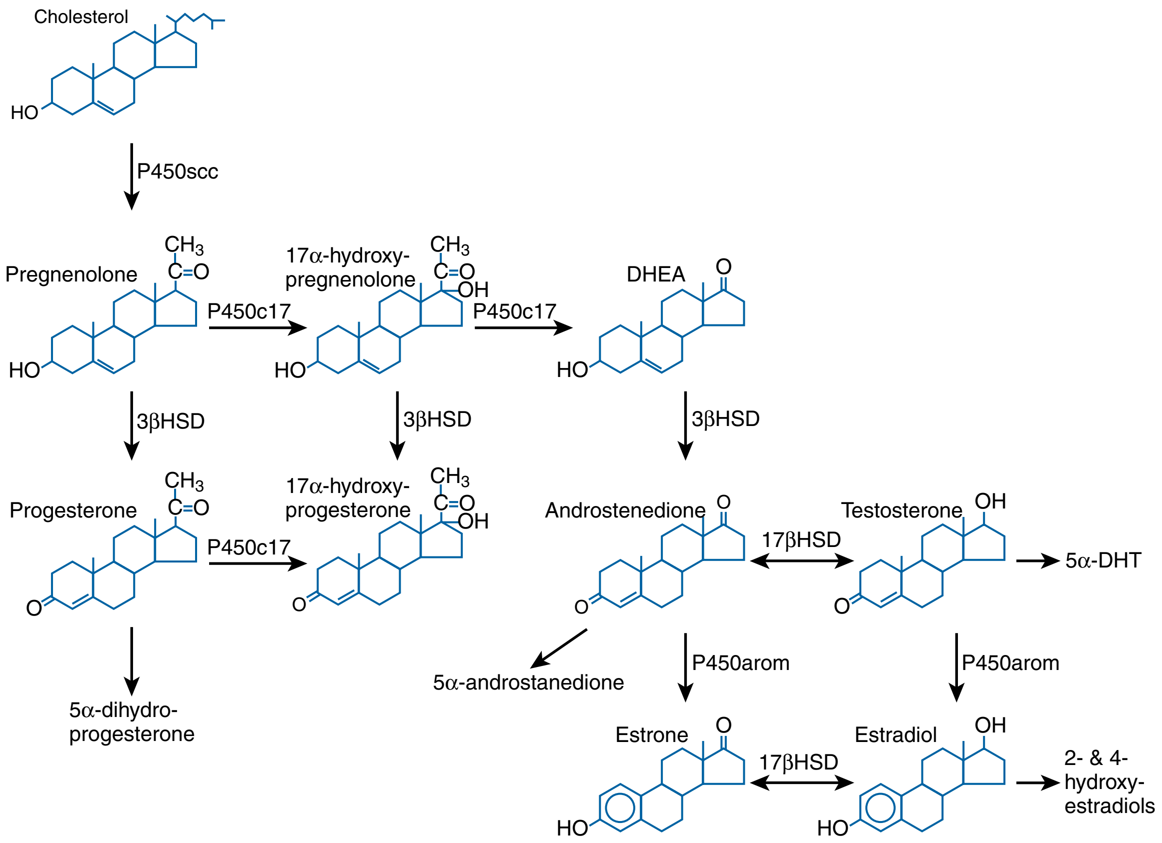

Figure 119.2 Major Pathways of Steroid Biosynthesis and Metabolism in the Human Ovary. Steroid metabolites in italics have unclear roles in the ovary, and their speculative functions are described in the text. *17βHSD,* 17β-Hydroxysteroid dehydrogenase; *3βHSD,* 3β-hydroxysteroid dehydrogenase; *DHEA,* dehydroepiandrosterone; *DHT,* 5α-dihydrotestosterone.

cholesterol into the steroidogenic pool away from SOAT1, preventing reesterification and resulting in a net depletion of cholesterol from the lipid droplets.

The Cholesterol Side-Chain Cleavage Reaction

The cholesterol side-chain cleavage reaction is the first committed step, as well as the rate-limiting process, in steroid hormone synthesis. This reaction takes place on the inner mitochondrial membranes, catalyzed by P450scc (Fig. 119.2) and its associated electron transport system, consisting of a flavoprotein reductase (ferredoxin or adrenodoxin reductase) and an iron sulfoprotein (ferredoxin or adrenodoxin). The dissociation constant (K_d) for binding of cholesterol is about 5000 nM, whereas P450scc's affinities for the intermediate substrates (22R) 22-hydroxycholesterol and (20R, 22R) 20,22-dihydroxycholesterol are more than 60-fold higher ($K_d = 4.9$ and 81 nM, respectively). Thus, once cholesterol is bound to the enzyme, it is committed to complete the reaction sequence. The estimated K_d for pregnenolone is 2900 nM, which permits the dissociation of the final reaction product from the enzyme.

The rate of formation of pregnenolone is determined by multiple factors: (1) delivery of cholesterol to the mitochondria; (2) access of cholesterol to the inner mitochondrial membranes; (3) amount of cholesterol side-chain cleavage enzyme, and secondarily its flavoprotein and iron-sulfur protein electron transport chain; and (4) catalytic activity of P450scc. Acute alterations in steroidogenesis generally result from changes in the delivery of cholesterol to P450scc or availability of electrons from the adrenodoxin/adrenodoxin reductase, whereas long-term alterations involve changes in the quantities of enzyme proteins as well as cholesterol delivery.

The transport of cholesterol from various substrate pools (including lipid droplets, the plasma membrane, and endoplasmic reticulum) to the mitochondria involves the action of sterol transport proteins, including members of the steroidogenic acute regulatory protein–related lipid transfer (StART) domain superfamily (StARD1, StARD3, StARD4, StARD5), Aster-B (also known as GRAMD1B) and sterol carrier protein-2. These transport proteins may interact with other cytosolic proteins, including CEH, to facilitate cholesterol movement to the mitochondria.[6] However, it is the translocation of cholesterol deposited in the outer mitochondrial membranes to the relatively sterol-poor inner mitochondrial membranes through a multiprotein transducer complex that is the critical step in the cholesterol side-chain cleavage process.[7]

The steroidogenic acute regulatory protein (StAR or StARD1), the prototypical member of the StART domain family, plays a pivotal role in the translocation process.[8] Expression of StARD1 mRNA and protein is correlated with steroidogenesis, and transfection of nonsteroidogenic cells with StARD1 and cholesterol side-chain cleavage enzyme system expression plasmids endows them with the capacity for pregnenolone synthesis. The discovery that inactivating mutations in the *StARD1* gene cause congenital lipoid adrenal hyperplasia (lipoid CAH) conclusively established an essential role for StARD1 in adrenal and gonadal steroidogenesis.[8] Patients suffering from this relatively rare autosomal recessive disorder are characterized by impaired biosynthesis of all classes of adrenal and gonadal steroid hormones due to a defect at the cholesterol side-chain cleavage step. However, 46,XX females with lipoid CAH develop female sexual characteristics at puberty and menstrual bleeding despite nonfunctional StARD1 proteins and adrenal insufficiency.[9] These findings demonstrate that production of small amounts of hormone can occur by StARD1-independent processes, including estrogen production by the ovary, which can be sufficient to produce secondary sexual development and endometrial growth.

In response to gonadotropin stimulation, StARD1 is synthesized as a 37-kDa preprotein containing an amino-terminal targeting sequence that directs it to the mitochondria. On the mitochondrial outer membrane, StARD1 interacts with a multiprotein complex (transducesome) to promote cholesterol translocation to the inner mitochondrial membrane through cycles of unfolding and refolding of the StART domain. The transduceome is thought to contain translocator protein (TSPO), voltage-dependent anion channel 1 (VDAC), acyl-coenzyme A binding domain-containing protein 3 (also known as PAP7), PKA regulatory subunit (RI alpha), and proteins of the 14-3-3 family. The specific roles of each component in StARD1 action are not yet known. For example, TSPO (also known as the *peripheral benzodiazepine receptor*) was once thought to play a critical role in StARD1 action, but steroidogenesis occurs normally in mice with a targeted mutation in the *Tspo* gene. TSPO has more recently been linked to the regulation of fatty acid oxidation and reactive oxygen species formation in steroidogenic cells.[10,11]

StARD1 contains several consensus sequences for cAMP-dependent protein kinase phosphorylation. Phosphorylation of Ser57 mediates StARD1 binding to the transduceosome, with the assistance of 14-3-3 protein family members. Phosphorylation of Ser195, which is located in the StART domain, is thought to affect the transition between folded and unfolded state and endow StARD1 with enhanced activity.[12] Although the StARD1 StART domain can bind cholesterol, sterol binding does not appear to be a requirement for its activity.

Residence time on the outer membrane is a determinant of the steroidogenic response. The action of StARD1 is terminated by import into the mitochondria and proteolytic processing of the targeting sequence to yield the 30-kDa "mature" form of the protein.[13] With the removal of StARD1 from the outer mitochondrial membrane, the translocation of cholesterol to the inner membranes ceases. Turning steroidogenesis back on requires the synthesis of new StARD1 molecules.

Pregnenolone generated by the action of the cholesterol side-chain cleavage enzyme can undergo further metabolism by enzymes closely associated with the mitochondria. Tom22, spanning the outer mitochondrial membrane to the inner mitochondrial space, interacts with the 3β-hydroxysteroid/Δ^5-Δ^4 isomerases, which are required for the conversion of pregnenolone to progesterone, 17α-hydroxypregnenolone to 17α-hydroxyprogesterone, and dehydroepiandrosterone to androstenedione (see Fig. 119.2).[14] Using nicotinamide adenine dinucleotide (NAD^+) as a cofactor, these enzymes catalyze the dehydrogenation of the 3β-hydroxyl group and the subsequent isomerization of the Δ^5 olefinic bond to yield the Δ^4,3-ketone structure.[14]

The importance of 3β-HSD to steroidogenesis is highlighted by the observation that inhibitors of 3β-HSD, such as epostane, effectively block progesterone synthesis and interrupt early human pregnancy. Two different but highly homologous human *3β-HSD* genes have been identified and localized to chromosome 1p13.1. The type I gene *(HSD3B1)* is expressed primarily in the human placenta, skin, and adipose tissue. The type II gene *(HSD3B2)* encodes the primary 3β-HSD enzyme expressed in the gonads and adrenal cortex. The type II 3β-HSD in human corpus luteum has been localized to the peri-mitochondrial endoplasmic reticulum by electron microscope cytochemistry. The enzyme is, therefore, positioned to convert pregnenolone produced by the mitochondrial cholesterol side chain-cleavage system to progesterone. Because steroidogenic cells have a large capacity to generate progesterone when presented with exogenous pregnenolone, 3β-HSD is not thought to be a rate-determining enzyme. However, the level of 3β-HSD increases following trophic hormone stimulation.[15]

Synthesis of Androgens

Theca cells of the follicle and theca lutein cells of the corpus luteum express P450c17 (CYP17A1), the key enzyme in androgen biosynthesis. This endoplasmic reticulum enzyme catalyzes two reactions in the ovary: (1) hydroxylation of pregnenolone and progesterone at C17 and (2) conversion of 17α-hydroxypregnenolone into dehydroepiandrosterone (lyase reaction). The 17α-hydroxylation reaction requires a pair of electrons and one molecule of O_2; a second electron pair and a molecule of O_2 are needed for the lyase reaction. The electrons are transferred from NADPH to the P450c17 heme iron by NADPH-cytochrome P450 reductase (POR), the importance of which is demonstrated by disordered steroidogenesis in patients harboring mutations of the *POR* gene, encoding NADPH-cytochrome POR.[16] The importance of POR is highlighted by the spectrum of conditions uncovered by its deficiency, chiefly menstrual cycle disorders, adrenal insufficiency, and disorders of sexual development.[17,18]

Several factors determine whether substrates undergo only 17α-hydroxylation or the subsequent scission of the 17,20 bond. These include the nature of the substrate, the flux of reducing equivalents, post-translational modification of P450c17, and allosteric effectors. The human P450c17 only utilizes Δ^5 substrates for 17,20 bond cleavage (see Fig. 119.2). Thus, 17α-hydroxyprogesterone is not metabolized to androstenedione at significant rates in humans. Phosphorylation of P450c17 by the kinase, p38α, appears to be necessary for maximal 17,20-lyase activity.[19] Cytochrome *b5* increases 17,20-lyase activity by acting as an allosteric modulator between POR and P450c17 rather than an electron donor. Females with mutations in the *CYB5A* gene, which encodes cytochrome *b5* can undergo normal sexual development and are fertile.[20]

The 11-oxyandrogens (e.g., 11-ketotestosterone, 11-ketoandrostenedione, 11β-hydroxy testosterone, and 11β-hydroxyandrostenedione) are produced by the adrenal cortex, which expresses 11β-hydroxylase (*CYP11B1*) and 11β-HSDs.[21] The 11-oxyandrogens bind to and activate androgen receptors (ARs), but evidently cannot be aromatized *in vivo* since 11-oxoestrogens cannot be detected in blood. There is evidence that ovarian theca cells also express *CYP11B1* and *HSD11B2*, albeit at lower levels than in the adrenal cortex, and can be a source of these bioactive steroids.[22]

Synthesis of Estrogens

Estrogens are synthesized in granulosa cells and granulosa lutein cells by the action of P450arom. In most cases, P450arom-expressing cells utilize androgen precursors derived from another cell type, placing ovarian estrogen synthesis under complex regulation epitomized by the "two-cell, two-gonadotropin" model of follicular steroid biosynthesis. According to this model, LH drives thecal synthesis of androgens, which are subsequently aromatized to estrogens in adjacent granulosa cells (Fig. 119.3). FSH is the primary stimulator of *P450arom* gene expression in granulosa cells, which contain more than 99% of the aromatization capacity of the follicle.[23] However, all granulosa cells are not equal in their capacity to form estrogens. There is a gradient of activity, with the highest aromatase expression located in the mural granulosa cells at the basement membrane, and the lowest levels in cells adjacent to the antrum.

Aromatase catalyzes three sequential hydroxylations of a C19 substrate using three molecules of NADPH and three molecules of oxygen to produce a C18 estrogen characterized by a phenolic A ring, with the elimination of the C19 methyl group as formic acid. The

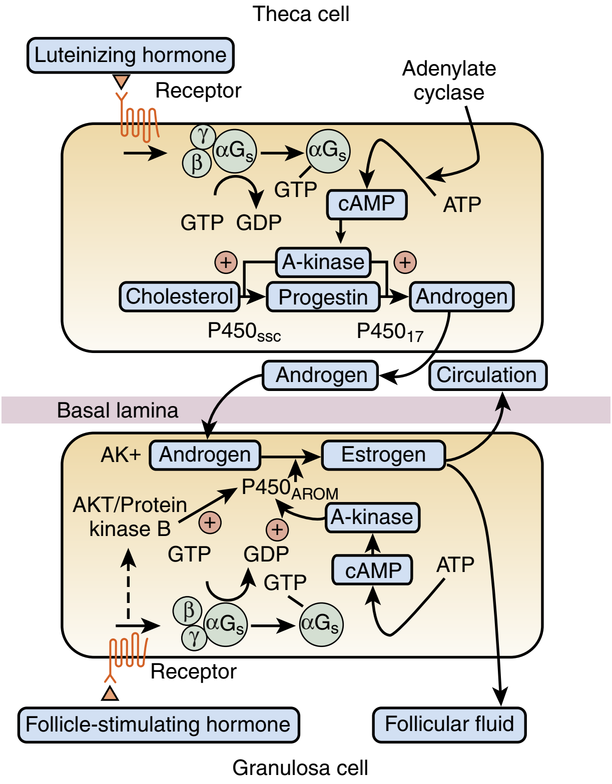

Figure 119.3 Gonadotropin Regulation of Follicular Androgen and Estrogen Biosynthesis and the Two-Cell, Two-Gonadotropin Model. *P450arom,* Aromatase; *P450c17,* l7a-hydroxylase; *P450scc,* cholesterol side chain–cleavage enzyme.

first hydroxylation yields a C19 hydroxyl derivative; this is followed by a second hydroxylation step to produce an unstable gem-diol, which collapses to yield a C19 aldehyde. The final hydroxylation event involves the formation of a 19-hydroxy-19-hydroperoxide intermediate, resulting in the subsequent elimination of a formic acid molecule and aromatization of the steroid A ring. This sequence of reactions takes place at a single active site on the enzyme, with reducing equivalents transferred to P450arom by NADPH-cytochrome POR.[24] The aromatase protein is encoded by a single gene *(CYP19A1)* on chromosome 15q21.1, which gives rise to mRNAs of various sizes as a result of the use of tissue-specific alternative promoters.[25] The promoter (promoter II) that drives ovarian aromatase expression lies adjacent to the exon encoding the translation start site. In granulosa cells, FSH stimulates the transcription of both *CYP19A1* and the gene encoding NADPH-cytochrome POR. Mutations in the gene encoding aromatase may be associated with ambiguous genitalia at birth, abnormal pubertal development and polycystic ovaries, and aromatase deficiency may lead to premature ovarian insufficiency compared with other steroid biosynthesis disorders like lipoid CAH.[26]

Gonadal tissues reduce 17-ketosteroids to 17β-hydroxysteroids, which have greater biological potency. The type I enzyme is also referred to as the *estrogenic* 17β-HSD since it catalyzes the final step in estrogen biosynthesis by preferentially reducing the weak estrogen, estrone, to yield 17β-estradiol (see Fig. 119.2), a potent estrogen, using either NADH or NADPH as a cofactor. Having a 100-fold higher affinity for C18 steroids over C19 steroids, the type I enzyme is located in the cytosol and is expressed in granulosa cells under the influence of FSH.[27] Although it is not normally expressed in the ovary, the type III enzyme is referred to as the *androgenic* 17β-HSD because it catalyzes the final step in androgen biosynthesis, the reduction of the weak androgen androstenedione to the more potent androgen testosterone. The primary androgen produced by the theca is androstenedione.[27] However, a small amount of testosterone is also made by the ovary. The absence of type III enzyme mRNA from the human ovary indicates that another 17β-HSD must be responsible for its production. Type V and Type VII 17β-HSDs are both candidates, but the type V enzyme, also known as AKR1C3, most likely is the enzyme because it is expressed in theca and luteal cells.

Steroid Hormone Metabolites

Metabolites of progesterone, testosterone, and estradiol are produced in the ovary. This is particularly true for the corpus luteum, which produces substantial amounts of 17α-hydroxyprogesterone and 5α-dihydroprogesterone. The secretion of both of these progesterone metabolites parallels the production of progesterone during the luteal phase. Since pregnancy can be established and maintained in the absence of these molecules, they do not appear to have obligatory roles in reproductive physiology.

Two distinct isozymes of 5α-reductase, namely type I *(SRD5A1)* and type II *(SRD5A2)*, have been identified. Both isozymes reduce the double bond between C4 and C5 and can convert progesterone to 5α-dihydroprogesterone, testosterone to dihydrotestosterone (DHT), and androstenedione to 5α-androstenedione. Whereas *SRD5A1* mRNA expression has been clearly shown in the ovary, mRNA expression of *SRD5A2* is debated.[28,29] DHT is present in follicular fluid and ARs are present in granulosa cells, but the precise role of DHT in normal human ovarian physiology remains to be elucidated (see the section entitled "Role of Androgens" later in the chapter). The primary estrogens, estradiol and estrone, can undergo hydroxylation at C2 and C4 positions in the ovary, resulting in the formation of catechol estrogens, which contain a dihydroxybenzene A ring. Metabolism of estradiol to the catechol estrogens, 2-hydroxyestradiol and 4-hydroxyestradiol, is catalyzed by estrogen 2-hydroxylase *(CYP1A1)* and estrogen 4-hydroxylase *(CYP1B1)*, respectively. Both of these metabolites bind to ERα and ERβ with 7% to 13% relative binding affinity compared with estradiol.[30] Catechol estrogens can be further *O*-methylated by catechol-*O*-methyl transferase (COMT) to form methoxy estrogens. These metabolites appear to have important roles in controlling ovarian angiogenesis, acting as inhibitors of hypoxia factor-1a.

MicroRNA Regulation of Steroidogenic Enzymes

MicroRNA (miRNA), small interfering RNA and piwiRNA, are subtypes of small non-coding RNAs. These RNAs are numerous and are present in cells throughout the body, playing a key role in the post-transcriptional regulation of a number of biological processes. Notably, a single miRNA may regulate up to hundreds if not thousands of different mRNAs, and a single mRNA may be affected by multiple miRNAs. The effects of miRNAs can be positive or negative, upregulating gene function or silencing translation of mRNA depending on the conditions present within the cell. The multitude of possible effects has led to difficulty in interpreting the physiological role of specific miRNAs, although there is growing evidence that they play a significant role in modulating the coordination required for follicle recruitment, maturation, and ovulation. In the ovary, they appear to have roles in regulating cell growth, differentiation, apoptosis, and other cell functions,[31] including gonadotropin receptor function, growth factor signaling, and steroidogenesis. For example, miRNA-33 has been shown to play a key role in controlling cholesterol metabolism[32]; miRNA-136-3p has been reported to affect LH receptor expression[33]; has-miR-548ba resides within the FSH receptor gene and regulates follicle growth and activation; and has-miR-7973 resides within the aromatase gene and modulates extracellular matrix and cell-cell interactions.[34]

KEY POINTS

- Cholesterol acquisition and metabolism to produce a variety of steroid hormones is a major function of the ovary.

PEPTIDE HORMONES AND GROWTH FACTORS PRODUCED BY THE OVARY

Transforming Growth Factor-β Superfamily

The transforming growth factor-β (TGF-β) superfamily, which includes TGF-β molecules, activins, inhibins, anti-Müllerian hormone (AMH), and the oocyte-derived proteins growth differentiation factor-9 (GDF-9) and bone morphogenetic protein-15 (BMP-15), play critical roles in ovarian function. These peptides mainly act locally to control follicular function, but several—including inhibins, activins, and AMH—are released into the systemic circulation. Activins and inhibins are disulfide-linked dimers of subunits derived from larger preproteins. Activins are dimers consisting of two β-subunits, βA and βB, assembled into three different combinations, namely activin A (βA-βA), activin B (βB-βB), and activin AB (βA-βB). One unique α-subunit is complexed to either of the two β-subunits to give two isoforms of inhibin, inhibin A (α-βA) and inhibin B (α-βB). In addition to their role as intraovarian regulators (described later in this chapter), inhibins appear to have important functions in the control of FSH secretion (see Chapters 118 and 120). Inhibins and estrogens inhibit, whereas gonadotropin-releasing hormone (GnRH) stimulates FSH secretion by the anterior pituitary gland. Although infusion of activin A has been shown to stimulate FSH secretion in monkeys, it is believed that circulating activins are rendered inactive by binding to follistatin, a single-chain glycoprotein that does not share significant homology with the actin/inhibin α- or β-subunits. Less is known about the regulation of inhibins, although an alternative cleavage site within the α-subunit releases a pro-peptide which appears to limit the synthesis and bioactivity of inhibins.[35,36]

The two different forms of inhibin display a divergent secretory pattern. Circulating inhibin B levels closely parallel serum FSH levels, rising in the early follicular phase and then declining, followed by a midcycle peak and a subsequent decline during the luteal phase. In contrast, serum inhibin A levels are low during the early follicular phase and rise with the growth of the dominant follicle. In the luteal phase, the granulosa and theca-luteal cells of the corpus luteum are a source of inhibin α-subunits, with the corpus luteum primarily secreting inhibin A.[37] Because inhibin B is produced by growing small antral follicles, low circulating levels of inhibin B are correlated with diminished ovarian reserve. Both inhibin A and inhibin B are used as granulosa cell tumor markers.

AMH is produced as a preprohormone and must be processed to become the active.[38] AMH is cleaved by furin, or possibly related convertases, at a conserved N-terminal site. Mutations that eliminate this site result in an inactive hormone and persistent Müllerian duct syndrome in males.[38] Following cleavage, the pro-region remains associated with the mature form of AMH until it binds the AMH receptor, and may even play a role in receptor binding.[39] Both AMH cleavage, and the subsequent competence of cleaved AMH, appear to vary in different body fluids. For example, cleaved AMH is significantly more capable of binding its receptor in follicular fluid than in serum, resulting in lower proportions of cleaved AMH required to exert an effect. Conversely, cleaved AMH is much more prevalent in serum and much less capable of binding its receptor. This raises the possibility of a mechanism by which cleaved AMH is rendered inactive in serum, and suggests that the level of cleaved AMH in biological fluids does not necessarily reflect AMH activity.[40]

Relaxin

Relaxin is an important hormone for maternal adaptation to pregnancy. In humans, there are seven relaxin genes; relaxins 1 to 3 and insulin-like peptides (INSLs) 3 to 6. Relaxin 2 is produced by the corpus luteum, mainly during pregnancy. All the relaxin family members are two-chain peptide hormones processed by cleaving a prohormone. Immunohistochemical studies have localized relaxin 2 to large luteal cells but not small luteal cells. During a non-conception cycle, luteal relaxin immunostaining was low in the early luteal phase; it increased progressively, reaching the highest level in late luteal phase, and then decreased greatly in corpora albicantia.[41] The pattern of relaxin secretion by the corpus luteum of pregnancy mirrors its steroidogenic function, with levels reaching peak concentrations between 8 and 12 weeks of gestation, declining subsequently to levels that are maintained until term. Human chorionic gonadotropin (hCG) appears to be the primary stimulus for luteal relaxin secretion, which is independent of progesterone secretion. INSL3 is the most studied of the other family members; it is involved in both follicle growth and thecal androgen production.[42] It acts in an autocrine/paracrine manner within the follicles to drive the production of androstenedione and its conversion to estrogens by granulosa cells, which in turn promotes expression of more INSL3 in a positive feedback loop, a system countered by BMPs and the LH surge. This system governs estradiol production within an antral follicle through the follicular phase. Higher levels are seen in women with polycystic ovary syndrome (PCOS), and lower levels in women with diminished ovarian reserve.[42] Although other INSLs are expressed in the ovary, their functions are not well established.

KEY POINTS

- The ovary is a dynamic enocrine organ that produces both lipid and peptide hormones.

GONADOTROPIN CONTROL OF OVARIAN STEROID PRODUCTION

Follicle-Stimulating Hormone and Luteinizing Hormone

Gonadotropins control the growth and differentiation of the steroid hormone–secreting cells of the ovary, intrinsically linking form and function. A defined sequence of gonadotropin action propels the growth of follicles and the production of steroid hormones. Positive feedback on the pituitary gland by high concentrations of estrogen leads to the ovulatory surge of LH, which in turn triggers a dramatic differentiation event, resulting in structural reorganization of the preovulatory follicle, release of the ovum, and striking changes in the steroidogenic capacity of the luteinizing cells (see Chapter 120).

Follicular growth, which culminates in ovulation and corpus luteum formation, requires both FSH and LH. Steroidogenic competence of the ovarian follicle is not achieved in the absence of FSH, even if LH is present in abundance. FSH promotes proliferation of the granulosa cells and increase in follicle size, and it induces the expression of genes involved in estradiol biosynthesis.[43] Mutations resulting in inactive FSH β-subunit or inactivation of both alleles of the FSH receptor gene produce symptoms of primary hypogonadism with deficient ovarian estrogen production in the face of elevated plasma LH levels. Likewise, FSH cannot achieve complete regulation of follicular development by itself. In gonadotropin-deficient women or LH-deprived monkeys treated with FSH alone, follicles grow to a preovulatory size, but because of a relative deficiency in androgen precursors, there is no parallel increase in estradiol production.[44,45] The small amount of estradiol that is made in this situation may be derived from androgens secreted by the adrenal cortex or thecal androgens produced in response to paracrine factors released by the granulosa cells. During the last phase of follicular maturation, when granulosa cells acquire LH receptors, LH alone can sustain follicular estradiol synthesis.[45] This LH substitution is thought to compensate for the diminished levels of FSH of the late follicular phase and allow LH action on the granulosa to rescue the dominant follicle from the fate of atresia of the remainder of the cohort.[45,46]

LH stimulation is also indispensable for normal luteal hormone production. Suppression of LH release leads to a prompt decline in progesterone levels that precede changes in the abundance of mRNAs encoding steroidogenic enzymes and structural luteolysis. This acute regulation of ovarian progesterone secretion is controlled by LH via the expression of StARD1. StARD1 mRNA and protein, present in both theca-luteal and granulosa-luteal cells throughout the luteal phase, are highly expressed in the early and midluteal phases, whereas declining StARD1 mRNA and protein levels are characteristic of the late luteal phase. Moreover, StARD1 protein levels in the corpus luteum are highly correlated with plasma progesterone levels. Suppression of LH levels during the midluteal phase markedly decreases plasma progesterone levels and abundance of StARD1 mRNA transcripts in the corpus luteum.[47] In addition, primate luteal cells activate cholesterol efflux mechanisms during luteolysis.[48]

Mechanisms of Gonadotropin Action

Activation of the LH receptor results in a rapid increase in steroid production from the ovary. This is due to post-translational changes to existing proteins such as the phosphorylation and activation of CEH and the phosphorylation of StARD1, actions mediated mainly by proteins phosphorylated by the cAMP-dependent protein kinase (PKA) and other kinases, including extracellular signal-regulated kinase (ERK) 1/2.[2] This results in a rapid enhancement of cholesterol delivery to the inner mitochondrial membranes.

Longer-term regulation of steroid hormone production over hours or days is exerted at the level of gene transcription. Increases in cAMP concentrations stimulate transcription of virtually all of the genes involved in steroid hormone synthesis. Although these genes do not all contain consensus cAMP response elements in their promoters, steroidogenic factor-1 (SF-1), encoded by the *NR5A1* gene, is involved in the control of most of the steroid synthetic genes. SF-1–binding elements are present in the promoters of the *StARD1, CYP11A1, HSD3B2, CYP17A1,* and *CYP19A1* genes.[49] The interaction of SF-1 with other transcription factors, including cAMP response element–binding protein (CREB)–binding protein (CBP), its coactivators, and steroid receptor coactivator-1 (SRC-1), may coordinate the cAMP response.

SF-1 expression decreases after ovulation, but mRNA levels of another orphan nuclear receptor controlling steroidogenic genes, liver receptor homologue - 1 (LRH-1) (encoded by *NR5A2*), are higher in corpus luteum than in mature follicles. Unlike SF-1, the expression of LRH-1 is induced significantly in the corpus luteum during pregnancy.[50] The stage-specific expression of LRH-1 in the ovary implies its specific role in regulating follicular and luteal functions. Transfection of granulosa cells with LRH-1 induces dose-dependent *HSD3B2* promoter activity.[51] Mice lacking LRH-1 expression in granulosa cells fail to ovulate, and expression of the *Stard1* and *Cyplla1* genes is impaired.[52] Collectively, these data demonstrate the importance of LHR-1 in luteal steroidogenesis.

The GATA family of transcription factors has recently emerged as an important group of transcription factors regulating expression of multiple steroidogenic enzymes. This basic helix-loop-helix (bHLH) family includes GATA-4 and GATA-6, which have roles in regulating the expression of *StARD1*, *CYP11A1*, and *CYP17A1*, among other steroidogenic enzyme genes.[53] The GATA family of transcription factors also interacts with other transcription factors, including SF-1 and Sp1, as part of a combinatorial code that regulates steroidogenic enzyme gene expression.

FSH and LH mediate granulosa cell gene expression and differentiation via their respective cell surface receptors through three major signaling pathways, PKA, PKB and protein kinase C (PKC). FSH activates multiple pathways, including phosphatidylinositol 3-kinase (PI3K)/PKB, mitogen-activated protein kinase (MAPK)/ERK, and p38 MAPK.[54] Studies of human granulosa-like tumor cells demonstrate that PKA is the main protein kinase activated by FSH, and that cAMP pathways are mainly mediated by PKA. PKA in turn regulates many factors which promote early follicular differentiation and inhibit cell proliferation.[55] In fact, even in the absence of FSH, expression of a constitutively active PKA subunit qualitatively mimics most of the transcriptional regulation exerted by FSH, with even more robust upregulation of transcripts involved in ovulation.[56] PKB is activated via PKA-dependent and PKA-independent signaling, and appears to play a role in regulating up to 60% of the FSH-dependent genes in granulosa cells through one of its major targets, forkhead box protein O1 (FOXO1). Stimulation of granulosa cells by FSH in the presence of PKB led to an amplification of FSH-induced aromatase and LH receptor mRNA levels, and its role in the synthesis of estradiol may have clinical relevance in controlled ovarian hyperstimulation treatments for fertility.[55]

The transcription of genes encoding steroidogenic enzymes is also suppressed at specific stages of follicular and luteal function. For example, after the LH surge, the expression of thecal P450c17 and granulosa aromatase and 17β-HSD decline transiently. Activation of the LH receptor also activates the inositol phosphate cascade, which is able to reduce aromatase expression and enhance progesterone production. Aromatase is similarly suppressed with the activation of PKC or expression of the constitutively active form of $G\alpha_q$, but mutant forms of the LH receptor that do not activate the phosphoinositol cascade do not inhibit aromatase.[57] PKC appears to function in parallel with the PKA pathway in later stages of follicular maturation, regulating several inflammatory factors which are suspected to facilitate ovulation in response to the LH surge, and others involved in granulosa cell luteinization.[55]

Factors that block expression of steroidogenic proteins include the orphan nuclear receptor, DAX-1, encoded by the *NR0B1* gene, which interacts directly with SF-1 to prevent activation of the transcriptional machinery. Stimulation of P450arom promoter activity by SF-1 in ovarian granulosa cells is inhibited by DAX-1 and WT1; all three transcription factors are expressed in human granulosa cells, indicating finely coordinated regulation of P450arom expression.[58,59] Post-transcriptional control (e.g., changes in mRNA stability) is also important in certain circumstances, and may account in part for the actions of insulin-like growth factors (IGFs) and small RNAs on the expression of components of the steroidogenic machinery.[59]

Other Hormones with Possible Actions in the Ovary

Besides FSH and LH, other hormones have been reported to exhibit gonadotropic activity. These include prolactin, growth hormone (GH), insulin, IGFs, GnRH, and kisspeptin. Although prolactin plays an important role in regulating luteal function in rodents, the physiological role of prolactin in human ovarian function is less certain. The human ovary expresses prolactin, which can be measured in follicular fluid in the long and short prolactin receptor isoforms. Although high levels of prolactin can suppress granulosa cell estrogen production, the menstrual disturbances observed in hyperprolactinemic women are primarily due to suppression of pituitary gonadotropin secretion.

GH has been reported to have direct effects on animal and human granulosa cells. Its cognate receptor is expressed on granulosa cells of human antral follicles and luteal cells. In addition, GH administration increases the ovarian response to gonadotropins in hypopituitary- or growth hormone–deficient individuals. Yet, supplemental GH does not appear to have dramatic effects on gonadotropin action in individuals with normal pituitary function.

Ovarian theca and granulosa cells express the insulin receptor through which insulin augments steroid production. The mechanisms underlying the insulin effect on steroidogenesis remain to be clarified. Insulin can increase steady-state levels of steroidogenic enzyme mRNAs, but it is not yet known whether this is a transcriptional or post-transcriptional response. To date, insulin response elements have not been identified in steroidogenic enzyme genes. There is, however, evidence for insulin effects on mRNA stability. Additionally, insulin is known to rapidly activate translation, but it is yet to be determined if such a translational action takes place in ovarian cells.

Kisspeptin (KISS1), acting through its G-coupled protein receptor (KISS1R), plays a critical role in female reproduction, controlling gonadotropin secretion, onset of puberty, ovulation, and the metabolic regulation of fertility. More recently, the action of kisspeptin/KISS1R in the ovary has been explored, and there is convincing evidence that it exerts a wide variety of effects in a number of mammalian species, including humans. KISS1 can both attenuate initial follicle recruitment and promote development of preovulatory follicles by downregulating FSH receptor and increasing circulating AMH, suggesting a role as a downstream target of LH signaling. In porcine and ovine models, treatment with kisspeptin-10 temporally increases GDF-9 and BMP-15 expression to mediate oocyte maturation. In murine and ovine models, kisspeptins have been shown to induce ovulation and potentially functions as a downstream target of prostaglandins (PGs), although KISS1R knockout models can still ovulate with extended GnRH and gonadotropin stimulation. Finally, KISS1 directly stimulates progesterone synthesis and secretion from granulosa cells by increasing mRNA expression of StARD1, P450scc, and 3β-HSD, and may play a role as a downstream mediator of neurokinin B (NKB) stimulation of estrogen production in granulosa cells, although this relationship requires further investigation.[60]

KEY POINTS

- Gonadotropins are essential regulators of steroidogenesis.

INTRAOVARIAN REGULATORS

While gonadotropins are the primary regulators of ovarian function, intraovarian factors modulate gonadotropin action. Their stage- and cell-specific actions orchestrate the complex dynamics of folliculogenesis and ovarian function over the life span. These intraovarian factors modulate gonadotropin receptor expression and function, as well as downstream signaling pathways. They have roles in follicle formation, granulosa and theca cell differentiation, basement membrane development, and other critical aspects of ovarian morphogenesis and function. They also likely account for differences in the rate of individual follicle growth, rescue of follicles from atresia, arrest and resumption of meiosis, dominant follicle selection, and the timing of key events of ovulation and luteolysis. The list of potential paracrine factors that can influence steroid production by theca and granulosa cells is long and diverse. It includes growth factors belonging to the TGF-β superfamily (e.g., AMH, GDF-9, BMP-15, activins, inhibins), cytokines, epidermal growth factor-related peptides (e.g., epiregulin, amphiregulin, and betacellulin), platelet-derived growth factor, fibroblast growth factors, TGF-α, IGFs, INSL3, hypothalamic peptides (e.g., kisspeptin and GnRH) estradiol, and progesterone (Table 119.1).[61–63]

TABLE 119.1 Intraovarian Regulators That Affect Ovarian Hormone Production

Growth Factor/ Cytokine	Ovarian Actions
Activin	Stimulates follicular growth and maturation and FSH receptor expression Inhibits thecal steroidogenesis
Adiponectin	Regulates granulosa steroidogenesis
Chemerin	Inhibits granulosa steroidogenesis
EGF	Stimulates mitosis of granulosa cells Inhibits expression of aromatase
FGF	Stimulates mitosis of granulosa cells Inhibits steroidogenesis
GDF-9	Increases follicular growth Regulates granulosa cell steroidogenesis Enhances thecal development
GnRH	Inhibits steroidogenesis Activates oocyte maturation
IFN-γ	Decreases granulosa cell steroidogenesis
IGF-1, IGF-2	Stimulates granulosa cell and theca cell mitosis and steroidogenesis, augments gonadotropic-stimulated steroidogenesis
IL-1	Inhibits gonadotropin-stimulated steroidogenesis
IL-2	Augments progesterone production
IL-6/IL-11/OSM/LIF	Suppresses FSH-stimulated steroidogenesis
Inhibin A, inhibin B	Increase thecal androgen synthesis
INSL3	Stimulates thecal androstedione production
KGF	Enhances luteal progesterone production Stimulates granulosa cell division Increases inhibin-α expression
Kisspeptin	Follicular development, oocyte maturation and ovulation, granulosa cell progesterone production
Leptin	Low dose enhances steroidogenesis
PDGF	Higher doses suppress estrogen and progesterone production Augments FSH-induced LH receptor expression and steroidogenesis, enhances theca proliferation
Prohibitin	Knockdown in granulosa cells is associated with suppressed StARD1, P450scc, 3β-HSD, and aromatase activity, decreased FSH-mediated steroidogenesis
Resistin	Stimulates some steroidogenic enzymes Stage-specific IGF modulation
TGF-β	Augments FSH-mediated steroidogenesis Augments FSH receptor expression Inhibits thecal steroidogenesis
TNF-α	Inhibits gonadotropin-stimulated steroidogenesis

Cholesterol Precursors

Intermediates in the cholesterol biosynthetic pathway from lanosterol have been found to induce oocytes to resume meiosis. The compound 4,4-dimethyl-5α-cholesta-8,14,24-triene-3β-ol was extracted from human follicular fluid and named *follicular fluid meiosis-activating substance (FF-MAS)*. A related compound, 4,4-dimethyl-5α-cholest-8,24-diene-3β-ol, was isolated from bull testis and called *T-MAS*. Present in micromolar concentrations in preovulatory follicular fluid, both compounds are synthesized from lanosterol by P450 14α-demethylase encoded by the *CYP51* gene. The accumulation of FF-MAS and T-MAS in mature follicles may be the result of increased synthesis or inhibition of subsequent steps in cholesterol synthesis. Gonadotropins have been reported to cause a several-fold increase in *Cyp51* gene expression in rodent ovaries, which could contribute to enhanced MAS formation, and blocking CYP51 function reduced the ability of FSH to induce meiosis in cultured rat follicles.[64] However, the physiologic roles of FF-MAS and T-MAS in human oocyte maturation *in vivo*, if any, remain uncertain at this time.

Role of Estrogens

In addition to their systemic effects on the reproductive tract, hypothalamus, and pituitary gland, estrogens act on granulosa, theca, and luteal cells in the ovaries of laboratory animals and domestic species. Not only are estrogen receptors (ERs) expressed in the ovary, but high levels of estrogens are also characteristically found in the antral fluid of healthy mature follicles. There are conflicting reports in the literature regarding the expression of the two ER subtypes, ERα and ERβ, in the primate ovary.[65] The most convincing of these studies indicates that both ER subtypes are expressed in the germinal epithelium, and granulosa cells, with ERβ predominating over ERα in medium-sized and preovulatory follicles, theca cells, and luteinized granulosa cells. ERα transcripts have also been detected by polymerase chain reaction in human oocytes by some researchers, but these findings have not been confirmed by others. The discrepancies among various reports likely reflect sensitivities of the detection methods used. Existing data support the notion that the ovary is a site of estrogen action via the classical receptor-mediated signaling pathways.

Given the high intraovarian estrogen concentrations achieved during follicular maturation and corpus luteum function, the physiologic roles of estrogen within the primate ovary and the mechanisms by which they might influence cellular function (i.e., genomic versus nongenomic actions) are matters of debate.[65] Indeed, the extremely high levels of estradiol reached in the antrum of the preovulatory follicle (~1 μg/mL) raise serious questions as to the roles of the classical ERs, which would be fully saturated by ligand during the later stages of follicular maturation. Estrogens have pleiotropic effects on animal granulosa cells. They promote proliferation and exert anti-atretogenic effects. Estrogens also augment intercellular gap junction and antrum formation, and increase the ER content of granulosa cells. Estrogens synergize with gonadotropins at several levels (e.g., promotion of ovarian growth, LH and FSH receptor expression) and augment aromatase activity. However, high levels of estrogens are not essential for the growth of follicles to the size equivalent to the preovulatory stage.[66] There are pharmacologic data suggesting that estrogens are important for oocyte function.[67] *In vitro* studies on primate granulosa cells have yielded inconsistent findings with respect to the actions of estrogens. Estradiol inhibits progesterone secretion by rhesus monkey granulosa cells, whereas in marmoset granulosa cells it has no effect on progesterone production, but stimulates aromatase in the presence of IGF-1. Exogenous estrogen exerts a luteolytic effect on the primate corpus luteum, probably through actions on the central nervous system.

In summary, although the primate ovary expresses the receptors that allow a variety of cells to respond to estradiol, the physiologic significance of estrogens in follicular maturation and luteal function in the primate ovary remain to be elucidated. It is evident that follicle growth per se does not require high levels of estradiol, but the orchestration of events that result in a mature oocyte capable of developing into a viable embryo following fertilization may require estrogen action.

Estrogen metabolites (discussed earlier in this chapter) have been proposed to be paracrine/autocrine regulators of steroidogenesis and follicular development. A balance of pro-angiogenic and anti-angiogenic estrogen metabolites appears to be necessary for follicular development. Furthermore, 4-hydroxyestrone, 16-ketoestradiol, and 2-hydroxyestradiol have proliferative and pro-angiogenic actions,[68] whereas 2-methoxyestradiol and 2-methoxyestrone have anti-angiogenic activities. The anti-angiogenic activity of 2-methoxyestradiol can be ascribed to inhibition of the transcription factor, hypoxia-induced factor-1α,[69] which may have a role in controlling neovascularization of the developing corpus luteum and changes in luteal vascular during luteolysis.[70] Genetic variants of the *COMT* gene associated with decreased 2-methoxyestradiol have been associated with premature ovarian insufficiency.[71] Alterations in the balance of pro-/anti-angiogenic estrogen metabolites are found in the follicular fluid of anovulatory women with PCOS.[68]

Role of Androgens

In the human, infra-human primate, and rat ovary, ARs are expressed mainly in granulosa cells and to a lesser extent in theca cells and stroma, suggesting that in addition to serving as substrates for estrogen production, thecal androgens may have paracrine and autocrine functions. Androgens have a number of effects on the primate ovary. It has been proposed that androgens have complex actions on granulosa cells, amplifying the effects of FSH during intermediate stages of follicular development, but potentially inducing atresia during the late preovulatory period. Administration of testosterone or DHT to rhesus monkeys promotes activation of primordial follicles, as well as increased granulosa cell division in small follicles, suggesting a folliculotropic action. Moreover, ARs were positively correlated with a marker of cell proliferation (Ki-67) and negatively correlated with apoptosis. These observations are in sharp contrast with the notion that androgens are atretogenic, a concept that emerged primarily from studies on the rodent ovary in which androgens block granulosa cell proliferation *in vitro* and promote follicular atresia. Taken together, these discrepancies suggest species-specific androgen actions in the ovary.

Stage-dependent effects of androgens on granulosa-cell function *in vitro* have been reported in the marmoset.[72] Androgens enhanced FSH-stimulated aromatase expression and progesterone production, while inhibiting hCG-stimulated aromatase activity and progestin synthesis in cells from large preovulatory follicles. In the rhesus monkey, high levels of DHT given after pituitary downregulation, extending into to a period of exogenous gonadotropin stimulation, resulted in a marked decrease in estrogen production and lower ovarian weights.[73] In mice, there appear to be dose-dependent actions, with low levels of androgen inducing rapid follicular maturation and high levels of androgen inhibiting follicular growth and oocyte maturation.[74] Evidence that androgens have a detrimental effect on human follicular function includes the observation that follicular fluid enriched in DHT and poor in estradiol is characteristic of atresia. However, this steroid profile may be a consequence rather than a cause of atresia. Favoring a causal relationship are reports that high follicular concentrations of 5α-reduced androgens such as DHT act as competitive inhibitors of granulosa cell aromatase activity.[75] Thus, androgens may exert both positive and negative effects on follicular growth and function in a stage- and dose-dependent manner through ARs, as well as by non–receptor-mediated mechanisms.

There has been much discussion in recent years about the possibility of using androgen priming to increase oocyte yield and quality in IVF cycles by increasing the antral follicle pool prior to hyperstimulation in women with diminished ovarian reserve. The logic and caveats to this approach are reviewed by a recent article from the Andersen group.[76] Though systemic androgen can influence smaller follicles, it does not appear to alter follicular fluid concentrations of androgen in larger follicles. Clinical trials employing treatments to influence intrafollicular androgen levels are ongoing. As data emerges from these trials and analysis of systemic versus local effects of androgen on intact human follicles is completed, we may gain a better understanding of the specific roles of androgens in the ovary.

Role of Progesterone

Progesterone plays a key role in the periovulatory period and appears to be essential for the normal luteinization process and maintenance of luteal function. Ovulation does not occur in mice with targeted deletions of the progesterone receptor (PR) gene (the A form of the receptor), or in animals treated with the PR antagonist, RU486. A number of genes encoding enzymes implicated in ovulation that appear to be dependent on periovulatory progesterone have been identified, including those encoding metalloproteinases and cathepsin L. Pharmacological blockade of ovarian progesterone production with a 3β-HSD inhibitor indicated that progesterone exerts antiapoptotic and pro-differentiation effects on luteinizing cells and maintains luteal function.

In women, granulosa cells from preovulatory follicles do not contain significant amounts of PRs, although progesterone may play a role in inhibiting granulosa cell differentiation and steroidogenic activity through PR membrane component 1 (PGRMC1) in rats.[77] Granulosa cells of the dominant follicle, however, highly express PR at the time of the LH surge.[78] After follicle rupture, PR expression persists in the luteinized granulosa cells of the corpus luteum,[79] with mRNA concentrations of both PR isoforms (PR-A and PR-B) at the early and midluteal phases being higher than those at the late luteal phase.[79] These data are concordant with the hypothesis that progesterone is a “local luteotropin” that promotes luteal development and sustains luteal structure and function.[80]

Progesterone also appears to play a role in oocyte maturation. In rhesus monkeys treated with the progestin R5020, a significant percentage of oocytes resumed meiosis and entered metaphase II despite the absence of a gonadotropin surge or follicle rupture.[81] Collectively, the cited studies indicate that progesterone produced in response to the midcycle LH surge is important for luteinization of the dominant follicle, oocyte maturation, ovulation, and subsequent maintenance of luteal function.

Transforming Growth Factor-β Superfamily

Inhibins are produced mainly by granulosa cells during the follicular phase and augment LH-stimulated thecal androgen synthesis, but they have no direct effect on granulosa cell steroidogenesis. However, FSH-stimulated inhibin production by granulosa cells indirectly augments estrogen production by stimulating thecal androgen production for use as estrogen precursors in the granulosa cells. Since FSH also increases the expression of P450arom and NADPH cytochrome POR, the increased substrate is readily metabolized to estrogen by the dominant follicle.[82]

Activins, primarily produced by granulosa cells, have more complex actions in the follicle. Both activin and TGF-β exert their effect, in part, through a canonical Smad pathway, activating Smad2 and Smad3 which then interact with Smad4 and translocate to the nucleus to exert a variety of stage-specific effects.[83] They potentially play a role early in follicular growth by stimulating the expression of FSH receptors, aromatase and inhibin by granulosa cells. TGF-β also increases the expression of the inhibitory Smad7, which provides a negative feedback loop and promotes granulosa cell apoptosis.[83] Activins suppress thecal androgen production and block the stimulatory effects of inhibin on thecal steroidogenesis. Consequently, activins can keep thecal androgen synthesis in check during early follicular development. Activins also increase the production of IGF-binding proteins (IGFBPs) IGFBP-2 and IGFBP-4 by granulosa cells, which, in turn, modulate IGF effects. In primates, inhibin A is not expressed in small follicles, but gradually increases in enlarging follicles. This results in a shift from an activin-dominated environment to one that is progressively more dominated by inhibin.[83,84] Follistatin is a monomeric protein first identified in and isolated from follicular fluid. An activin-binding protein, it is produced by granulosa cells under FSH stimulation and blocks the actions of activin. Serum levels of follistatin do not fluctuate across normal menstrual cycles. Likewise, intrafollicular concentrations of free follistatin do not vary with size or maturity of the follicle. However, follistatin levels are increased in women with PCOS,[85] and female transgenic mice overexpressing follistatin exhibit small ovaries due to a block in folliculogenesis at various stages, confirming its role in follicular development.[86]

AMH is expressed in granulosa cells of preantral and small antral follicles of the ovary. Expression of AMH receptor has been localized to granulosa and theca cells of growing follicles of the rat ovary.[87] Compared with wild-type controls, ovaries of prepubertal AMH-null mice contained more growing follicles, whereas ovaries of adult AMH-null mice had significantly fewer primordial follicles.[88] By 13 months of age, AMH-null ovaries were almost depleted of primordial follicles. Collectively, these observations suggest an indirect role for AMH in inhibiting the recruitment of primordial follicles to the growing pool. AMH appears to prevent entry into the growth phase by coordinated regulation of growth and inhibitory genes, and normal follicular recruitment and ovulation are dependent on a thecal androgen-induced reduction in production of AMH from granulosa cells. It also inhibits aromatase induction by FSH in granulosa cells, and on the basis of *in vitro* studies conducted on a murine Leydig cell line, it is likely that AMH inhibits theca cell androgen production.[89]

In women, serum AMH levels are positively correlated with the number of small antral follicles detectable by ultrasonography, but are negatively correlated with age. As antral follicle count declines with age, reflecting diminishing ovarian reserve, decreased follicular production of inhibin B leads to reduced pituitary suppression of FSH. The rapid decline in AMH with age is purported to be related to this rise in FSH, either by direct inhibition or indirectly by inhibiting oocyte-specific growth factors GDF-9 and BMP-15.[90] Women with PCOS, who have increased numbers of small growing follicles, have elevated AMH levels. The persistently elevated levels of androgens in these women may disrupt the inhibitory role androgens play in decreasing AMH to promote follicular recruitment.[91] Women on hormonal contraceptives also can have lower AMH levels,[92] although women with ovarian insufficiency due to *FSHR* mutations have near normal AMH levels.[93] Clinical studies suggest that AMH can be a good serum marker of ovarian reserve, although best utilized as a predictor of ovarian response to exogenous gonadotropins in fertility therapies. Note that standardization of existing assays remains to be accomplished, and normative values need to be further validated across age ranges and other conditions such as obesity, that may influence results.[94] AMH secretion is thought to be independent of the ovarian cycle. However, some reports suggest that AMH levels can vary across the follicular and luteal phases.[95,96]

The oocyte also participates in the paracrine dialogue involving the somatic cells in the follicle. GDF-9 is highly expressed by growing oocytes, and to a lesser extent by primate granulosa cells. Disruption of the *Gdf9* gene in mice prevents follicle development beyond the primary/early secondary stage. The follicles of GDF9-deficient mice arrest in growth at the early secondary stage, yet their oocytes continue to grow at a faster rate than wild-type oocytes, and progress to advanced stages of differentiation seen in the antral follicles of normal mice. However, there are ultrastructural abnormalities in the interconnections between granulosa cells and oocytes. The theca also fails to form around the follicles, implicating GDF-9 in the organization and/or proliferation of this follicular component.

In vitro, GDF-9 has a variety of species-specific effects on granulosa and theca cells.[97] In rodents, GDF-9 stimulates granulosa cell differentiation, including induction of LH receptors and steroidogenesis. In early preantral follicles, GDF-9 induces follicle growth and thecal differentiation.[98] In cumulus cells, GDF-9 promotes expression of proteins that are incorporated into the proteoglycan extracellular matrix of the cumulus oophorus and follicular fluid. It also stimulates COX-2 and PG synthesis and progesterone formation.[99] LH receptor expression is suppressed, which would discourage luteinization of the cumulus cells. These combined actions of GDF9 confer a unique phenotype to those granulosa cells immediately adjacent to the oocyte that become the cumulus cells with further follicle development. GDF-9 inhibits human granulosa-luteal and antral theca cell steroidogenesis *in vitro*, with the inhibitory effect on theca cells being more pronounced.[100] It also stimulates theca cell proliferation, a finding consonant with the apparent role of GDF-9 in controlling thecal development in the murine ovary.

BMP-15 is another member of the TGF-β superfamily produced by oocytes. It is structurally related to and shares a similar expression pattern with GDF9, with which it can heterodimerize. Although BMP-15 has no effect on FSH-stimulated estradiol production, it decreases FSH-induced progesterone production, indicating that BMP-15 is a selective modulator of FSH action. *In vitro*, BMP-15 stimulates granulosa cell mitosis. Mutations in the human *BMP15* gene that reduce mature protein production, activity, or synergy with GDF-9 cause primary ovarian insufficiency, as do missense variants in the BMP receptor genes, *BMPR1A* and *BMPR1B*.[101,102]

Eicosanoids

PGs are members of the eicosanoid family of biologically active molecules derived from arachidonic acid, which is in turn mobilized from cell membrane phospholipids mainly via the action of phospholipase A2 (PLA2). Arachidonic acid is converted to PGs by the two isozymes of PG endoperoxide synthase-1 and -2 (PTGS-1/-2, also known as cyclooxygenase-1/-2, COX-1 and COX-2). COX-1 is constitutively expressed at low levels, but induction of COX-2 in granulosa cells before ovulation is highly conserved across many mammalian species. COX-2 knockout mice are infertile due to ovulation failure.[103] The preovulatory gonadotropin surge markedly increases COX-2 expression and concentrations of both PGE_2 and $PGF_2\alpha$ in follicular fluid. Transgenic mice lacking the PGE_2 receptor subtype EP2 show decreased ovulation and exhibit abnormal cumulus expansion.[103] A role for $PGF_2\alpha$ in ovulation is unclear, but it has a well-established role as a physiologic luteolysin in animals. For example, administration of $PGF_2\alpha$ to ewes decreases serum progesterone levels and mRNA abundance of both StARD1 and 3β-HSD type II in the corpora lutea.[104]

Insulin-Like Growth Factors and Their Binding Proteins

In response to FSH, granulosa cells produce IGFs as well as IGFBPs, which have higher affinities for the IGFs than the receptors that mediate IGF action.[61–63] IGF-1 is the primary IGF produced in animal follicles, whereas IGF-2 is the major IGF in the human ovary. Both IGFs bind the type I IGF receptor (IGF1R), which is a tyrosine kinase receptor similar to the insulin receptor and is responsible for IGF downstream signaling in the cell. An *in vivo* IGF1R knockdown model in mice demonstrates its central importance in the regulation of follicle growth, and the survival and differentiation of granulosa cells. Mice without functional IGF1R in granulosa cells showed increased apoptosis at all levels of follicular development, lack of responsiveness to FSH (without alteration in FSH receptor expression), and lower levels of preovulatory aromatase, LH receptor, and inhibin α.[105] The type II receptor has a very different structure with only a single transmembrane domain and a small intracytoplasmic component. It does not transmit signals but binds IGF2 and controls its bioavailability. In general, IGFs amplify the actions of FSH on granulosa cells, including effects on cell proliferation, cAMP accumulation, and transcriptional activation of some genes, including the *StARD1* gene. Similarly, IGFs increase theca cell androgen and progesterone production and amplify the stimulatory effects of LH.[106]

The pattern of expression of IGFBPs is determined by the stage of follicular maturation and the status of the follicle.[61–63] IGFBP-2 is expressed by theca and granulosa cells of small antral atretic follicles, whereas IGFBP-3 is expressed by theca and granulosa cells of the dominant follicle. IGFBP-4, expressed by ovarian stroma, theca cells, and the granulosa cells of small antral follicles and the dominant follicle, is a potent inhibitor of IGF action *in vitro*. Inactivation by cleavage by the IGFBP-4 protease, also known as *pregnancy-associated plasma protein-A* (PAPP-A), acts to increase IGF bioavailability. PAPP-A is secreted by granulosa cells of large follicles but not small follicles. Its proteolytic activity is modulated by stanniocalcins (stanniocalcin-1 and -2), which are potent PAPP-A inhibitors.

Healthy follicles are characterized by a microenvironment in which IGFs are present in the unbound form.[107] The high levels of free IGF are achieved by both reduced expression of IGFBP-2 and increased inactivation of IGFBP-4. In contrast, atretic follicles have higher levels of both IGFBP-2 and IGFBP-4, which restrict bioavailability of IGF. The IGF system represents a prototype for amplifying the effects of FSH during the follicular phase, permitting the dominant follicle to survive in the face of declining FSH levels.

Other Intraovarian Regulators

Oxytocin is implicated in the regulation of gap junction formation between luteal cells, stimulation of estradiol synthesis, and the process of luteolysis. Primate corpora lutea have the highest contents of oxytocin during the midluteal phase, and oxytocin receptor transcripts are detectable in the corpus luteum at this time. However, the observation that oxytocin knockout mice do not show abnormalities in corpus luteum function suggests that oxytocin is not a major factor in controlling the rodent corpus luteum.

The proinflammatory cytokines IL-1α and IL-1β inhibit steroid production and suppress the steady-state levels of StARD1 and steroidogenic enzymes in ovarian cells.[108] These cytokines, together with their cognate receptor IL-1R1, are produced by resident ovarian macrophages and both granulosa and theca cells. Studies have shown multiple functions of the IL-1 system in the developing follicle. *In vitro*, IL-1 inhibited FSH-induced estradiol and progesterone production by granulosa cells and also gonadotropin-induced androstenedione production by theca cells. IL-1 treatment can increase PG accumulation in the rat ovary by stimulating the expression of two of the key enzymes in PG formation, PLA2 and COX-2. Although the physiological roles of these cytokines in the ovary remain to be fully characterized, evidence suggests that the IL-1 system participates in the control of folliculogenesis, ovulation, and luteal function.

In addition to playing a pivotal role in the hypothalamus-pituitary-gonadal axis, GnRH also regulates steroidogenesis in the ovary as a local autocrine/paracrine factor. Two isoforms of this decapeptide hormone have been identified, GnRH-1 and GnRH-2. mRNA transcripts of both GnRH isoforms and GnRH-1 receptor are expressed in granulosalutein and ovarian surface epithelial cells.[109] Progesterone secretion from granulosa cells in culture was decreased by the addition of a GnRH agonist, an effect reversed by the coadministration of a GnRH antagonist. At low concentrations, the GnRH agonist, buserelin, stimulates estrogen production in granulosa-lutein cells, but suppresses steroidogenesis at higher concentrations.[110] GnRH-1, GnRH-2, and GnRH-1 receptor mRNA expression levels in the ovary are regulated by multiple factors, including FSH, hCG, estradiol, and GnRH-1 and GnRH-2 themselves.

Many substances originally identified as adipokines because they are secreted by adipose tissue are also produced by ovarian cells or have receptors that are expressed in the follicles or the corpus luteum. Interaction between these metabolic regulators and regulation of reproductive functions has long been suspected, but ongoing characterization of the adipokines has provided insight into the mechanisms and complexity of these interactions. Various adipokine receptors are expressed in follicles and the corpus luteum, though regulation of the specific types can vary by species. Granulosa and theca cells have also been reported to produce some adipokine proteins endogenously, such as adiponectin and leptin. The expression patterns of the adipokines and their receptors are stage- and sometimes species-specific. Leptin, adiponectin, chemerin, and resistin have all been reported to regulate human ovarian steroid production.[111–114] They each can modulate insulin or IGF effects in granulosa or theca cells *in vitro*. Leptin and adiponectin have both been shown to modify progesterone production by luteal cells.[114]

Altered serum levels of adipokines have been described in women with PCOS, and follicular fluid levels of adipokines have been associated with egg retrieval and fertilization rates. Leptin is negatively correlated with embryo number, whereas resistin is positively correlated with it, but the correlations are not definitive enough to be used as predictors of oocyte health.[115] The exact roles of the various adipokines in human ovarian function are still not entirely clear, but there is ample evidence that this family of factors is involved in the intersection of fertility and energy balance and perhaps in the endocrine dysfunction of PCOS and obesity.

KEY POINTS

- Ovarian-derived steroids and peptide hormones function as key paracrine and autocrine regulators of ovarian function.

HORMONE PRODUCTION DURING THE OVARIAN LIFE CYCLE

The Fetal and Prepubertal Ovary

The human fetal ovary displays very limited steroidogenic activity. It contains no detectable StARD1 protein in theca or granulosa cells, and expresses very low levels of P450scc. Homogenates of fetal ovaries convert pregnenolone into progesterone, 17α-hydroxyprogesterone, and 5α-reduced compounds. However, androgens are not formed in any significant quantity, indicating the lack of 17,20-lyase activity. Consistent with these observations, P450c17 mRNA in the fetal ovary is less than 2% of the levels found in fetal testis. Homogenates of fetal ovaries can, however, aromatize androstenedione and testosterone at low rates. The paucity of 17,20-lyase activity, as well as low aromatase expression, would restrict fetal estradiol synthesis.[116]

The Ovary During Reproductive Life

The plasma levels of the two major female sex steroid hormones, estradiol and progesterone, change dramatically during the menstrual cycle, primarily reflecting their rate of secretion from the ovary. During the follicular phase, the theca of maturing follicles contributes 30% of the circulating androstenedione, increasing to 60% immediately prior to ovulation. The rising estradiol levels in the follicular phase are derived almost exclusively from the follicle selected for ovulation. Following ovulation, follicular concentrations of steroids downstream of P450c17 (estrogen and testosterone) are decreased, as is the capacity for conversion of androgens to estradiol.[117] The luteinization of the theca and granulosa cells gives rise to the corpus luteum, comprising granulosa-lutein (large) cells and theca-lutein (small) cells, each displaying a different repertoire of steroidogenic enzymes. Capable of progesterone production, both cell types express StARD1, P450scc, and 3β-HSD type II. Theca-lutein cells express P450c17 and appear to be the primary site of 17α-hydroxyprogesterone production as well as the source of androgen substrates to be converted to estrogens by the aromatase-expressing granulosa-lutein cells,[118] a compartmentalization of steroidogenic enzymes reminiscent of the theca-granulosa cooperation in estrogen synthesis during the follicular phase. Granulosa-lutein cells and theca-lutein cells have an intimate relationship in the formed corpus luteum, and their interactions may be promoted by the action of locally produced hormones, including oxytocin, which stimulates the formation of gap junctions between these cells, facilitating intercellular communication.

The steroidogenic activity of the corpus luteum is dependent upon LH stimulation.[119] Administration of a GnRH antagonist to nonhuman primates results in an immediate and profound decline in plasma progesterone levels and sharp reduction in ovarian StARD1 mRNA expression but without significant changes in P450scc and 3β-HSD mRNA levels. In monkeys with hypothalamic lesions that destroy GnRH-producing neurons, luteal function can be maintained by pulsatile administration of GnRH. Cessation of GnRH infusion results in a rapid fall in progesterone levels that can be restored by reinitiation of infusion. Interestingly, the functional life span of the corpus luteum in this experimental paradigm cannot be extended beyond the usual life of 14 to 16 days despite continued administration of GnRH. Only treatment with progressively increasing amounts of LH or hCG can "rescue" the corpus luteum from luteolysis.[120] These observations suggest that luteolysis in primates is the result of a loss of sensitivity to LH, presumably as a consequence of intraluteal events, and that decreased luteal sensitivity to LH can be overcome with higher levels of gonadotropin stimulation.

Excessive ovarian enlargement and increased production of estrogens occurs in ovarian hyperstimulation syndrome (OHSS), a condition most commonly associated with ovulation induction with exogenous gonadotropins. Very rarely, OHSS occurs spontaneously as a consequence of FSH receptor mutations in the transmembrane domains that increase sensitivity to hCG[121] or a consequence of excessive hCG levels (e.g., hydatidiform mole) or thyrotropin production secondary to profound hypothyroidism.

During early pregnancy, the corpus luteum, which is essential for maintenance of pregnancy during the initial 7 weeks, produces large amounts of progesterone. Secretory function then declines, as assessed by the measurement of 17α-hydroxyprogesterone levels, a steroid that is not secreted by the placenta and is, therefore, assumed to provide an index of luteal function (Fig. 119.4). In the absence of an hCG rescue signal, the corpus luteum undergoes a process of functional and structural regression that has been likened to an immune-mediated event characterized by apoptotic death of luteal cells as well as luteal cell necrosis/autophagy, processes that both contribute to structural luteolysis.[122]

Abnormal production of ovarian steroid hormones, particularly androgens, occurs rarely during gestation as a result of luteoma of pregnancy and hyperreactio luteinalis. Maternal virilization and occasional virilization of female fetuses may occur. Both conditions are benign and resolve during the postpartum period.

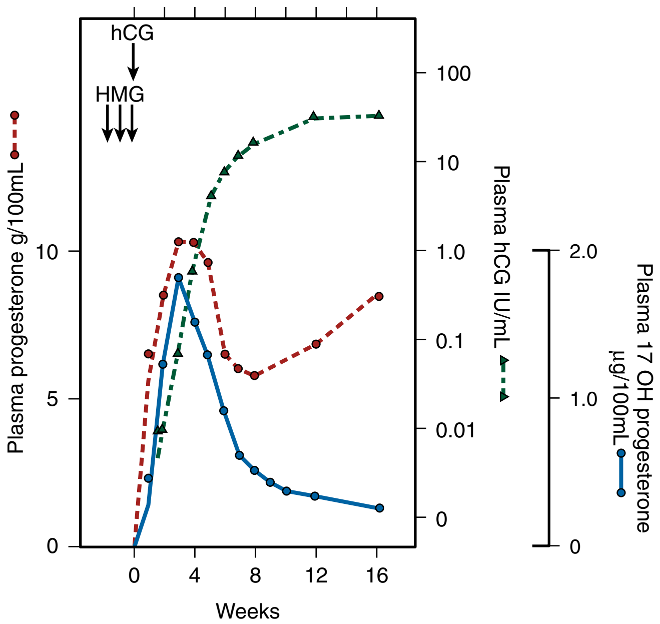

Figure 119.4 Mean Plasma Levels of Progesterone, 17-Hydroxy-Progesterone, and Human Chorionic Gonadotropin (hCG) Following Induction of Ovulation With Human Menopausal Gonadotropins (HMG) and hCG. Endocrine Activity of the Postmenopausal Ovary

The postmenopausal ovary contains two different populations of cells with steroidogenic capacity: hilar cells and stromal cells, including residual thecal elements. *In vitro* studies suggest that the postmenopausal ovary has some steroidogenic potential. Incubation of postmenopausal ovarian stromal slices with pregnenolone yielded progesterone, dehydroepiandrosterone, and testosterone. Incubation of strips of ovarian hilar tissue from postmenopausal women revealed a steroidogenic pattern similar to that of the postmenopausal ovarian stroma. However, the overall amount of steroid produced was substantially greater compared with stroma. Measurable *in vitro* formation of estradiol by postmenopausal cortical stroma and hilar cells has also been reported.[123,124] Immunohistochemical studies found that less than 1% of stromal cells showed evidence of expression of P450scc, 3β-HSD, and P450c17.

The postmenopausal ovary is thought to be a source of circulating testosterone, although there may be considerable variation among individuals with respect to androgen output. The circulating levels of testosterone in postmenopausal women are only slightly lower than those observed in premenopausal women. The postmenopausal ovary probably can contribute no more than 20% of the daily production of androstenedione, and multiple lines of evidence indicate that the adrenal glands are the major source of androstenedione in women. Although some authors have concluded that the postmenopausal ovary is a significant site of androgen biosynthesis, others have questioned this idea. Cauley et al.[125] examined hormone levels in postmenopausal women with and without ovaries and observed no statistically significant differences in circulating levels of testosterone or androstenedione between the two groups. Couzinet et al.[126] reported that plasma androgen levels were very low in all postmenopausal women with adrenal insufficiency and were similar between oophorectomized and non-oophorectomized postmenopausal women with normal adrenal function. Reportedly, P450scc mRNA levels were increased 3-fold in the ovarian stroma of postmenopausal women with endometrial cancer or hyperplasia, compared with postmenopausal women without endometrial pathology.[127] Although P450arom mRNA was not detectable in any of the ovaries examined, the same study found P450c17 mRNA expression by Northern analysis in the ovarian stroma of all women with endometrial cancer or hyperplasia, but only in two of the five control postmenopausal women, suggesting a potential to produce androgens in some postmenopausal ovaries. Collectively, these data suggest that the ovarian contribution to circulating androgens is variable among postmenopausal women.

Estrogens in postmenopausal women appear to arise almost exclusively from extra-glandular aromatization of androstenedione.[128] Oophorectomy results in no significant reduction in urinary estrogen excretion by postmenopausal women. However, adrenalectomy after oophorectomy virtually eliminates measurable estrogens from the urine. *In vitro* studies concluded that the postmenopausal ovarian stroma is unable to aromatize androgens. However, others have suggested that the postmenopausal ovary may synthesize limited amounts of estrogens because the concentrations of estradiol and estrone are two times higher in ovarian venous blood than in peripheral blood of postmenopausal women.[129]

There is some evidence that ovarian androgen production in postmenopausal women can be gonadotropin-dependent. Administration of hCG to postmenopausal women results in a small increase in circulating levels of testosterone.[130] Daily injection of hCG causes hyperplasia of the ovarian hilar cells and histochemical evidence suggestive of active steroidogenesis.[131] Administration of hCG, but not adrenocorticotropic hormone, resulted in increased androgen but not estrogen production by the ovaries.[132] Binding sites for both LH and FSH were identified in the cortical stroma and in hilar cells.[133] Addition of hCG to hilar cells results in increased cAMP formation and steroid biosynthesis, indicating preserved responsiveness to gonadotropins. Taken together, these observations suggest that ovarian androgen biosynthesis of the postreproductive ovary is at least partially gonadotropin-dependent.

The postmenopausal ovary is occasionally involved in pathologic endocrine activity. Stromal hyperplasia can occur, with the ovary enlarging with hyperplastic stromal nodules consisting of lipid-rich luteinized cells that resemble theca interna. The ovaries with stromal hyperplasia produce large amounts of androstenedione, resulting in hirsutism and virilization. Hilar cells can give rise to functional hilar cell tumors that produce excess amounts of androgens, leading to virilization.[134] Signs and symptoms of estrogen excess may also be evident in circumstances of significant peripheral aromatization. For instance, the finding of 3-fold higher P450scc mRNA levels in the ovarian stroma of postmenopausal women with endometrial cancer and endometrial hyperplasia suggests that aberrant steroid biosynthetic activity in the postmenopausal ovary might lead to these two disorders known to be associated with excessive estrogen stimulation.[127]

KEY POINTS

- The ovary is an active endocrine organ throughout the life span. Ovarian-derived products have clinincal utility as markers of ovarian function.

CONCLUSION

The ovary is a dynamic endocrine organ with manifold intrinsic and extrinsic actions depending on a complex interplay of signaling through the lifespan. A principal function in production of important cholesterol-derived reproductive hormones under the direction of gonadotropins is well-studied, though the precision with which they are modulated under specific physiologic and pathological states continues to be elucidated. Further work understanding the complex genetic and epigenetic control over ovarian steroid hormone production and within the various ovarian niches will be crucial in the development of the next generation of personalized therapeutics. New complex diagnostics may also arise to allow us to begin to use the timing, mix, and level of ovarian protein and steroid production to evaluate reproductive and general health as well as measuring more complex responses to the environment.

Conclusions, 2016

The steroid hormones estradiol-17β and progesterone serve key roles in female reproductive function and behavior by binding to their cognate receptors in the uterus, ovaries, mammary glands, and brain. In non-pregnant cycling females, estrogens and progesterone produced by the ovaries serve critical roles in endometrial development and its preparation for blastocyst attachment and implantation and mammary gland development and differentiation. Progesterone is the predominant steroid hormone of pregnancy and is required for implantation of the blastocyst and for the maintenance of myometrial (uterine smooth muscle) quiescence. In rodents, the corpus luteum continues to contribute to circulating levels of steroid hormones throughout pregnancy. However, in humans, certain nonhuman primates, and ruminants, the placenta gains the capacity to serve as the main source of estrogens and progesterone sometime during the first trimester and throughout pregnancy.

Estrogen and progesterone actions are primarily mediated by their nuclear receptors, which are members of the ***nuclear receptor (NR) family***, comprising 48 ligand-activated transcription factors in humans that are present in the chromatin of target cells in their activated states.[1,2] Most NR family members are bound by small lipophilic ligands, including steroid hormones, thyroid hormones, the seco-steroid 1,25-dihydroxyvitamin D_3, retinoids, sterols, phospholipids, heme, and fatty acids; however, this receptor family also contains "orphan" members for which no ligand has yet been identified. Members of the NR family can be placed into subgroups based on similarities in structure and the ligands that they bind. The estrogen (ER) and progesterone receptors (PR) belong to the ligand-activated steroid hormone receptor subgroup. The ERs comprise two closely related receptors for estradiol-17β, ERα and ERβ, encoded by the *ESR1* (*NR3A1*) and *ESR2* (*NR3A2*) genes, respectively. The PR consists of two major isoforms, PR-A and PR-B, and two minor splice forms, PR-C and PR-M, resulting from differential transcription initiation from a single *PGR* gene (*NR3C3*). This family also consists of receptors for the glucocorticoids, cortisol and corticosterone (GR, encoded by the *NR3C1* gene); the mineralocorticoids, aldosterone and deoxycorticosterone (DOC) (MR, encoded by the *NR3C2* gene); and the androgens, testosterone and 5α-dihydrotestosterone (AR, encoded by the *NR3C4* gene).

INTERACTION OF STEROID HORMONES WITH TARGET CELLS

Steroids travel in the blood predominantly bound to several classes of serum proteins. Within the circulation, estrogens are bound to sex hormone-binding globulin, which binds estradiol-17β, as well as testosterone, with relatively high affinity ($K_d \sim 10^{-9}$ M). Circulating estrogens also are weakly bound to serum albumin. Progesterone is bound in the circulation to corticosteroid-binding globulin, which also binds circulating glucocorticoids. The majority of circulating estrogen and progesterone is bound to these globulins and is in equilibrium with a relatively small amount of free steroid, which can enter cells. Because of their lipophilic nature, estrogens and progesterone can freely diffuse across plasma and nuclear membranes of all cells but are sequestered only within target cells that contain their specific receptors (Fig. 120.1). In the absence of hormone binding, ER and PR exist primarily in the nucleus as monomers that are associated with a complex of proteins, including two molecules of a 90,000-Dalton phosphoprotein, heat shock protein (hsp) 90, one molecule of hsp70, immunophilins, and a number of other proteins.[3] The hsp complex prevents the monomeric receptors from binding to DNA and folds them in such a way that they have high affinity and specificity for their corresponding hormones. The binding of hormone to its receptor causes a conformational change in the receptor that results in its dissociation from the hsp complex.[3] The hormone-bound receptor monomer then interacts with another hormone-bound

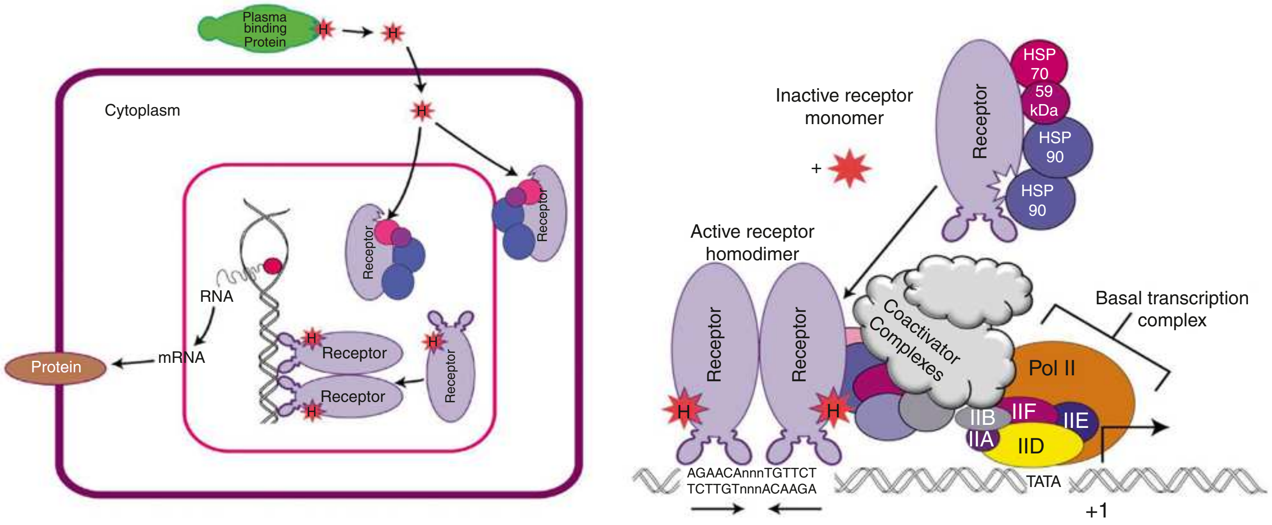

Figure 120.1 Interaction of steroid hormones with their target cells, receptor activation, DNA binding, and recruitment of coregulatory complexes.

receptor monomer to form a homodimer, which has a greatly increased affinity for hormone response elements (HREs) in DNA (see Fig. 120.1). Phosphorylation of the receptor homodimer, either just before or after binding to DNA, likely contributes to the transformation of the receptor dimer to a transcription modulating state.

KEY POINTS

- The estrogen and progesterone receptors are ligand-activated transcription factors that belong to the NR family.

The consensus HREs for ER and PR are inverted repeats/palindromes that can lie near the promoter, or hundreds to thousands to hundreds of thousands of bp upstream. HREs also can lie within the transcribed region, or even downstream of the target gene. The estrogen response element, which specifically binds ERα and ERβ, has the consensus sequence AGGTACnnnTGACCT, where "n" is any nucleotide, whereas the progesterone response element (PRE) has the consensus sequence AGGACAnnnTGTTCT. Notably, the naturally occurring response elements may differ considerably from the consensus sequence. Upon binding to their corresponding response elements in DNA, the ER and PR homodimers recruit a complex of coregulators (see Fig. 120.1). Coregulators do not bind to DNA directly, but rather serve as scaffolds that recruit large protein complexes containing histone modifying enzymes, such as histone acetyltransferases (HATs) or histone methyltransferases. Such histone modifications facilitate the opening of chromatin, making it accessible to additional regulatory proteins and enable recruitment of general transcription factors to form a stable preinitiation complex at the gene promoter. Coactivators and interacting proteins also bridge transcription factors with the basal transcription complex, resulting in further stabilization, recruitment of RNA polymerase II (RNA Pol II) and initiation of gene transcription.

NUCLEAR RECEPTOR STRUCTURE

Through sequencing and x-ray crystallographic studies, great insight has been gained into the structure of members of the NR family and the structural basis for ligand interaction, dimerization, DNA binding, and coactivator interaction.[4] All members of the steroid receptor family have the same modular multidomain structure (Fig. 120.2). The portion of these receptors from the N-terminus to the DNA-binding domain (DBD, **A/B domain**) is the most variable in length and sequence. This region is intrinsically disordered and has not been amenable to x-ray crystallographic analysis. The A/B domain contains an activation function domain (AF-1) that binds coactivators in a ligand-independent manner. It also contains sequences that are posttranslationally modified by phosphorylation. Just downstream of the A/B region is the highly ordered **DBD (Domain C)**, which is the most conserved domain among all members of the NR family, and especially among the steroid receptors. The DBD is composed of ~70 amino acids and contains nine perfectly conserved cysteine residues. This domain contains two repeated units enriched in the amino acids Cys, Lys, and Arg. Each of these units is folded into a finger-like structure containing four cysteines that coordinate a zinc ion (see Fig. 120.2). Amino acids at the base of the more N-terminal Zn-finger within the DBD comprise the "proximal" or P-box, which is critical for DNA sequence recognition by making base-specific contacts with the major groove of DNA. The amino acids at the base on the more C-terminal Zn-finger comprise the "distal" or D-box, which is important for receptor dimerization and recognition of spacing of the two half-sites of the DNA response element. All NRs also contain a flexible "hinge region" (**Domain D**), which lies just C-terminal to the DBD. The hinge region contains a nuclear localization sequence, as well as sites for posttranslational modification. Near the carboxy-terminal end of the receptor molecules is the conserved **ligand-binding domain** (**LBD, Domain E**), composed of largely hydrophobic amino acids. This domain also contains a ligand binding-activated transcription activation domain, termed ***activation function*** **2** (AF-2). The LBD contains 12 α-helices and 4 β-strands that fold to form a ligand-binding pocket that varies

KEY POINTS

- Estrogen and progesterone travel in the circulation largely bound to serum proteins. The small amounts of circulating free steroids can enter cells and specifically bind to their cognate receptors within the nuclei of target cells.
- Upon hormone binding, ER and PR dissociate from a complex of hsps and bind to their HREs in DNA as homodimers.
- Once bound to DNA, ER and PR homodimers recruit a complex of coregulators that contain histone-modifying activities, which relax the chromatin structure to allow assembly of a basal transcription complex and of RNA Pol II to catalyze transcription initiation (see Fig. 120.1).

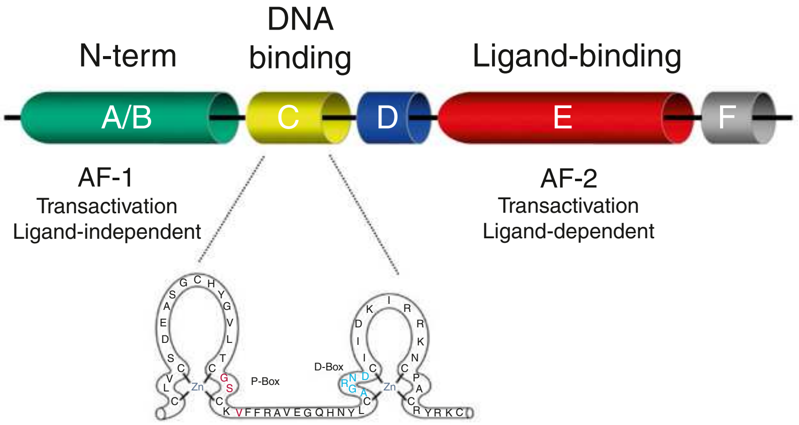

Figure 120.2 Functional domains of steroid hormone receptors, with focus on the transcription activation domains, the highly conserved DNA-binding domain and the amino acids that contribute to receptor recognition of the hormone response elements and to the two Zn-finger structures.

greatly in size among NR family members to accommodate their specific ligands. Upon ligand binding, the position of Helix-12 (H12) within the AF-2 domain is dynamically altered to provide a binding surface for coactivator molecules via their LXXLL motifs, contributing to transcriptional activation. The LBD also contains sequences for interaction with hsp90. C-terminal to the LBD is the **F domain**, which is present only in ERα and ERβ (see Fig. 120.2). The F domain of ERα appears to serve a role in transcriptional activation, coactivator interactions, dimerization, and receptor stability.

KEY POINTS

- All members of the steroid receptor family have the same modular multi-domain structure (see Fig. 120.2).
- The most highly conserved domain is the DBD (Domain C), which contains two repeated units enriched in the amino acids Cys, Lys, and Arg. Each of these units is folded into a finger-like structure containing four cysteines that coordinate a zinc ion.
- In general, there are two transcription activation domains (AF-1 and AF-2). AF-1, near the N-terminus, participates in transcriptional activation in the absence of hormone binding. AF-2, within the LBD, activates transcriptional activity in a ligand-dependent manner. PR-B contains an addition AF domain (AF-3) near its extended amino terminus.

COACTIVATORS AND COREPRESSORS

Receptors for estrogen and progesterone and other members of the NR family undergo conformational changes upon binding their respective ligands but do not have the capacity to activate or inhibit transcription in and of themselves. Rather, upon hormone binding and dimerization, the receptors bind to their HREs in DNA and recruit scaffolding proteins, termed coactivators and corepressors, with histone-modifying activities that alter the transcriptional activities of specific genes. Since the original characterization of the first steroid receptor coactivator, SRC-1, 25 years ago,[5] >400 coregulators have been isolated and characterized.[6] Based on function, coregulators can be grouped into two major categories: ***coactivators***, which associate with agonist-bound NRs to upregulate gene expression, and ***corepressors***, which selectively repress gene expression through interaction either with unliganded or antagonist-bound NRs.

Coactivators

Within the eukaryotic nucleus, DNA is tightly packaged in chromatin as a repeating array of nucleosomes and as higher-order structures, comprising condensed chromatin.[7,8] Nucleosomes consist of ~146 bp of DNA wound around a histone octamer, containing two copies of the histone proteins H2A, H2B, H3, and H4. The favorable electrostatic interactions between the negatively charged phosphodiester backbone of DNA and positively charged lysines and arginines in the histone tails contribute to chromatin condensation, which is generally repressive to transcription.[9] While steroid hormone receptors can bind to their response elements within nucleosomal DNA,[7] the surrounding genomic regions are unavailable for binding and assembly of the transcriptional machinery required for transcription activation. This requires the recruitment of coactivators with histone-modifying activities and of ATP-dependent remodeling complexes.

A cDNA encoding the first NR coactivator to be identified and characterized, steroid receptor coactivator 1 (SRC-1), was isolated from a yeast two-hybrid system using the LBD and hinge region of the human PR as bait.[5] Transient transfection assays in mammalian cells indicated that SRC-1 activation of PR transcriptional activity was agonist-dependent and required agonist-bound PR binding to its cognate DNA response element. Moreover, SRC-1 was found to mediate transcriptional activation by other members of the steroid receptor family bound to their respective ligands and response elements. Furthermore, ligand-dependent transcriptional activation of ERα was observed to be dependent upon the interaction of key hydrophobic residues within H12 of ERα with short sequences within SRC-1 containing the amino acids LXXLL (where L = leucine and X = any amino acid).[10] It was proposed that LXXLL motifs were required for interaction of a number of different coactivator proteins with NRs.[10]

SRC-1 is one of three members of the p160 coactivator family, which also includes SRC-2/TIF-2 and SRC-3/AIB1. Although the p160 coactivators interact with a variety of other transcription factors, their actions are strongly tied to steroid receptor activation and are closely linked to reproductive function.[11] Studies using knockout mice indicate that although structurally similar, each SRC family member has specific physiological functions.[12] For example, although *SRC-1*$^{-/-}$ mice were found to be fertile, females manifested reduced estrogen-stimulated uterine growth, and a decreased progesterone-dependent uterine decidual response.[13] Female *SRC-2*$^{-/-}$ mice displayed placental hypoplasia and hypofertility,[14] as well as an impaired decidual response, further exacerbated by the combined deficiency of SRC-1.[15] *SRC-2*$^{-/-}$ male mice manifested infertility due to defects in spermatogenesis.[16] Notably, mice that were double KO for *Src-1* and *Src-2* died at birth of respiratory distress,[17] suggesting a deficiency of pulmonary surfactant production. Female *Src-1*$^{+/-}$/*Src-2*$^{+/-}$ crossed with genetically like males manifested remarkably delayed parturition,

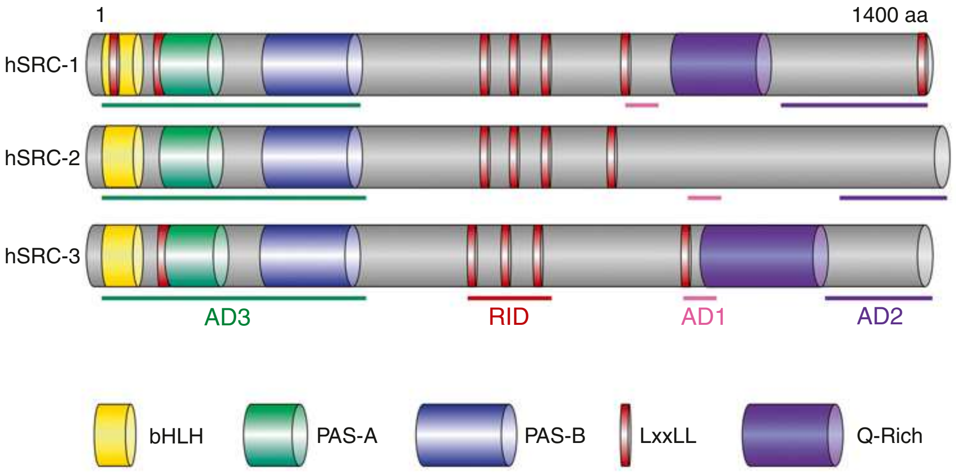

Figure 120.3 Steroid receptor coactivator (SRC) family members, SRC-1, SRC-2, and SRC-3, serve as modular scaffolds for binding of transcription factors, such as steroid receptors, and other coregulators with histone-modifying activities. For abbreviations, see text.

associated with decreased myometrial nuclear factor-κB (NF-κB) activation and contractile gene expression (i.e., connexin 43 [CX43] and oxytocin receptor), impaired luteolysis, and a failure of circulating progesterone levels to decline at term.[18] Interestingly, WT females bred to *Src-1/-2* double-deficient males exhibited similarly delayed parturition, molecular and hormonal changes, indicating that the defect causing delayed labor was fetal in origin.[18] In this regard, lungs of *Src-1/-2* double-deficient fetuses exhibited markedly decreased expression of surfactant protein-A (SP-A) and lysophosphatidylcholine acyltransferase-1, a key enzyme for synthesis of surfactant dipalmitoylphosphatidyl choline (a highly surface-active glycerophospholipid) and platelet-activating factor (PAF), a proinflammatory glycerophospholipid.[18] The effects of *Src-1/-2* double-deficiency in the fetal lung were mediated by impaired glucocorticoid and cytokine signaling through glucocorticoid receptor (GR) and CCAAT enhancer-binding protein transcription factors.[18,19] These findings reveal that fetal lungs when mature produce SP-A and PAF signals to initiate labor; moreover, SRC-1 and SRC-2 coactivators serve crucial roles in the regulation of these fetal parturition signals. SRC-3, which is amplified in breast and ovarian cancer,[20] serves as a key modulator in the upregulation of ERα transcriptional activity.[21] SRC-3 levels also are elevated in endometrial hyperplasia and adenocarcinoma; high expression levels were correlated with poor prognosis.[22]

As mentioned, SRC family members serve as modular scaffolds for binding of transcription factors, such as steroid receptors, which bind to three LXXLL motifs in the receptor interaction domain (RID) within the central regions of the SRCs (Fig. 120.3). SRCs also interact with other transcription factors, including NF-κB, which binds to the C-terminal activation domain 1 (AD1), and with members of the signal transducer and activator of transcription (STAT) family and tumor protein P53 (TP53), which bind to the N-terminal basic helix-loop-helix-Per-Arnt-Sim (bHLH-PAS) domain (AD3) (see Fig. 120.3). Although bHLH-PAS domains present in a variety of transcription factors are known to bind to DNA, SRC family members have no apparent DNA-binding ability. Rather, SRCs also serve as scaffolds for recruitment and binding to other coregulators. For example, the AD1 domain binds to other SRCs and to the HATs, p300 and CREB-binding protein (CBP), which catalyze acetylation of lysine residues in the N-terminal tails of nucleosomal histones. As mentioned, electrostatic interactions between the negatively charged phosphodiester backbone of DNA and positively charged lysines and arginines in the histone tails contributes to chromatin condensation. Coactivator-mediated acetylation and or methylation of these lysine and arginine residues, respectively, results in a neutralization of these interactions and a relaxation and "opening" of chromatin structure.

SRC-1 and SRC-3 also have intrinsic HAT activity, whereas SRC-2 does not.[11,23] The region of SRC-1 that contains HAT activity also binds the HAT, p300/CBP-associated factor (PCAF). The subsequent acetylation of key lysine residues in positively charged histones and relaxation of chromatin structure facilitates the binding of other transcription factors and coregulatory complexes, and assembly of the RNA Pol II transcription machinery to promote transcriptional activation of specific genes, as described above. Notably, p300/CBP also catalyze acetylation of lysine residues on non-histone proteins, which include a variety of transcription factors. For example, acetylation of lysine residues within the ERα hinge region,[24] as well as NF-κB, STAT3, and TP53,[25] increase their DNA-binding and/or transcriptional activity.[25] The AD1 domains of SRCs also bind the coactivator-associated arginine methyltransferase-1 (CARM1/PRMT4) and PRMT1,[26] which methylate histones on arginine residues to promote recruitment of p300/CBP and increase target gene transcription.

KEY POINTS

- Coregulators comprise ***coactivators***, which associate with agonist-bound NRs to upregulate gene expression, and ***corepressors***, which selectively repress gene expression through interaction either with unliganded or antagonist-bound NRs.
- Coactivators and corepressors do not bind to DNA directly; rather, they are recruited to ligand-bound dimeric ER or PR and other transcription factors bound to DNA. Once bound, coregulators can posttranslationally modify histones to relax or condense chromatin structure, act as modular scaffolds (see Fig. 120.3) to recruit other coregulators containing histone-modifying activities, and bridge to members of the basal transcription complex at gene promoters.
- Activated NRs bound to their HREs also can recruit ATP-dependent DNA remodeling complexes that directly break histone–DNA contacts via energy generated by ATP hydrolysis to allow repositioning of nucleosomes.
- The p160 family of coactivators (SRC-1, SRC-2, and SRC-3) are strongly associated with steroid receptor activation and closely linked to reproductive and developmental biology (including fertility, fetal lung development, and the initiation of parturition) and cancer.

While the histone modifications catalyzed by various coactivators recruited by steroid receptors contribute to activation of gene expression, they do not substantially affect the core particle structure of nucleosomes. However, the modification of nucleosomal histones often precedes the binding of large, multisubunit ATP-dependent remodeling complexes (e.g., SWI/SNF) that directly break histone–DNA contacts via energy generated by ATP hydrolysis. This, in turn, allows the sliding and repositioning of nucleosomes.[27] BRG1 comprises the central ATPase of SWI/SNF and other ATP-dependent remodeling complexes. BRG1 and associated factors have the capacity to directly bind to steroid hormone receptors. In studies of glucocorticoid activation of the mouse mammary tumor virus promoter, it was observed that after glucocorticoid binding to the GR and recruitment of histone-modifying coactivators, SWI/SNF is recruited to the promoter through an interaction of BRG1 with GR. This results in the ATP-dependent repositioning of nucleosomes allowing recruitment of Mediator proteins and assembly of the preinitiation complex with RNA Pol II binding and transcription initiation.[27]

Corepressors

Unlike the steroid hormone receptors, NRs for retinoic acid and thyroid hormone are bound to HREs within the regulatory regions of their target genes in the absence of hormone binding. As such, the unliganded receptors recruit the corepressors, nuclear receptor corepressor (NCoR) and silencing mediator of retinoic acid and thyroid hormone receptors (SMRT) to repress target gene expression. NCoR and SMRT, in turn, serve as docking platforms for enzymes that maintain chromatin in a "closed" repressed state.[28,29] In the case of NCoR and SMRT, a motif called the corepressor nuclear receptor (CoRNR) box, interacts with a hydrophobic groove that is exposed within the unliganded receptor. The predominant histone-modifying enzyme associated with NCoR and SMRT is histone deacetylase 3 (HDAC3), which catalyzes histone deacetylation. This maintains electrostatic interactions between the positively charged core histones and negatively charged nucleosomal DNA, resulting in a repressed higher-order chromatin structure. Upon hormone binding, a conformational change in the receptor causes the corepressor complex to dissociate and be replaced by a complex of coactivators, which interacts with the receptor through an LXXLL motif, and catalyzes histone acetylation or other posttranslational modifications that result in an opening of chromatin structure, as described above.

With regard to ER and PR, NCoR and SMRT are recruited to ERα and PR *in vivo* when they are bound to antagonists or tissue-selective estrogen receptor modulators (SERMs). Tamoxifen, a SERM, antagonizes estrogen action in the mammary gland, but serves as an agonist in the uterus. Tamoxifen treatment of MCF-7 human breast cancer cells was found to cause rapid recruitment of endogenous ERα to estrogen-responsive regions of the estrogen target genes *pS2* and *c-Myc*.[30] This occurred with recruitment of NCoR complexes containing HDAC3 and was temporally associated with deacetylation of the N-terminal tails of histones H3 and H4 and dissociation of RNA Pol II from the *pS2* and *c-Myc* promoters, contributing to the inhibition of gene expression.[30] Mifepristone, also known as RU486, has partial agonist/antagonist activity for PR and GR. Like progesterone itself, RU486 binds to PR with high affinity, promotes PR dissociation from the complex of hsps, dimerization, and binding to its HREs in DNA. However, modeling of the PR LBD crystal structure bound to RU486 suggested that H12 is displaced in a conformation that blocks coactivator binding to the AF2 domain.[31,32] While NCoR does not interact with agonist-bound PR, it has high affinity for PR bound to RU486, both *in vitro* and *in vivo*. Thus, both NCoR and SMRT bind preferentially to antagonist-bound, compared with agonist-bound, ER and PR. Moreover, overexpression of these corepressors antagonizes the partial agonist activities of SERMs like tamoxifen and of RU486 bound to ERα and PR, respectively. It has been suggested that cell-specific concentrations of corepressors may help to determine whether tamoxifen or RU486 acts as an agonist or an antagonist of receptor-mediated gene transcription.[33]

Glucocorticoids exert anti-inflammatory actions, in part, via tethering to the Jun subunit of AP-1 or to NF-κB transcription factors bound to the promoters of genes encoding proinflammatory cytokines. In lieu of recruitment of the NCoR and SMRT corepressor complexes, as described above, glucocorticoid receptor (GR)-mediated suppression of AP-1 or NF-κB transcriptional activity requires the recruitment of SRC-2/Glucocorticoid receptor-interacting protein 1, GRIP1.[34] Accordingly, conditional GRIP1-deficient mice manifested increased circulating levels of proinflammatory cytokines, TNFα, IL-1β, and IFNγ in response to a lipopolysaccharide (LPS) challenge. As previously described, SRC-2 has been characterized as NR coactivator; however, the mechanisms for its role in corepression are unclear and may depend upon the target gene and its transcriptional state.[35]

Progesterone/PR also has anti-inflammatory actions and is believed to promote myometrial quiescence during pregnancy by inhibiting the expression of proinflammatory (e.g., *IL-8* and *COX-2*) and contractile genes, including *CX43*/*GJA1* and the oxytocin receptor (*OXTR*).[36,37] This occurs, in part, via the tethering of PR to AP-1[38] and to NF-κB[36] transcription factors bound to the promoters of *CX43* and *OXTR* genes, and is associated with progesterone/PR-mediated recruitment of corepressors p54Nrb[38] and GATAD2B,[36] respectively. Interestingly, GATAD2B, which is known to interact with the repressive nucleosome remodeling and deacetylase (NuRD) complex,[39] was observed to decline in the myometrium of women in labor and in the pregnant mouse myometrium during late gestation and in labor. The corepressor p54nrb, which binds to PR tethered to AP-1 bound to the *CX43* promoter and recruits the multiprotein repressive Sin3A complex containing HDAC1 and HDAC2, declines markedly in pregnant rat myometrium toward term.[38]

MECHANISMS OF ESTROGEN ACTION

Estrogen actions are predominately mediated via the binding of estradiol-17β (E_2) to two closely related members of the NR family, ERα (ESR1)[40] and ERβ (ESR2),[41] which are encoded by separate genes. ERβ shares ~84% homology with ERα in its DBD but only 58% homology in its LBD and lesser amounts of similarity in its other domains. These structural differences are reflected in different binding affinities of ERα and ERβ for various estrogenic steroids and non-steroidal molecules.

Estrogen Receptor Ligands

As mentioned, estrogens are synthesized in the ovaries of cycling mammals and in the placentas of humans, certain nonhuman primates, and ruminants during pregnancy. Estrogens also are synthesized in the hypothalamus, amygdala, and hippocampus of the brain, in the Leydig and Sertoli cells of the testis, in bone, and adipose tissues of humans, and in endometriosis and adenomyosis lesions (see Chapters 125, 126). The key enzyme in estrogen biosynthesis is aromatase (encoded by the *CYP19A1* gene),[42,43] which converts C_{19}-androgens (e.g., testost erone, androstenedione, dehydroepiandrosterone) to C_{18}-estrogens (e.g., estradiol-17β (E_2), estrone (E_1), estriol (E_3)). In most tissues, the androgen substrate is synthesized in tissues and cells distal to the site of aromatization. For example, in the ovary, estrogens are synthesized in the granulosa cells of preovulatory follicles from androstenedione and testosterone produced by cells of the theca interna and ovarian stroma. In the placenta, estrogens are synthesized from circulating 16α-OH-dehydroepi androsterone synthesized by the fetal adrenal. In adipose tissue, estrogens are synthesized by aromatization of circulating androstenedione secreted by the adrenal cortex.[44] Estetrol (E_4) is a relatively weak estrogen synthesized from estradiol and estriol exclusively by the fetal liver during pregnancy.[45] Its function during pregnancy is essentially unknown.

KEY POINTS

- The corepressors NCoR and SMRT interact with unliganded thyroid hormone receptor and retinoic acid receptor bound to their HREs in DNA and recruit HDAC3 to deacetylate histones and promote chromatin condensation.
- These corepressors also bind to antagonist-bound ER and PR to promote chromatin condensation, as above.

The four naturally occurring estrogens, estradiol-17β (E_2, E_1, E_3, and E_4, are 18-carbon steroids with a phenolic A ring. E_2 binds with similarly high affinities to ERα and ERβ. E_2 binds to ERα with a ~25-fold higher affinity than does E_1, and a ~9-fold higher affinity than does E_3.[46] While the relative binding affinities of E_1 for ERα and ERβ are comparable, E_3 has a relatively higher binding affinity for ERβ than for ERα.[46] E_4 binds preferentially to ERα, compared with ERβ, and binds to ERα with a 4-fold lower affinity than does E_2.[45] The plant sterols/phytoestrogens, genistein, coumestrol, and daidzein, and commercially available diarylpropionitrile (DPN) have a considerably higher binding affinity for ERβ than for ERα. On the other hand, 4-propyl-1,3,5-tris (4-hydroxyphenyl) pyrazole (PPT) is highly selective for ERα and has no transactivation potential for ERβ when tested in intact cells.[46]

KEY POINTS

- Estrogen actions are primarily mediated by two members of the NR family, ERα and ERβ.
- The three naturally occurring estrogens—E_2, E_1, and E_3—are synthesized by aromatization of C_{19}-steroid androgens.
- E_2 binds with much higher affinity to ERα and ERβ than do E_1 and E_3. ERβ binds E_3 and plant sterols with relatively high binding affinity compared with ERα.

Estrogen Receptor Structure

Because of intrinsically disordered regions within the N-terminal A/B domain and the hinge region (D domain), the full-length ERα and ERβ have not been amenable to structural studies by x-ray crystallography. Instead, co-crystals of the ERα-DBD bound to an ERE, as well as ERα-LBD bound to estradiol-17β, or to other agonists and antagonists have been analyzed. Combined data from x-ray crystallography, biochemical, biophysical, and cell-based studies have provided important insight into structure-function relationships of ERα. As is the case for other steroid receptors, the LBD of ERα comprises 12 α-helices (H1–H12). In the absence of hormone binding, the LBD of the ERα monomer is partially disordered and bound by hsp90 and other immunophilins, as described above. Upon E_2 binding, the hsps dissociate, ERα dimerizes and is stabilized in a conformation in which H12 folds over the ligand-binding pocket to form an active AF2 conformation, comprising a hydrophobic groove into which coactivators can bind. By contrast, when an SERM, such as tamoxifen, binds to the LBD, the tamoxifen side chain prevents H12 from forming an active AF2 conformation. Thus, H12 docks in the AF2 hydrophobic coactivator-binding groove and blocks coactivator binding. Notably, while tamoxifen can act as an ERα antagonist in the breast, it has ERα agonist activity in the uterus, liver, and bone. This has led to the concept that the cellular environment plays an important role in determining whether an SERM acts as an ER agonist or antagonist.[47]

ERα plays a major role in the growth and pathogenesis of human breast cancer. In estrogen-dependent breast cancer, treatment with SERMs, such as tamoxifen, and with aromatase inhibitors has proved efficacious in enhancing survival; however, treatment resistance frequently develops. In fact, with prolonged treatment, tamoxifen action can be switched from that of an antagonist to that of an agonist.[47] This may be due to alterations in the cellular environment. In ~40% of recurrent ERα-positive breast cancers, mutations in the LBD have been detected, resulting in a constitutively active state of ERα in the absence of agonist binding and a loss of responsiveness to ERα SERMS and antagonists or aromatase inhibitor therapy. Structural analyses of wild-type (WT) versus various mutant forms of ERα have provided important insight into the mechanisms of estrogen-dependent activation of WT ERα and for the constitutive activation of the mutant receptor. The most highly constitutively active forms of ERα harbor mutations in tyrosine-537 (e.g., Y537S) within the loop between H11 and H12; this prevents the receptor from adopting an "off" state in the absence of ligand. When WT ERα binds agonist ligand, H12 bends over the ligand-binding pocket to expose the coactivator-binding groove. This creates a spring-like strain within the loop that enables it to snap back into the inactive conformation in the absence of bound ligand. The Y537S mutation markedly alters the spring-like properties of the H11-H12 loop, keeping H12 in the agonist-bound conformation in the absence of estrogen binding. The effects of various mutations within the ERα LBD resulting in various degrees of constitutive activation are described in great detail by Katzenellenbogen et al.[48]

KEY POINTS

- As is the case for other steroid receptors, the LBD of ERα comprises 12 α-helices (H1–H12).
- Upon E_2 binding, ERα dimerizes and H12 folds over the ligand-binding pocket to form a hydrophobic groove into which coactivators can bind.
- By contrast, when a SERM such as tamoxifen binds, the tamoxifen side chain prevents H12 from forming an active AF2 conformation and coactivator binding is blocked.
- In a significant proportion of ERα-positive breast cancers, there are mutations in the loop between H11 and H12 that keep the receptor in an active conformation in the absence of ligand.
- Tamoxifen acts as an ERα antagonist in the breast, but has ERα agonist activity in the uterus, liver, and bone, suggesting that the cellular environment plays a role in determining its action as an ER agonist or antagonist.

Estrogen Receptor-Coactivator Interactions

Because of multiple intrinsically disordered regions within full-length NRs and coregulators, it has not been possible to solve the x-ray crystal structure of full-length NRs bound to full-length primary (e.g., SRCs) and secondary (e.g., p300/CBP) coregulators. Using the powerful technique of cryo-electron microscopy (cryo-EM) together with biochemical studies, Chiu, O'Malley and colleagues revealed the quaternary structure of full-length ERα bound to a 700-bp ERE in a complex with SRC-3 and p300.[49] Their intriguing findings indicate that ERα binds to the ERE as a dimer, with each molecule of ERα recruiting one molecule of SRC-3 to its AF-2 domain (Fig. 120.4)[162]. Interestingly, the AF-1 domain near the ERα N-terminus aligns in the structure in proximity with the C-terminal ERα AF-2 domain and participates in SRC-3 recruitment, providing support for prior biochemical findings suggesting that transcriptional activation of ERα is facilitated by interaction of N- and C-terminal domains of ERα.[50] Both molecules of SRC-3, in turn, act together to recruit a single molecule of p300. The p300 did not interact directly with ERα or with DNA in the cryo-EM structure.[49] The p300 in the complex exhibited conformational variability which may contribute to its ability to interact with other coregulators.[49] In this regard, subsequent cryo-EM studies by this group revealed that there is a sequential interaction of ER and different primary (SRC-3) and secondary (p300 and CARM1) coactivators at the ERE in DNA. Prior studies indicated that the arginine methyltransferase, CARM1,[51] acted synergistically with p300/CBP to enhance ER-mediated gene transcription.[52] The cryo-EM and associated biochemical studies indicated that following the binding of the ERα dimer to DNA, there is binding of two molecules of SRC-3 and p300, as

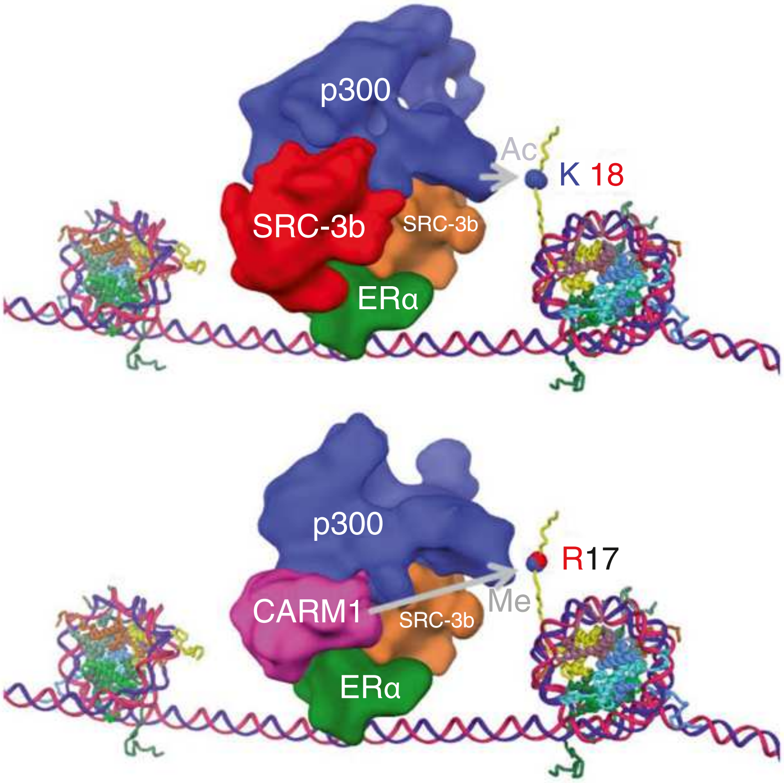

Figure 120.4 **Cryo-electron microscopy structure of ERα-coactivator interactions.** Shown is the quaternary structure of full-length ERα bound to a 700-bp estrogen response element in a complex with SRC-3, p300, and CARM1. The sequential interaction of the hormone response element-bound ERα dimer with SRC-3, p300, and CARM1 is described.[53] (From Yi P, Wang Z, Feng Q, et al. Structure of a biologically active estrogen receptor-coactivator complex on DNA. *Mol Cell.* 2015;57:1047–1058.)

reported previously.[49] Upon binding of p300, interaction of the second molecule of SRC-3 is destabilized and replaced by the binding of CARM1 (see Fig. 120.4), which now has access to methylation sites in ERα, SRC-3, and p300.[53] This causes a conformational change in p300 with further induction of its HAT activity and a cooperative increase in the histone H3 methyltransferase activity of CARM1. Thus, the cooperative interaction of sequentially recruited primary and secondary coactivators to the ERα dimer bound to DNA contributes to estrogen activation of gene expression.[53]

Molecular Mechanisms of Estrogen Receptor Action

In addition to its genomic effects, described directly below, estrogen also has rapid and acute effects on cells that appear to be mediated by a number of alternative signaling pathways. These pathways can be activated by E_2 (***ligand-dependent***) or by other signaling mechanisms within the cell (***ligand-independent***) (Fig. 120.5).

Genomic Actions by Direct ER Binding to EREs in DNA. The nuclear forms of ERα and ERβ mediate genomic actions of estrogens to alter transcription of specific genes. As mentioned, the binding of E_2 to ERα or ERβ promotes its dissociation from a complex of hsps and binding of the ER homodimer to EREs, which can be localized from hundreds to hundreds of thousands of bp upstream of their target genes. In ChIP-microarray studies of ERα binding to chromosomes 21 and 22 in the MCF-7 human breast cancer cell line, it was observed that while a relatively small number of functional EREs were localized proximal to the promoters of their target genes, the majority existed hundreds of thousands of base pairs away.[54] Importantly, binding motifs for the Forkhead protein FoxA1 were found proximal to a large proportion of the ER binding regions that contained a canonical ERE. Notably, FOXA1 was found to serve an essential role in the interactions of ERα with chromatin and the subsequent expression of estrogen target genes.[54] Thus, FOXA1, which can bind to condensed chromatin via its winged-helix structure, allows the local opening of chromatin structure to facilitate ER binding to its response elements in DNA. Moreover, chromosome capture assays indicated that estrogen-mediated gene transcription was associated with physical interaction of these distal EREs with the promoters of the estrogen-regulated genes.[54]

KEY POINTS

- Because of several intrinsically disordered domains, the structure of ER and other members of the NR family have not been solvable by x-ray crystallography.
- Instead, cryo-EM has been used to solve the quaternary structure of ERα bound to its HRE in DNA, in association with SRC-3, CBP, and CARM1.
- This confirms that ERα binds to its HRE as a homodimer, and that the AF-1 and AF-2 domains participate in recruitment of one molecule of SRC-3 each, which in turn together, recruit p300.
- One molecule of SRC-3 is then destabilized and replaced by coactivator CARM1 (see Fig. 120.4).

As described above, the binding of ER to its response elements is followed in time by the recruitment of primary and secondary coactivators, which posttranslationally modify histones to cause a further opening of chromatin structure to facilitate the binding of ATP-dependent remodeling complexes to break histone-DNA contacts, allowing repositioning of nucleosomes and assembly of the general transcription machinery and RNA Pol II, resulting in transcription initiation.

Genomic Actions by ER Tethering to Other Transcription Factors Bound to DNA. Ligand-dependent alternative mechanisms include the E_2-induced tethering of ERα or ERβ to other transcription factors bound

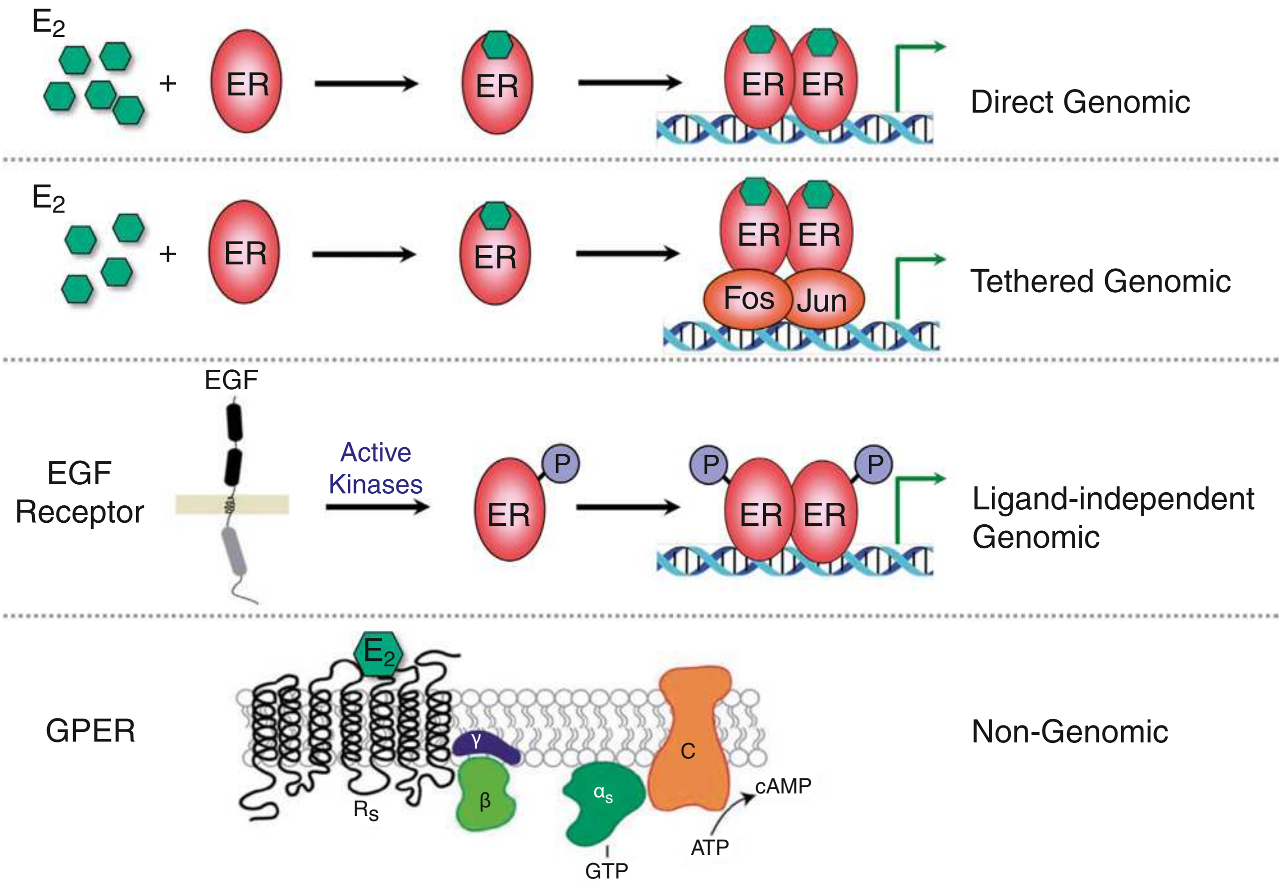

Figure 120.5 Molecular pathways in estrogen receptor action. These actions include direct binding of ER homodimers to DNA and tethering to Sp1 or AP-1 transcription factors bound to DNA, ligand-independent activation of ER bound to HREs in response to growth factor-mediated phosphorylation and rapid non-genomic effects.

to their response elements in DNA, as has also been described for GR and PR (see Fig. 120.5). These include ERα tethering to specificity protein 1 (Sp1) bound to G/C-rich response elements, as well as ERα or ERβ interaction with Fos/Jun bound to AP-1 response elements. Sp1 is required for E_2 regulation of many genes involved in cell proliferation, differentiation, and angiogenesis in cancer cell lines.[55] Genes found to be E_2-responsive via the interaction of ERα with Sp1 bound to GC-rich sites include: *ESR1*, *PGR*, *PRLR*, *EGFR*, *IGF1R*, *HOXA10*, *cMYC*, *cathepsin D*, and *telomerase*, to name a few.[55,56] Notably, transcription of these genes is activated both by binding of E_2 or ER antagonists. ERα binding to Sp1 was found to increase the stability of Sp1-DNA interactions. Whereas ERα can interact with Sp1 in a ligand-independent manner, enhanced transcription of target genes is driven by coactivator recruitment, which is E_2-dependent. Notably, in cancer cell lines expressing ERβ, E_2 did not activate promoters driven by ERβ-Sp1 interactions. From domain-swapping experiments, it appeared that the AF-1 domain of ERα was critical for E_2-dependent transactivation, whereas the corresponding AF-1 domain of ERβ was inactive.[57]

Both ERα and ERβ can tether to Fos/Jun bound to AP-1 sites in the promoters of a number of genes involved in cell growth, motility, and differentiation, including *MMP1*, *FN1*, *cyclin D1*, and *IGFBP4*. Recruitment of ERα to AP-1 bound to gene promoters stabilized the binding of p160 coactivators and p300 to the complex.[58] Gene activation by ERα tethered to AP-1 was stimulated both by E_2 and by antiestrogens. In the case of *cyclin D* promoter, wherein E_2 binding to ERα tethered to AP-1 had a stimulatory effect, E_2 bound to ERβ was inhibitory.[59] In contrast to findings of ER/Sp1 interactions, wherein ERβ was relatively inactive, in the case of ER/AP-1, antiestrogens enhanced ERβ-AP-1 transcriptional activation, whereas E_2 had little effect.[55]

Ligand-Independent ER Activation. ERs can be activated in a ligand-independent manner via phosphorylation mediated by a number of signaling cascades (see Fig. 120.5). For example, EGF was one of the first growth factors found to enhance ERα transcriptional activity in an E_2-independent manner.[60] As opposed to E_2 activation of ERα, which occurs via the AF-2 domain, EGF signaling activates ERα through its AF-1 domain. EGF induces phosphorylation of specific serine residues of ERα and ERβ by activation of MAPK and protein kinase B (Akt). ER phosphorylation may enhance recruitment of p160 coactivators. Insulin-like growth factor 1 (IGF-1) also causes ligand-independent activation of ERα through Akt signaling. As reviewed in detail previously, ligand-independent ER activation occurs in response to a variety of growth factor receptors, cytokines, second messenger pathways, and kinases.[60]

Non-Genomic Signaling. Rapid effects of E_2 also can be mediated by non-genomic signaling, whereby E_2 can bind to ER that is associated with the plasma membrane through interaction with other membrane proteins (e.g., caveolin-1, Shc, and insulin-like growth factor receptor)[61] and/or via lipid modification of ER by palmitoylation.[62] Rapid non-genomic estrogen effects also may be mediated by a G protein-coupled receptor, termed G protein-coupled ER1

(GPER1), also known as GPR30, which is coupled to $G_s\alpha$ in the plasma membrane (see Fig. 120.5).[63] E_2 binding to GPER1 is associated with rapid activation of intracellular signaling pathways, such as adenylyl cyclase, AKT, and MAPK. Notably, the SERM 4-OH tamoxifen and the selective estrogen receptor downregulator (SERD) ICI182,780 also act as agonists of GPER1.[64] Rapid non-genomic effects of E_2 appear to serve functional roles in the brain, testes, and cardiovascular system.

KEY POINTS

- E_2 has genomic and non-genomic actions (see Fig. 120.5).
- Genomic actions include: (1) direct binding of ER homodimers to HREs, recruitment of coactivators, posttranslational modifications of histones and relaxation of chromatin structure; (2) Tethering of ER to other transcription factors (e.g., Sp1, AP-1) bound to response elements in DNA, with recruitment of coactivators and modification of histones.
- Ligand-independent activation of ER bound to HREs is induced by growth factor and cytokine signaling.
- Rapid, non-genomic actions are mediated by E_2 binding to ER associated with the plasma membrane, or with GPER1.

Use of Gene-Targeted Mice To Ascertain the Biology of Estrogen Receptor Function

Genetically engineered mice have been used extensively to investigate the role of ERα and ERβ in the regulation of mammalian physiology *in vivo*. Not only has this approach been used to dissect the function of the ERs in the regulation of tissue homeostasis, but also to dissect the functional role of the domains of the ERs (reviewed in Hamilton et al.[65]). The ablation and mutagenesis of ERα and ERβ resulting in the αERKO and βERKO mouse, respectively, have revealed both distinct and overlapping functions in animal physiology. The phenotypes of the individual and combined ablations of ERα and ERβ are discussed below.

Phenotype of the αERKO Mouse. The phenotypic analysis of the αERKO mouse revealed both predictable and surprising results. As expected, the αERKO female mice were sterile. Although female reproductive tract development was normal, the females displayed failure to mate, hypoplastic uteri, hyperemic ovaries with failure to undergo natural ovulation, no detectable corpora lutea and rudimentary mammary gland development.[66–68] The uteri and vaginas were not responsive to estrogen stimulation with no increase in uterine weight and no vaginal cornification. The impact of ERα ablation on ovulation was due to a combination of the disruption of the hypophyseal-ovarian axis, as well as a direct effect on the ovary.[69] Surprisingly, αERKO males were sterile. The male sterility was not due to a direct role of ERα in spermatogenesis, but due to an impairment of fluid resorption in the rete testis that indirectly reduced spermatogenesis with time.[70] Phenotypes of the αERKO mouse have been seen in humans with familial mutations in ERα.[71,72] In addition to investigating the role of ERα in the reproductive system, the αERKO mouse has been used to investigate its role in the skeletal system, cardiovascular system, and metabolism (reviewed in Hewitt et al.[73]).

Phenotype of Mice With Tissue-Specific Ablation of ERα. The global knockout models for ERα action have defined the role of the loss of estrogen responsiveness in the whole animal. Since estrogen impacts many organ systems in the hypothalamo-hypophyseal-gonadal-uterine axis, some of the phenotypes of ERα ablation on specific target organs are confounded by indirect endocrine effects. Conditional ablation of the ERα has been used to shed light on the role of ERα not only in a specific tissue but also within compartments of that tissue. Mice lacking ERα in the pituitary gonadotrophs have impaired fertility. These mice displayed higher serum levels of luteinizing hormone (LH) but lacked the LH surge required for ovulation. This demonstrated that ERα regulation of the control of gonadotropin feedback is in part dependent on ERα in the pituitary.[74] Ablation of ERα in the mammary epithelium demonstrated that ERα regulated the establishment of the mammary gland architecture and lobuloalveolar gland development[75] (see Chapter 127). Conditional ablation of ERα in the skeletal system demonstrated that ERα is critical for the maintenance of bone mass.[76] Liver-specific ablation of ERα demonstrated that ERα plays a key role in hepatic gluconeogenesis and lipid accumulation in the liver.[77] However, the most in-depth investigation of ERα has been on the role of ERα in the regulation of female reproductive tract function.

The female reproductive tract serves as a conduit for gamete transport to the site of fertilization in the oviduct and the subsequent preparation of the uterine tissue for implantation and fetal development. Prior to embryo implantation, the uterus undergoes specific changes that allow the embryo to attach, establish appropriate contacts with maternal tissue, and receive proper nutrition during pregnancy. The process of embryo implantation is precisely coordinated and is limited to a specific time period termed the “window of receptivity.”[78] The window of receptivity and the ability of the uterus to support implantation are under the control of the ovarian steroids E_2 and P_4. In the uterus, after ovulation, estrogen acting through ERα regulates the proliferation of the uterine epithelium prior to implantation. ERα also regulates the expression of the cytokine leukemia inhibitory factor 1, LIF.[79] This is a cytokine expressed in the uterine glandular epithelium that signals to the endometrial luminal epithelium to regulate embryo attachment.[80] Genetically engineered mouse models have demonstrated that the processes regulated by ERα are through paracrine, as well as direct, mechanisms.

Uterine epithelial proliferation in response to estrogen stimulation is one of the classical examples of stroma to epithelial paracrine signaling. The initial observation that ERα in the uterine stroma regulated epithelial cell proliferation was accomplished by tissue reconstitution experiments using αERKO and WT uterine epithelia and stroma.[81] These reconstitution studies demonstrated that ERα in the stroma was critical for the regulation of uterine epithelial proliferation, while ERα in the epithelial compartment was not able to induce epithelial proliferation. These reconstitution assays were later confirmed when ERα was specifically ablated in the uterine epithelium and estrogen was still capable of inducing epithelial proliferation.[82] Stromal cell production of IGF-1 and fibroblast growth factors (FGFs) are critical in regulating epithelial cell proliferation.[83,84] The role of ERα in the uterine epithelium was found to be important for the regulation of expression of LIF in the uterine glands.[82,85] This analysis showed that ERα acting in both the epithelium and stroma compartments was critical for the regulation of uterine function. The role of ERα signaling in the mouse uterus is shown in Fig. 120.6.

In addition to the regulation of uterine epithelial cell proliferation and embryo implantation, conditional ablation of the ERα in the female reproductive tract uncovered novel findings with respect to the role of ERα in pregnancy. Epithelial specific ablation demonstrated that ERα regulated the many processes supporting fertilization and embryo transport. ERα regulates the ability of the uterus to liquify the seminal fluid that is necessary for sperm to reach the site of fertilization. ERα also regulates the transport of the embryos through the oviduct and protects the embryo from protease-mediated embryo degradation.[86–88] This work demonstrates that ERα is critical for all aspects of preimplantation development of the embryo.

***In Vivo* Dissection of the Functional Domains of ERα.** In addition to identifying the role of the ERs *in vivo*, gene-targeted mice have been generated to identify the roles of the functional domains of ERα in

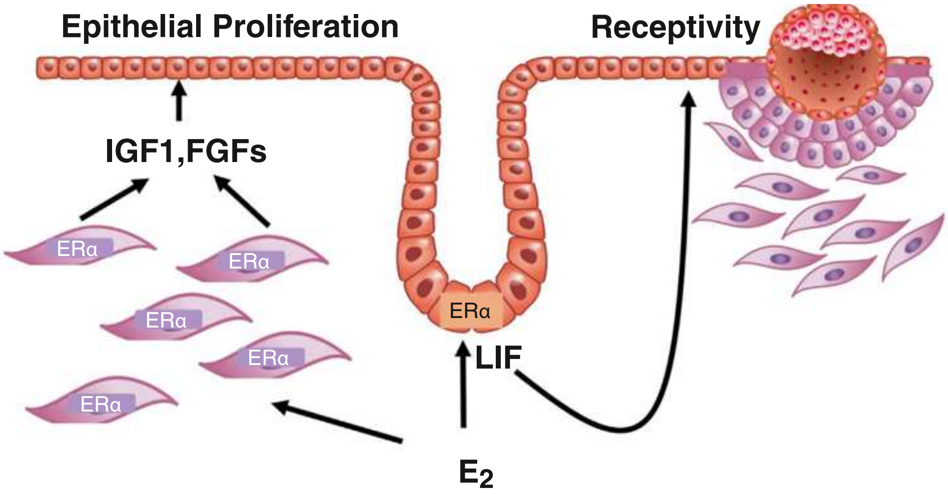

Figure 120.6 A schematic of the pathways regulated by ERα during the preimplantation period governing embryo implantation and cell proliferation.

order to determine the relative importance of the signaling pathways by which ERα regulates hormone responsive processes. Mice have been generated with mutations in activation domains, AF-1 and AF-2, the DBD, and LBD. These mutations not only defined the role of each domain in determining ERα activity but also the relative importance of the specific signaling strategies, such as classical, non-classical, and ligand-independent signaling in the physiology of an organ system *in vivo*.[73]

As mentioned above, ERα contains two transactivation domains. The AF-1 domain located in the amino terminus of ERα and the AF-2 domain located within the LBD. Mutations in the activation domains of ERα identified their relative importance in the regulation of the transactivation of gene expression and the ability of ligands to regulate transcriptional activity of ERα. Mice with mutations in the AF-1 domain showed that this domain was important for the hypertrophic response of the uterus to estrogen. Mice with mutations in this domain did not show an increase in stroma and epithelial proliferation in response to estrogen stimulation. However, the uteri of these mice did develop uterine edema in response to estrogen stimulation. This was due to the induction of vascular endothelial growth factor-A, Vegf-A.[89,90] Systematic analysis of these mice showed that the vascular system was intact, demonstrating that the AF-1 domain was not necessary for estrogen action on the vascular system.[89]

In contrast to mice with AF-1 mutations, mice with AF-2 mutations elicited a similar phenotype as the ERKO mouse, with female mice showing hypoplastic uteri, hemorrhagic and cystic ovaries, impaired mammary gland development, and high levels of serum LH and estradiol.[91] Male mice also showed a progressive sterility phenotype due to efferent duct fluid resorption.[92] Interestingly, ERα antagonists could induce a uterotropic response in female mice and reversed the male sterility phenotype. The antagonists did not impact serum levels of LH, demonstrating that while the antagonists could activate the mutant receptor in the uterus, it has no impact on the pituitary. This demonstrated the tissue-specific role of the AF-2 domain in regulating ligand specificity in ERα action.[91,92]

In order to define the *in vivo* role of ligand-dependent and ligand-independent activation of ERα, mice were generated with a mutation in the LBD. These mice showed a similar phenotype to the αERKO mice with respect to elevated serum LH levels, lack of ovulation, hemorrhagic cystic follicles, hypoplasia of the uterus, and underdeveloped mammary glands. This demonstrated that the majority of actions of ERα was dependent on ligand-dependent activation. However, when assaying the ability of growth factors to stimulate uterine proliferation, mice with the mutation in the LBD were responsive to growth factor stimulation whereas αERKO mice were not. This demonstrated the importance of ligand-independent ERα signaling in sensitizing the uterus to growth factor stimulation.[93]

Finally, genetically engineered mice were generated to investigate the role of classical versus non-classical ERα signaling. To investigate the role of ERα action by binding its DNA response element in the genome, or its non-genomic actions through tethering to other transcription factors, mice were generated with a mutation in the DBD. Two strategies were employed. The first strategy generated mice in which alanine was substituted for the glutamic acid at position 207 and for the glycine at position 208 in the first zinc finger of the DBD. The phenotype of these mice was surprising. Female mice heterozygous for these mutations in the DBD were sterile. They failed to ovulate and develop a corpus luteum. The mice had cystic uteri with endometrial hyperplasia and the mammary glands were hypoplastic. These ovarian and uterine phenotypes were independent of that observed in the αERKO.[94] Genome-wide studies of this ERα mutant revealed that this mutation of the DBD did not ablate DNA binding, but changed the specificity of the mutant ERα to bind HREs of other NRs. This gain of function phenotype could be due to a novel interaction of the DBD of the ERα mutant with the WT ERα or to a novel function generated by this mutation.[95] A second mouse model was generated with four amino acid substitutions at Tyrosine 201, Lysine 210, Lysine 214, and Arginine 215 in the DBD. The phenotype of these mice had a closer resemblance to the αERKO phenotype. These mice showed that the major activity of ERα is through the classical signaling.[96] These studies clearly demonstrate the importance of *in vivo* studies. DBD mutations that have been evaluated in a limited manner *in vitro* may not identify more globally important functions that would be identified *in vivo*.

Phenotype of the βERKO Mouse. Several lines of mice have been generated with different modifications of the ERβ gene locus.[67,97,98] Depending on the mouse model, males and females have either impaired fertility or are sterile. However, it is clear from these mouse models that the major impact of ERβ is on ovarian function and ovulation.[98] The most interesting phenotype is the result of the combined knockout of ERα and ERβ. The phenotype of this double knockout mouse results in the ovarian follicles which have granulosa cells that resemble the male Sertoli cell. This demonstrates that both ERs are critical for maintaining the phenotype of the granulosa cells in the ovaries.[67,69]

KEY POINTS

- Genetically engineered mice have been a useful tool in the structure and function analysis of ER activities.
- ERα is critical in regulating both male and female reproduction as well as other systems including metabolism, cardiovascular, and skeletal muscular systems.
- ERα regulates uterine function by directly activating the expression of specific target genes as well as coordinating the paracrine crosstalk between the cellular compartments of the endometrium.
- Mutations in the functional domains of ERα demonstrated that DNA binding in response to ligand binding is responsible for the majority of actions in the regulation of reproduction.
- ERβ regulates ovarian function and ERα and ERβ work together to maintain the sexually dimorphic phenotype of the ovarian follicles.

MECHANISMS OF PROGESTERONE ACTION

Progesterone Receptor Isoforms

Progesterone acts via binding to its NRs within reproductive tissues, including the uterus, mammary gland, ovary, and brain, and in nonreproductive tissues, including the cardiovascular system, bone, and the central nervous system.[99] In humans, there are two major PR isoforms, PR-A (94 kDa) and PR-B (114 kDa), which are alternative transcripts of a single gene[100,101] and differ only in the lengths of their A/B domains. PR-A and PR-B have identical DBD and LBD, but PR-B contains an additional 164 bp at its NH_2-terminus. Both PR-A and PR-B bind to PREs in DNA. PR-B contains the two major transcriptional activation domains found in PR-A and in other steroid hormone receptors (AF-1, AF-2), but has an additional AF domain within its extended NH_2-terminus (AF-3). Thus, in certain cell- and gene-specific contexts, PR-B is more transcriptionally active than PR-A, and PR-A can repress PR-B transcriptional activity by competing for binding to PREs and coregulators.[102,103]

A third N-terminally truncated PR isoform, PR-C, has been characterized, which lacks part of the DBD and is restricted primarily to the cytoplasm.[104,105] Because PR-C cannot bind to DNA but can bind to progesterone, it may inhibit PR function by sequestering available hormone away from PR-B. PR-C also can bind to PR-B and reduce its capacity to bind to DNA.[104]

A truncated mitochondrial form of PR (PR-M) encoded from the *PGR* gene has been identified. PR-M transcription initiates in the third intron of the *PGR* gene, contains a putative translation start site followed by 16 unique hydrophobic amino acids at its NH_2-terminus similar to that of import sequences of outer mitochondrial membrane proteins. This is followed by sequence identical to exons 4 to 8 of *PGR*. PR-M lacks the A/B and C domains and is missing a complete nuclear localization sequence.[106] In MCF-10A cells, which lack nuclear PR but express PR-M, progestin treatment was found to increase mitochondrial membrane potential and ATP production.[107] It has been suggested that PR-M mediates P_4 action to increase cellular energy production.[106]

Membrane G protein–coupled PR isoforms (mPRα and β), linked to $G_i\alpha$ adenylyl cyclase inhibition, p38 MAPK activation, and increased myosin light-chain phosphorylation also have been characterized in human myometrial cells.[108] Increased expression of mPR in the myometrium of women in labor, compared with those not in labor, was suggested to contribute to increased myometrial contractility.[108] Five subtypes of mPR have been described in neural tissues (α, β, γ, δ, ε), which bind P_4 and the neurosteroid allopregnanolone. Allopregnanolone, which binds with highest affinity to mPRδ, acts through Gαs to inhibit apoptosis and promote neuroprotection.[109]

KEY POINTS

- In humans, there are two major PR isoforms, PR-A and PR-B, which are formed by alternate transcription initiation from a single gene.
- PR-A and PR-B have identical DBD and LBD, but PR-B contains an additional 164 bp at its NH_2-terminus, which contains a third activation domain.
- Two other truncated PR isoforms are produced by alternative transcription initiation: (1) PR-C, which lacks part of the DBD, is primarily cytoplasmic, and may be an inhibitor of PR function; and (2) a mitochondrial form, PR-M.
- There are also several membrane-associated G protein-coupled PR isoforms.

Use of Gene-targeted Mice To Evaluate the Biology of PR-A and PR-B Function

The PR, by its name, is the NR of pregnancy. PR has been shown to regulate all aspects of female reproduction, from female sexual behavior to processes regulating pregnancy and maternal care of newborns through its actions in the central nervous system, pituitary, ovary, female reproductive tract, and mammary gland. Much of the *in vivo* analyses of PR action has been accomplished by the use of gene ablation, site-directed mutagenesis, and transgene expression of the receptors in mouse models.

Phenotypes of the Ablation of PR and Its Specific Isoforms. Using standard homologous recombination in embryonic stem cells, both PR-A and PR-B isoforms were ablated in the mouse, generating the PRKO model. The PRKO mouse demonstrated that PR regulated female sexual behavior, maternal behavior, ovulation, all aspects of uterine function, embryo implantation, immune function, and mammary gland development.[110–113] In addition to these functions, the PRKO mouse demonstrated that PR was responsible for inhibiting the mitogenic effects of E_2 on uterine epithelial proliferation.[110]

Following the ablation of both PR isoforms, site-directed mutagenesis was conducted to determine the individual functions of the PR-A and PR-B isoforms *in vivo*.[114,115] The specific ablation of PR-A *in vivo* demonstrated that in the mouse reproductive tract, PR-A was the dominant functional isoform. PR-AKO mice did not ovulate, and the uterus was not able to support pregnancy. However, PR-A ablation had no effect on mammary gland development. These isoform-specific ablated mice demonstrated that PR-B induced uterine epithelial proliferation in response to P_4 treatment. This is a unique role for the PR-B isoform since PR serves an important role in preventing uterine epithelial proliferation in response to E_2 stimulation.[115] Mice with specific ablation of PR-B showed normal ovarian and uterine function. However, mammary gland development was impaired.[114] Mice with targeted ablation of PR-A and PR-B demonstrated the specific roles of these isoforms in mouse reproduction, with PR-A being the major regulator of ovarian and uterine function, while PR-B regulates mammary gland development. These tissue-specific actions of the PR-A and PR-B isoforms in the mouse may be either due to their tissue-specific activation of target genes, or to the stoichiometry of the expression of these isoforms in different tissues. Such findings in mouse models do not address the role of these isoforms in human reproduction or that of other species where the stoichiometry of these isoforms may be different.

In addition to the investigation of the role of PR-A and PR-B by isoform ablation, *in vivo* site-directed mutagenesis has been used to investigate the role of phosphorylation on the activation of PR. Using site-directed mutagenesis, serine 191 of PR was mutated to an alanine. The resulting mouse showed a 19% decrease in litter size and alteration in the expression of a subset of PR target genes and of PR binding to selective enhancers.[116] This analysis demonstrated the *in vivo* significance of the activation of PR by phosphorylation signaling cascades. The gene-targeted mice, described above, have elucidated the role of

PR in the whole animal. Cell-specific knockouts and gene activation have also been used to decipher the role of PR *in vivo*.

Molecular Mechanisms of Progesterone Action in the Endometrium and on Blastocyst Implantation

Preimplantation Mouse Uterus. PR regulates transcription in both epithelial and stromal cell compartments of the endometrium at specific stages during the preimplantation period. PR functions to directly regulate the transcription of genes required for cell autonomous function, as well as to coordinate the paracrine crosstalk between the epithelial and stromal cells.[81] The expression of PR in the epithelium is spatially and temporally regulated. PR expression increases in the uterine epithelium during the preimplantation period and is lost from the epithelial compartment prior to embryo attachment.[117] The loss of PR in the epithelial compartment marks the window of receptivity.[118] Expression of PR in the uterine epithelium during the preimplantation period functions to inhibit the postovulatory cell proliferation caused by the ovulatory E_2 surge and primes the uterine epithelium and stroma for embryo implantation and the support of the developing embryo.[119] In the endometrial stroma, PR expression increases prior to embryo implantation and is maintained in the stroma throughout pregnancy. PR expression in the stromal fibroblasts promotes their proliferation and allows these cells to undergo decidualization. Decidualization of these stromal cells involves a change in morphology from a fibroblastic phenotype to an epithelioid-like phenotype. Decidualization supports embryo development by supplying nutrition to the embryo and protecting the embryo by modulating maternal inflammation and immune response.[79] The signaling pathways required for PR regulation of uterine function have been identified using the PRKO mouse, as well as mice with compartment-specific ablation of PR, as described above.

KEY POINTS

- Ablation of PR demonstrates that this receptor is critical for all aspects of reproduction including postpartum behavior.
- Specific ablation of the PR-A and PR-B isoforms demonstrated that PR-A is the major regulator of uterine function during the preimplantation period, whereas PR-B is critical for mammary gland development.

PR Regulated Epithelial-Stroma Crosstalk. PR regulates the paracrine crosstalk that controls epithelial cell proliferation and stromal cell decidualization. This crosstalk is initiated by PR induction of the epithelial morphogen Indian hedgehog (IHH) (Fig. 120.7).[119–121] IHH then signals to the endometrial stromal cells to regulate the activity of the orphan nuclear receptor COUP-TFII.[121] COUP-TFII regulates the expression of PR in the stromal cells.[122] Stromal PR in turn regulates the proliferation of the uterine epithelium by regulating the transcription of the helix-loop-helix transcription factor Hand2 in stromal cells.[84] Hand2 serves to inhibit the expression of FGFs by the stromal cells. The decrease in FGF signaling halts epithelial cell proliferation. PR also regulates the growth factor sensitivity of stromal cells to facilitate the decidual reaction. Stromal PR increases the levels of epidermal growth factor receptor 1 (EGFR1) in these cells.[123] Upon embryo attachment, the EGFR1-sensitive stromal cells increase the expression of bone morphogenetic protein 2 (BMP-2), and Wingless-related integration site (Wnt) family member Wnt4.[124] BMP-2 and Wnt4 expression is maintained in the stromal cells by PR. EGFR, BMP-2, and Wnt4 function to regulate the proliferation, cell survival, and differentiation of the stromal cells required for decidualization.[122,124,125] This signaling pathway is shown in Fig. 120.7.

Loss of Epithelial PR Is Required for Embryo Implantation. Not only is the presence of PR action critical for the establishment and maintenance of pregnancy, but also the loss of *PGR* expression in the murine uterine epithelium during the preimplantation period is critical for attachment.[118,126] Mice generated with the constitutive expression of PR-A in the uterine epithelium manifested defects in embryo attachment and stromal decidualization. Not only were PR-regulated genes expressed through the window of receptivity, but also two genes critical for implantation were deregulated. The ERα regulated gene *Lif* whose expression is critical for embryo implantation was inhibited by PR-A constitutive expression prior to implantation. In addition, the cellular localization of the transcription factor FOXO1 was altered. FOXO1 is localized in the nucleus of the uterine epithelium during the window of receptivity. Loss of FOXO1 results in the inability of the embryo to invade the uterine epithelium.[127] Continued expression of PR-A through the window of receptivity in the uterine epithelium caused the retention of FOXO1 in the cytoplasm, impairing embryo invasion. Therefore, in addition to its role in activation of genes required for embryo implantation, the timing of PR expression in the uterus also is of critical importance.

PR Interacting Transcription Factors. PR regulation of uterine function depends on the induction and activation of other uterine transcription factors. Chromatin immunoprecipitation, combined with whole genome sequencing, ChIP-seq, in mouse uterus and in primary human endometrial stromal cells was employed to identify these factors.[128] ChIP-seq analysis not only identified the direct targets of PR binding to response elements in the chromatin of the mouse uterus and human endometrial stromal cells but also identified motifs for other potential interacting transcription factors. These factors function to regulate gene expression in the endometrial cells. In mouse uteri, GATA2 and SOX17 motifs were identified as serving a role in PR binding with in the mouse genome.[128]

Gata2 and Sox 17 are transcription factors expressed under PR control in the epithelial compartment of the mouse uterus. Gata2 belongs to the six-member family of zinc-finger transcription factors that bind to the DNA consensus sequence (T/A)GATA(A/G) via two zinc-finger domains.[129] Sox17, a key regulator of embryo implantation, is a transcription factor belonging to the family of sex-determining region Y (SRY)-related high-mobility group (HMG) box, namely SOX.[130] Deletion of *Gata2* and *Sox17* in the uterus resulted in the inability of the uterus to support embryo implantation. GATA2 was demonstrated to regulate the expression of PR and cooperate with PR in the regulation of target gene transcription.[131] Sox17 was shown to regulate uterine epithelial gland development and the expression of *PGR* target genes. Analysis of PR, Sox17, and Gata2 regulation of the morphogen IHH showed that they bind to an enhancer located 19 kb distal to the *Ihh* promoter. CRISPR/Cas9 gene editing of this enhancer demonstrated that this region was critical for uterine-specific expression of Ihh. Thus, PR, Gata2, and Sox17 bind to a distal enhancer to regulate the expression of *Ihh* in the uterine epithelium. Analysis of the PR, Gata2, and Sox17 ChIP-seq data identified other genes containing overlapping binding sites for these transcription factors, many of which were associated with the regulation of uterine function. This indicates that regions of the PR interact with specific combinations of transcription factors to regulate uterine epithelial gene expression.[132]

KEY POINTS

- PR regulates embryo implantation by controlling epithelial proliferation and stromal cell differentiation during the preimplantation period.
- The timing and cell-specific expression of PR is precisely coordinated to render the uterus receptive for embryo implantation and support of the developing embryo.
- PR regulates a complicated paracrine signaling network to prepare the endometrium for embryo implantation.
- PR works with several other transcription factors in regulating uterine epithelial gene expression.

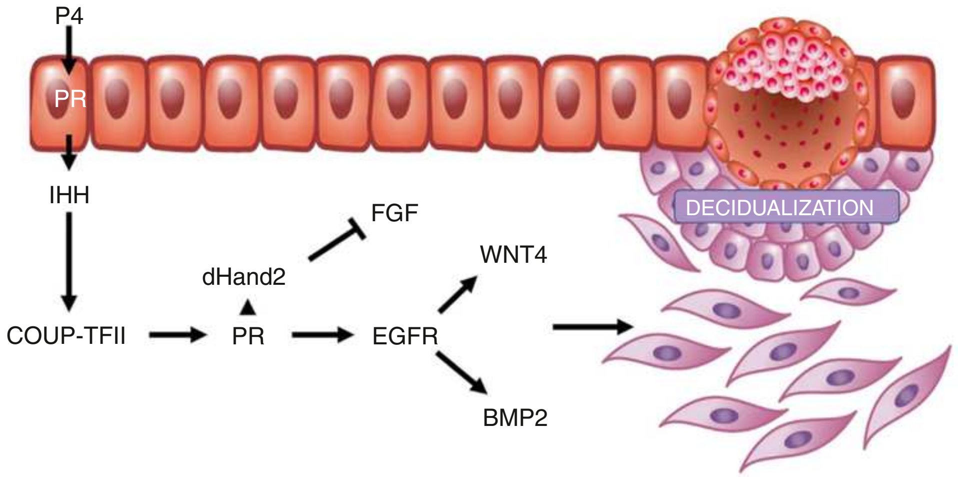

Figure 120.7 Pathways regulated by the PR in controlling epithelial to stroma two-way crosstalk in the regulation of embryo implantation.

Molecular Mechanisms of Progesterone Action in the Pregnant Myometrium

Throughout most of pregnancy, P_4 produced by the ovarian corpus luteum in rodents, and initially by the corpus luteum and subsequently by the placenta in humans, certain non-human primates, sheep, horses, cats, and guinea pigs, maintains myometrial quiescence.[133] The human placenta produces ~300 mg of P_4 per day,[133] resulting in circulating levels of ~10^{-7} M, which are far in excess of the K_d for P_4 binding to PR in target cells. The mechanisms whereby P_4/PR maintains myometrial quiescence are multifactorial and cooperative. One of the most important ways by which P_4/PR suppresses myometrial contractility is via its anti-inflammatory actions. The anti-inflammatory and immunosuppressive actions of P_4 during pregnancy were originally proposed by Siiteri et al. more than 40 years ago.[134,135] We now know that P_4 exerts these effects in the pregnant myometrium, in part, by: inhibiting transcriptional activity of the proinflammatory transcription factors, NF-κB[37] and activating protein 1 (AP-1),[38] via tethering of PR and recruitment of corepressors;[36,38,136]; upregulating expression of IκBα, which sequesters NF-κB in the cytoplasm and prevents its activation and nuclear translocation[37]; and by enhancing expression of MAP kinase phosphatase-1 (MKP-1)/dual specificity phosphatase-1 (DUSP1), an inhibitor of MAPK signaling.[137,138] Inhibition of MAPK, in turn, inhibits activation of NF-κB and AP-1 and their inductive effects on contractile gene expression (Fig. 120.8).[139]

An additional mechanism whereby P_4/PR maintains myometrial quiescence during pregnancy is by upregulating expression of the transcriptional repressor, ZEB1/TCF8/δEF1, which binds to the promoters of the contractile genes *OXTR* and *CX43* to inhibit their expression (see Fig. 120.8).[140–142] Furthermore, P_4 induces expression of the transcription factor STAT5b,[143,144] a negative regulator of the P_4-metabolizing enzyme 20α-hydroxysteroid dehydrogenase (20α-HSD) in reproductive tissues.[145] Thus, in the presence of elevated P_4/PR, STAT5b expression is increased, resulting in inhibited expression of 20α-HSD in the myometrium. This allows local levels of P_4 to remain elevated to maintain PR activation of myometrial quiescence.

Mechanisms for the Loss of PR Function in the Pregnant Myometrium Near Term Leading to Labor

In women and guinea pigs, circulating levels of P_4 remain elevated throughout pregnancy and into labor because of persistent high levels of placental P_4 production. Even in rodents, where circulating levels of P_4 decline precipitously at term, plasma levels remain in excess of the K_d for binding of P_4 to PR.[146] Thus, near term in all species, mechanisms must be in place to inhibit PR function and/or reduce tissue levels of P_4 leading to the initiation of labor. These include the following:

KEY POINTS

- PR acts in the myometrium to maintain quiescence during pregnancy by increasing expression of transcriptional repressors, such as ZEB1 and STAT5b.
- ZEB1 inhibits contractile genes (e.g., *OXTR*, *CX43*); STAT5b inhibits 20α-HSD.
- PR also maintains myometrial quiescence by tethering to and inhibiting activation of transcription factors (e.g., AP-1 and NF-κB) that increase transcription of contractile genes.

Altered Expression of PR Coregulators. Expression of selected SRCs and CBP was found to decline in the myometrium of women in labor, compared with non-laboring myometrium, and was decreased in the myometrial tissues of pregnant mice at term, along with decreased tissue levels of acetylated histone H3.[147] Thus, decreased expression of PR coactivators and a decline in histone acetylation in the myometrium during late gestation may impair the capacity of P_4/PR to transactivate genes that maintain myometrial quiescence. Accordingly, treatment of pregnant mice with the HDAC inhibitor, trichostatin A, during late gestation increased myometrial histone acetylation and delayed parturition by 24–48 hours.[147] The decline in PR coactivators and HAT activity may contribute to the decreased repressive activity of the inhibitory transcription factors ZEB1 and STAT5b near term. As mentioned, the decline in ZEB1 near term likely results in upregulation of the contractile genes *CX43* and *OXTR*. The decrease in STAT5b may promote increased expression of the P_4 metabolizing enzyme 20α-HSD, decreased myometrial P_4 levels and reduced PR activation.

In addition, corepressors, GATAD2B[36] and p54nrb,[38] which interact with PR and mediate its capacity to repress proinflammatory and contractile gene expression by tethering to NF-κB and AP-1, respectively, were found to decrease in rodent myometrium at term, contributing to the increase in myometrial contractility.

Increased Expression of Truncated PR Isoforms. As described above, in certain cell- and gene-specific contexts, PR-B is more transcriptionally active than PR-A. In this regard, PR-A was found to inhibit PR-B transcriptional activity in cultured human myometrial cells,[148] suggesting a potential antagonistic role of PR-A on PR-B action in the myometrium. Notably, PR-A and PR-B were found to be differentially

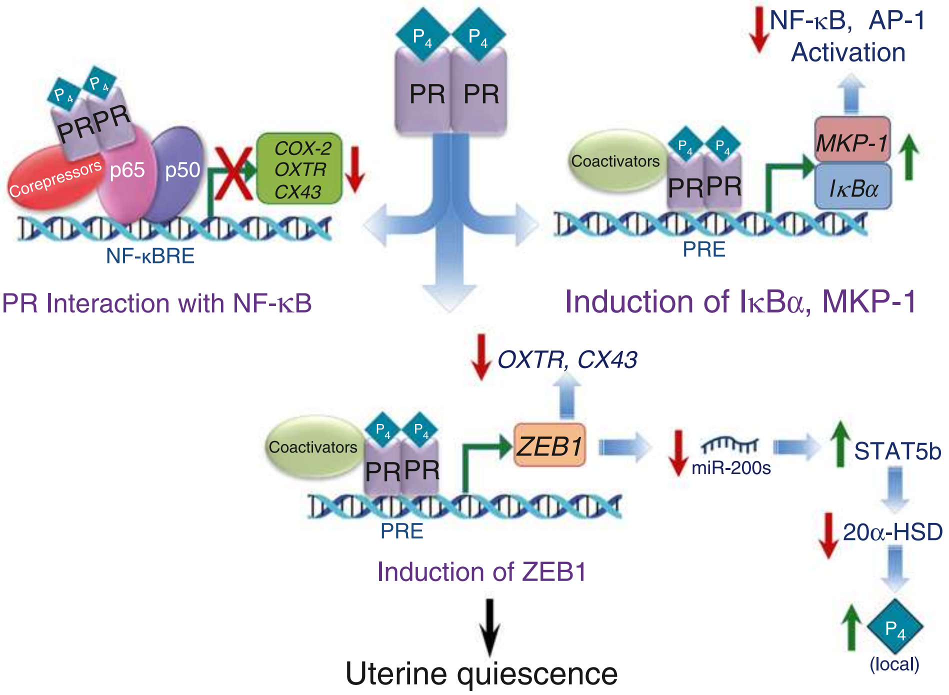

Figure 120.8 Mechanisms whereby P_4/PR mediates myometrial quiescence. These include: enhanced transcription of repressors of contractile genes (*e.g.* ZEB1) and of STAT-5b, which represses the gene encoding the P_4-metabolizing enzyme 20α-HSD; tethering to and repressing transcriptional activators of contractile genes (e.g., AP-1 and NF-κB). (Reproduced with the permission of Cold Spring Harbor Laboratory Press. Renthal NE, Williams KC, Montalbano AP, Chen CC, Gao L, Mendelson CR. Molecular regulation of parturition: a myometrial perspective. Cold Spring Harb Perspect Med. (2015) 5:181–96. doi: 10.1101/cshperspect.a023069.)

regulated in the human myometrium during pregnancy[149]; the ratio of PR-A to PR-B mRNA[150] and protein[148] was observed to be increased significantly in the myometrium from women in labor compared with those not in labor at term.

Moreover, in term fundal myometrium from women before and after the initiation of labor, a marked labor-associated increase in protein and mRNA expression of a truncated (~60 kDa) PR isoform, similar in size to PR-C was observed[151]; this was spatially and temporally associated with increased activation of myometrial NF-κB.[152] Similarly, a temporal increase in the expression of a truncated PR isoform of ~60 kDa also was observed in mouse uterus during late gestation.[151]

Increased Local Metabolism of P_4 to Inactive Steroids. Increased local metabolism of P_4 to inactive products in the uterus near term by 20α-HSD[145] serves a critical role in the decline in PR function that contributes to the initiation of parturition in all mammals. In the myometrium of pregnant women at term, a pronounced decrease in the ratio of P_4 to 20α-dihydroprogesterone (20α-OHP), an inactive metabolite of P_4 generated by 20α-HSD, was observed.[153] As discussed above, the gene encoding 20α-HSD is negatively regulated by STAT5b, which decreases in the pregnant mouse and human myometrium near term and in labor.[143]

Importantly, many of these mechanisms are driven by an increased inflammatory response with activation of NF-κB and AP-1 transcription factors, which is caused by increased uterine stretch, cooperative proinflammatory signals from mother and fetus, and a rise in circulating E_2 and ERα expression in the myometrium.[154]

Increased Levels of Circulating Estradiol-17β and Increased ERα expression in myometrium. Together with the decline in circulating P_4 levels and/or PR function, in most placental mammals, increased uterine contractility near term is associated with an increase in circulating estradiol-17β (E_2)[155,156] and/or increased ERα expression and activity.[150,157,158] Estrogens induce immune cell migration into the uterus and antagonize anti-inflammatory actions of P_4/PR.[113] Furthermore, ERα activation enhances transcription of *OXTR*,[159] *CX43*,[160] and cyclooxygenase 2 (*COX-2*/*PGHS*),[150] which catalyzes the production of contractile prostaglandins.[161]

KEY POINTS

- Multiple mechanisms contribute to a decline in PR function near term (see Fig. 120.8). These include:
- Decreased expression of PR coactivators;
- Increased expression of truncated PR isoforms; for example, increased expression of PR-A and PR-C, relative to PR-B;
- Increased metabolism of PR to inactive steroids within myometrium and cervix;
- Increased production of E_2 and expression of ERα in myometrium.

CONCLUSIONS

Estradiol-17β and progesterone serve critical roles in reproductive function that are primarily mediated by ERα/ERβ and by PR-A/PR-B, respectively. The majority of PR and ER actions are ligand-dependent, mediated by binding of E_2 or P_4 to their respective receptors, dissociation of the complex of hsps, receptor homodimerization, binding to their respective HREs in DNA or tethering to other transcription factors bound to their corresponding response elements. This, in turn, results in recruitment of coactivators or corepressor complexes, and changes in chromatin modifications to activate or inhibit target gene transcription. Through sequencing, biochemical analyses, x-ray crystallographic, and cryo-EM studies, the structures of members of the NR family and coregulators and the structural basis for ligand binding, dimerization, DNA binding, and coactivator and corepressor interactions have been elucidated.

Our understanding of the functional roles of ERα and ERβ and of PR-A and PR-B isoforms has largely been gained from studies of gene-targeted mice. While ERα and ERβ have rather wide-ranging roles in mediating estrogen regulation of female and male reproductive functions, as well as cardiovascular, bone, and metabolic homeostasis, PR primarily mediates progesterone actions in the initiation and maintenance of pregnancy. Mouse studies have demonstrated that PR regulates sexual behavior, ovulation, transport of zygotes through the oviducts into the uterine cavity, embryo implantation, and maintenance of myometrial quiescence during pregnancy. In addition, PR modulates maternal behavior, mammary gland development, and lactation. Like the ERs, ERα and ERβ, which are products of different genes, PR has two major isoforms (produced by alternative transcription initiation of a single gene) that synergize or antagonize one another's actions in a tissue-/cell-specific manner. Understanding the roles of these isoforms and the cell-specific factors that impact their different biological functions in normal and cancer cells will lead to better diagnostics and therapies to improve conditions that impact women's health.

CONTRACEPTIVE USE

Correct and consistent use of effective methods of contraception can prevent *most* unintended pregnancies. It is estimated that in low- and middle-income countries, approximately 218 million women want to avoid a pregnancy but are not using effective methods. This is mainly due to lack of supplies, political and cultural barriers, and limited and/or poor quality services.

Abortion is a common consequence of unintended pregnancy. While abortion is a very safe procedure when conducted in a legal setting, in countries where abortion is illegal or restricted, it is often performed under unsafe conditions and can result in women dying or suffering serious injuries. Globally, it is estimated that there are over 25 million unsafe abortions performed each year, that between 30 and 200 women die per 100,000 of these unsafe procedures, and that 7 million women require hospital treatment for complications of unsafe abortion.[1,2] These are preventable.

Unintended pregnancy can also lead to delayed or no antenatal care, with resulting maternal and neonatal health risks. In addition, if conception occurs within a year of giving birth, the newborn is at higher risk of preterm birth and neonatal death.[3]

Contraception allows women to choose when to have a baby and to space births. It can enable them to complete education and play an equal role in society. Women's lives may also be improved by non-contraceptive benefits, such as reduced menstrual blood loss, or through reduction in the risk of reproductive tract cancers (see below).

KEY POINTS

- Contraception saves the lives of millions of women.
- Contraception improves interpregnancy intervals and outcomes for babies.

METHODS AND THEIR EFFECTIVENESS

Contraceptive methods used by women (Table 121.1) include combined hormonal (estrogen/progestogen) contraceptive pills, patch, or vaginal ring, progestogen-only pills, implants, injections, hormone-releasing intrauterine devices (IUDs), copper intrauterine devices (Cu-IUDs) and barrier methods (condoms, diaphragms, and cervical caps), and sterilization. Hormonal contraceptives inhibit ovulation by suppressing luteinizing hormone (LH), thicken cervical mucus (inhibiting sperm penetration), and may affect development of the endometrium (Fig. 121.1). None of these methods is 100% effective at preventing pregnancy, and the effectiveness of a given contraceptive method depends on both mechanism of action (see Fig. 121.1) and correct, consistent, continued use. Uptake, compliance, and continuation depend on acceptability of the method to the user. Acceptability of a method may be influenced by age, fertility intentions, perceptions of effectiveness and safety, familiarity and experience of friends and/or family, ease of use, side effects, and non–contraceptive benefits.[4]

The effectiveness of a method of contraception is expressed by the failure rates associated with its use. Contraceptive failure rates during perfect use (defined as use according to instructions) demonstrate how effective methods can be. Failure rates during typical use show how effective methods are during actual use (including inconsistent or incorrect use).[5] Estimated perfect– and typical–use failure rates of the different methods (based on percentage of users experiencing an unintended pregnancy during the first year of use) are shown in Table 121.1. Long-acting reversible contraceptive methods such as the subdermal implant and intrauterine contraceptives which do not require any action by the user, once inserted, have typical-use failure rates within the first 12 months of use that are similar to those of perfect-use failure rates. In contrast, typical-use failure rates for methods that require compliance by the user (e.g., daily pill to be taken) are much higher than perfect-use failure rates.

TABLE 121.1 Contraceptive Methods and Percentage of Women Experiencing an Unintended Pregnancy Within the First Year of Use With Typical Use and Perfect Use

Method	Typical Use	Perfect Use
None	85	85
Fertility awareness-based methods	15	
Male condom	13	2
Female diaphragm	17	16
Combined pill and progestogen-only pill	7	0.3
Combined hormonal contraceptive patch and vaginal ring	7	0.3
Progestogen-only injectable	4	0.2
Cu-IUD	0.8	0.6
52-mg LNG-IUD	0.1	0.1
Progestogen-only implant	0.1	0.1
Female sterilization	0.5	0.5

From Trussell J, Aiken ARA. Contraceptive efficacy. In: Hatcher RA, Nelson AL, Trussell J, et al., eds. *Contraceptive Technology*. 21st ed. New York: Ayer Company Publishers, Inc., 2018.

Cu-IUD, Copper intrauterine device; *LNG-IUD*, levonorgestrel intrauterine device.

Discontinuation rates are higher for methods that do not require removal by a healthcare professional. Data indicate that approximately 50% of women discontinue a pill or injectable within the first year of use, whereas approximately 80% of women continue the implant or IUD at 12 months.[6] Reasons for discontinuation are often associated with perceived risks and real or perceived side effects.

KEY POINTS

- Effectiveness of a contraceptive method depends on its mode of action and the need for user compliance.

DRUG INTERACTIONS

Certain medications may decrease or increase serum levels of contraceptive hormones with resulting potential for contraceptive failure or adverse effects; likewise, hormonal contraception may alter exposure to other medications. Prescribers should ask women about all drug use and where necessary consult up–to–date and reputable online drug interaction information.

Some of the most common interactions affecting hormonal contraceptives are with medications such as carbamazepine and rifampicin that induce hepatic cytochrome P450 enzymes. These drugs could reduce the effectiveness of combined hormonal contraception (CHC) and the progestogen–only pill and implant, by their metabolism in the liver via

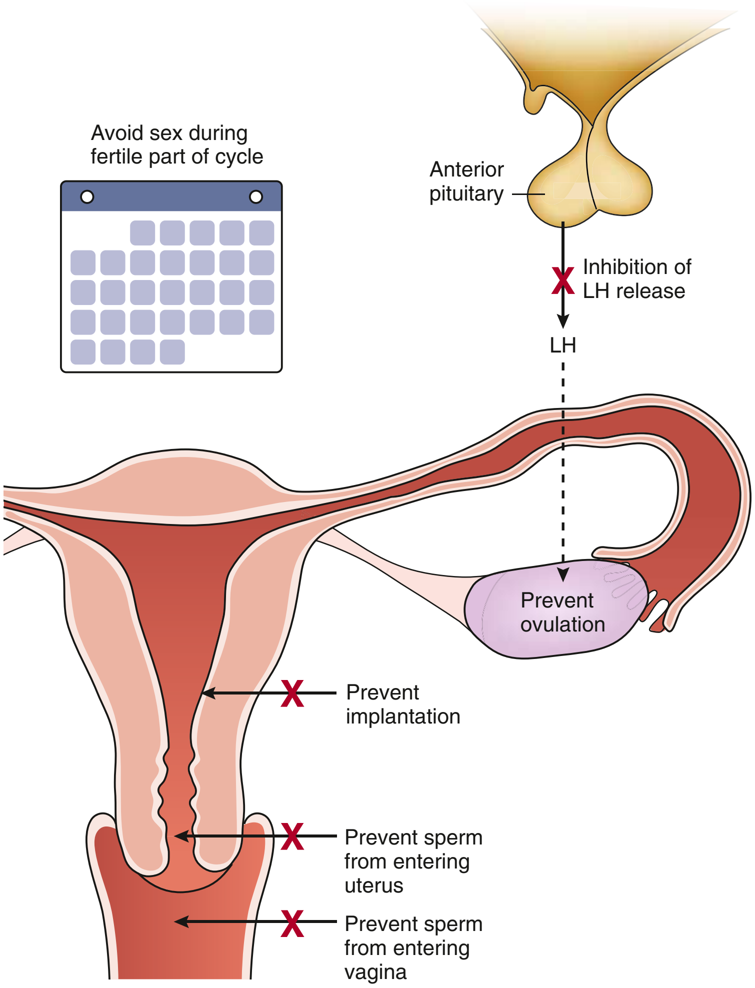

Figure 121.1 Mechanism of action of contraceptives.

this pathway. Enzyme inducers are not considered to affect the contraceptive effectiveness of injectable and intrauterine contraceptives.[7]

Conversely, as an example, use of CHC increases the clearance of the antiepileptic lamotrigine and reduces serum levels of this drug. Seizure frequency could therefore increase when initiating CHC, and lamotrigine side effects may increase in the pill–free interval or when discontinuing this method of contraception.

Contraceptive effectiveness of the combined oral contraceptive pill (and all other methods) is not considered to be affected by coadministration of nonenzyme-inducing broad–spectrum antibiotics.[7]

MEDICAL ELIGIBILITY CRITERIA

Many women who use contraception are fit and healthy and can safely use any effective contraceptive method. However, for women with specific medical conditions, use of particular contraceptive methods could be associated with increased risk of adverse health events. In an attempt to produce a set of international norms for providing contraception to individuals with a range of medical conditions and characteristics that could contraindicate a contraceptive method, the World Health Organization (WHO) developed a system addressing medical eligibility criteria (MEC) for contraceptive use.[8] The WHO MEC comprise a set of evidence-based recommendations for global use that help guide safe contraceptive prescribing decisions. The United States and United Kingdom have adapted these for use in their settings.[9,10] For each of a number of characteristics or medical conditions, the MEC tables indicate a category 1, 2, 3, or 4 for each contraceptive method. The four categories are defined in Table 121.2. Category 1 indicates that there is no restriction to use of that method by a woman with the condition, while category 4 indicates that use of that method by a woman with the condition represents an unacceptable health risk.

The MEC category only reflects the *safety* of use of the method. It is important to note that MEC do not indicate the *best* or *most effective* contraceptive method for a woman; such an evaluation must also take into account the fact that effectiveness of the method may be affected by the condition or the medication required for the condition as well as the woman's preferences and requirements. In addition, MEC categories relate to use of contraceptive methods *for contraception*, but not for other indications. So, for example, if a woman is using a contraceptive method for a non-contraceptive indication (e.g., management of symptoms of polycystic ovarian syndrome), then the risk-benefit balance could differ and the MEC category may not apply.

KEY POINTS

- Effective contraceptive methods are generally very safe (they are extremely safe compared to pregnancy), but assessment of medical eligibility is recommended, particularly for women with preexisting medical conditions.

TABLE 121.2 Medical Eligibility Criteria (MEC) for Contraceptive Use[8]

MEC Categories for Contraceptive Eligibility	
1	A condition for which there is no restriction for the use of the contraceptive method
2	A condition where the advantages of using the method generally outweigh the theoretical or proven risks
3	A condition where the theoretical or proven risk usually outweighs the advantages of using the method
4	A condition which represents an unacceptable health risk if the contraceptive method is used

High-Effectiveness Methods

The most effective methods of contraception are the long-acting reversible methods of contraception (LARC) such as the Cu-IUD, levonorgestrel intrauterine device (LNG-IUD), and progestin-only implant. Their contraceptive failure rate in the first year of use is under 1% with both perfect and typical use (see Table 121.1). (Note that enzyme-inducing drugs can reduce contraceptive effectiveness of the implant.)

Unfortunately, myths and misconceptions amongst both women and health care professionals surrounding use of LARC are major factors that limit their uptake.[11] Education, dispelling myths, and promoting the significant non-contraceptive benefits of LARC methods could improve uptake and continuation as these LARC methods have the potential to prevent many more unintended pregnancies for more women.

Intrauterine Devices

Intrauterine methods of contraception include Cu-IUD and LNG-IUD.

Available Cu-IUDs vary in size, shape, copper content, and duration of use. Most consist of a plastic frame with copper wire wound around the stem; some also have copper on the arms of the device. Cu-IUDs are effective for between 3 and 10 years depending on the device used.

LNG-IUD consists of an elastomere frame with a reservoir on the stem containing LNG. There are devices containing 52 mg, 19.5 mg, and 13.5 mg of LNG. The 52-mg device provides at least 6 years of contraception, and the 19.5-mg device provides 5 years of contraception, and the 13.5-mg device is effective for 3 years.

Cu-IUD and LNG-IUD work primarily by inhibiting fertilization due to the toxic effect of copper ions on ova and sperm or adverse effects of LNG on sperm penetrability and transport.[12,13] Both copper and hormonal IUDs also prevent implantation; Cu-IUD causes a local inflammatory reaction in the endometrium and LNG induces endometrial atrophy.[12,13] In addition, LNG causes thickening of the cervical mucus which prevents sperm from entering the uterus, although it is not known how quickly such changes are established.[14] With LNG-IUD, serum levels of LNG are detectable but much lower than peak levels observed with other LNG-containing contraceptives, and most women (80%) will continue to ovulate.[14a] Levels are also influenced by body mass index (BMI).[15]

Healthcare professionals can be reluctant to offer an IUD to nulliparous women or adolescents due to misconceptions that it will be difficult to insert or carry higher risks. However, the evidence to support use in these groups is reassuring. The WHO, Faculty of Sexual and Reproductive Healthcare UK, and American College of Obstetricians and Gynecologists all support the use of IUDs in young women and nulliparous women.[16–19]

All LNG-IUDs reduce menstrual blood loss[20,21]; there is approximately 90% reduction by 1 year of use of the 52-mg LNG-IUD. Unscheduled bleeding is, however, also common. In contrast, users of Cu-IUD may expect increased menstrual loss. Concurrent use of nonsteroidal anti-inflammatory drugs or an antifibrinolytic can reduce menstrual blood loss.[22]

Risks associated with IUD use are mainly related to the insertion procedure.[19] Perforation of the uterus at insertion is rare (1 per 1000); factors associated with increased risk of perforation include breastfeeding and being less than 6 months postpartum.[23] Around 1 in 20 IUDs are expelled. Expulsion is most likely to happen in the first 3 months after insertion.[24] The overall risk of pelvic inflammatory disease following insertion of IUD is low (about 0.5%). It is more likely in the first 3 weeks after insertion and in women at risk of sexually transmitted infections (STIs).[25] A sexual history should be obtained from every woman before IUD insertion with testing for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* in high-risk groups and populations where prevalence of infection is high.[19]

Women may have concerns surrounding the effects of IUDs on their fertility. However, the available evidence indicates that IUDs do not cause a delay in return to fertility or increase the risk of infertility.[26]

IUD users should be informed that their overall risk of ectopic pregnancy is much reduced compared with women who are using no contraception. Although the absolute risk of ectopic pregnancy is low, if a pregnancy does occur with an IUD *in situ* then the "relative" risk of that pregnancy being ectopic is higher. In a multicountry European prospective study (European Active Surveillance Study), approximately 20% of all pregnancies occurring during IUD use were ectopic.[27]

Progestogen-Only Implant

A single rod subdermal implant containing the progestogen etonogestrel (68 mg) is the currently available implant in the United States and Europe (Nexplanon). Implants in use in other parts of the world include: Uniplant (single rod, containing nomegestrol, and effective for 1 year) and Jadelle/Sino implant II (two rods, containing LNG, and effective for 5 years).

The progestogen-only implant works principally by inhibition of ovulation and provides contraception for 3 years.[28,29] Implants also prevent sperm penetration by altering the cervical mucus and may prevent implantation by thinning the endometrium. Nexplanon is a non-biodegradable, flexible rod, similar in size to a matchstick (40 mm × 2 mm). It is inserted subdermally using a preloaded inserter. The insertion site, 8–10 cm above the medial epicondyle over the triceps muscle, is chosen to minimize the risk of damage to underlying neurovascular structures.[30] The insertion device is designed to facilitate correct insertion in the subdermal layer. Nevertheless, poor insertion technique can still result in deep insertion with consequent difficult removal or (occasionally) neurovascular damage or intravascular insertion. Nexplanon insertion should therefore be conducted only by clinicians with appropriate training.

The implant is not usually visible, but should be easily palpable. If it is not palpable, it should be located. Nexplanon contains a small quantity of barium, which permits it to be visualized by x-ray. It can also be localized using low-frequency ultrasound probes, which can help aid removal of implants that are not easily palpable. Once inserted, there is no need for any routine follow-up until the device is due for replacement or the user wishes it removed. After removal, the contraceptive effect ceases immediately after removal and serum etonogestrel levels are undetectable within 1 week.[30]

Bleeding patterns are variable and unpredictable, and dissatisfaction with bleeding pattern is the most common reason for implant removal requests. While many women bleed less often than once a month and some are amenorrhoeic during Nexplanon use, bleeding episodes are often irregular, unpredictable, and can also be frequent and sometimes prolonged.[31]

MEDIUM EFFECTIVENESS METHODS

Progestogen-Only Injectable

Both depot medroxyprogesterone acetate (DMPA) and norethisterone enanthate (NET-EN) are long-acting progestogens used as contraceptive injectables. Worldwide, the most commonly used injectable is DMPA, with NET-EN less commonly used. Progestogen-only injectables work primarily through inhibition of ovulation. There is also a progestogen effect on cervical mucus that makes it less penetrable to sperm and on the endometrium, creating an unfavorable environment for implantation.[32]

DMPA is available as both an intramuscular (IM) preparation (150 mg) and a micronized subcutaneous (SC) formulation (104 mg). The IM injection is administered to the buttock or upper arm, and the SC injection to the abdomen or anterior thigh. Since SC injections are easier to give, the SC preparation can be administered by a wide range of trained providers and is also licensed for self-administration, thus expanding access for women to this method.[33,34] Injection site reactions are common with the SC preparation; users should be warned that approximately 1 in 10 women develop lipoatrophy (nodule or dimpling of the skin) at the injection site.[32]

IM and SC preparations are equally effective for contraception (estimated typical use failure 4%), and have the same mode of action (inhibition of ovulation), frequency of administration (every 13 weeks), bleeding pattern, and side-effect profile.[32] The injectable causes profound ovarian suppression, resulting in high rates of amenorrhea (over 50% at 1 year) although a small proportion of users experience heavy, persistent bleeding. The injectable is the only hormonal contraceptive method that may delay return of fertility after discontinuation—in some cases, ovulation may not return for a year or more after the last injection. This makes it unsuitable for short-term contraception use. DMPA may cause weight gain in some women, particularly adolescents with obesity.[35] DMPA is associated with loss of bone mineral density (BMD) (5% loss of BMD at lumbar spine) in the first few years of use and may be best avoided by individuals with other risk factors for osteoporosis. However, BMD loss seems to plateau, has not been associated with osteoporotic fractures, and recovers following discontinuation.[36]

There was formerly concern because observational studies in countries with high prevalence of human immunodeficiency virus (HIV) suggested that DMPA users might be at higher risk of acquisition of HIV than users of other hormonal methods. However, a large, robust multisite randomized controlled trial in sub-Saharan Africa recently demonstrated that use of DMPA does not increase the risk of acquisition of HIV among high-risk women.[37] The WHO therefore recommended in 2019 that the injectable can be safely used by women living with HIV or at high risk of HIV infection.[38]

Combined Hormonal Contraception

CHC contains both an estrogen and a progestogen, delivered as a pill, patch, or vaginal ring. The primary mechanism of contraceptive action is to suppress ovarian activity and prevent ovulation.

Contraceptive effectiveness of CHC is highly dependent on the user. When used perfectly, the risk of unintended pregnancy in the first year of use of the pill is < 1%, but with typical use, it has been estimated to be about 7%. Severe vomiting or diarrhea, use of weight loss drugs that cause malabsorption, and bariatric surgery could all potentially reduce absorption (and thus effectiveness) of combined oral contraception. Drugs that induce the enzymes that metabolize estrogens and progestogens reduce contraceptive effectiveness of all combined contraceptive methods.

Current use of CHC is associated with increased risk of venous thromboembolism (VTE).[39] Although the absolute risk of VTE remains low during CHC use (estimated at 5–12 per 10,000 users per year), CHC should be avoided by at-risk individuals including those with thrombophilia or significant additional risk factors such as obesity and immobility. CHC users must be aware of increased thrombotic risk associated with immobility during travel and illness, and CHC should be stopped (and replaced with other effective contraception) several weeks ahead of major surgery.[40] Individuals with risk factors for cardiovascular disease such as hypertension, older age, smoking, and

TABLE 121.3 Examples of World Health Organization Medical Eligibility Criteria Category 4 Conditions for Use of Combined Hormonal Contraception[8]

- Smoking after age 35 years
- Blood pressure ≥ 160/100
- Migraine with aura
- Multiple risk factors for cardiovascular disease
- Cerebrovascular accident (current or past)
- Ischemic heart disease (current or past)
- Venous thrombosis (current or past)
- Known thrombogenic mutations
- Current breast cancer

migraine with aura should avoid the use of CHC because of the associated increased risk of thrombotic stroke and myocardial infarction.[41,42] Absolute risk of these arterial events in women of reproductive age is low even during use of CHC, with approximately two thrombotic strokes and one myocardial infarction per 10,000 CHC users per year. Current CHC use is associated with a very low increased risk of breast cancer and cervical cancer that reduces over 10 years after stopping CHC.[43] Use of CHC is contraindicated after a breast cancer diagnosis. The MEC reflect these potential CHC-associated health risks (Table 121.3).

Ever use of CHC is, however, associated with a significant reduction in risk of endometrial, ovarian, and colorectal cancer[44](Table 121.4). The risk reduction for endometrial and ovarian cancer increases with the duration of CHC use and may persist for 30 years after CHC cessation.

CHC offers additional non-contraceptive benefits. Withdrawal bleeding is generally regular, lighter than menstruation, and may be less painful. Thus, CHC may be a good option for individuals with heavy menstrual bleeding and dysmenorrhea. By elevating serum hormone-binding globulin, CHC reduces free testosterone levels and may improve acne and hirsutism related to androgen activity, including in polycystic ovarian syndrome.[45] CHC may be used to provide both contraception and hormone replacement in premature ovarian insufficiency, although menopausal symptoms often recur during any hormone-free interval.

CHC Pill

The most familiar and widely used combined contraceptive is the combined oral contraceptive pill. Most combined oral contraceptive pills contain a low dose (between 20 and 35 mcg) of the potent synthetic estrogen, ethinylestradiol, in combination with one of a range of progestogens. Most are monophasic preparations (all pills in the pack contain the same dose of estrogen and progestogen) and are designed to be taken for 21 consecutive days followed by a 7-day pill-free interval before restarting. The break in pill taking triggers a regular, 4-weekly withdrawal bleed. This bleeding pattern is acceptable to many women because they are familiar with the concept of monthly menstruation. During the pill-free interval, however, ovarian suppression is reduced, and there is a risk of escape ovulation if pill taking is not restarted on time.

Users of a monophasic preparation, designed to be taken as a regular regimen of 21 days of pills followed by 7 hormone-free days, may choose to shorten the pill-free interval to 3 or 4 days or omit it altogether. This might reduce the risk of escape ovulation and can reduce or avoid the withdrawal bleed[46] as well as withdrawal-associated symptoms such as pelvic pain and headache. Some pill preparations have a sequential change in ethinylestradiol and progestogen dose across the cycle. Such biphasic or triphasic formulations have not been demonstrated to have significant benefit over monophasic pills.[40]

The different progestogens in CHC may offer individual users different side-effect profiles. There is no one combination that is consistently associated with fewest side effects for all users. Risk of VTE is increased during use of all CHC. Absolute risk of a VTE still remains very low, but is lower for CHC pills containing norethisterone, LNG, or norgestimate than for those containing newer progestogens.[47]

With cyclical 21/7 pill use, CHC pills containing 30 or 35 mcg ethinylestradiol are generally associated with better cycle control than 20-mcg pills. Risk of venous and arterial thrombosis appears to increase with increasing ethinylestradiol dose.[47,48]

CHC pills containing 17β-estradiol and estradiol valerate rather than ethinylestradiol have been developed. These appear to have favorable metabolic profiles relative to ethinylestradiol-containing pills, but current evidence is too limited to confirm or exclude a superior cardiovascular risk profile.[49]

CHC Patch and Vaginal Ring

The combined transdermal patch delivers ethinylestradiol and norelgestromin. For 3 consecutive weeks, a patch is applied to the skin and worn for 7 days. After the third week of patch use, a 7-day patch-free interval is taken.[40]

The combined vaginal ring delivers ethinylestradiol and etonogestrel; a flexible ring is worn inside the vagina for 21 days, then removed by the user for a 7-day hormone-free interval before inserting a new ring. As with pill taking, patch and ring users may opt to use these preparations in a continuous regimen or shorten the hormone-free interval.[40]

TABLE 121.4 Risk of Cancer Among "Ever" and "Never" Users of Oral Contraceptives in the Royal College of General Practitioners' Oral Contraception Study[43]

	Cases Observed (total number, ever and never users)	Incidence Rate Ratio (99% CI), Ever Versus Never Use of OC	Risk Attributable to Ever OC Use (number per 100,000 woman years)
Breast cancer	2071	1.04 (0.91–1.17)	+4.78
Invasive cervical cancer	192	1.31 (0.84–2.04)	+3.89
Endometrial cancer	295	0.66 (0.48–0.89)	–10.14
Ovarian cancer	336	0.67 (0.50–0.89)	–11.17
Colorectal cancer	688	0.81 (0.66–0.99)	–11.31
Any cancer	7002	0.96 (0.90–1.03)	–23.65

46,022 subjects observed for up to 44 years. 884,895 woman-years of observation of ever users of OC. 388,505 woman-years of observation of never users of OC.
CI, Confidence interval; *OC*, oral contraception.

Progestogen-Only Pill

The progestogen-only pill (POP) is used less commonly than the combined oral contraceptive pill. Yet, it is as effective as CHC and is extremely safe, being devoid of the cardiovascular risks of estrogen-containing pills. There are very few contraindications to POP use. Its favorable safety profile was important in the decision to make an interim "bridging" supply possible from pharmacies in the United Kingdom along with emergency contraception (EC).[50] The POP containing 75 mcg desogestrel has been shown to inhibit ovulation; most other "traditional" POPs, however, inhibit ovulation in less than one half of cycles, relying on the progestogenic effect of thickening cervical mucus (impedes entry of sperm) for contraception.[51] Until 2021, all POP pills needed to be taken every day (without a pill-free interval) and (in order to maintain effectiveness) within a narrow time window (3 to 12 hours). A new drospirenone POP that inhibits ovulation is taken in a regimen of 24 days of pills, followed by a 4-day pill-free interval. The regimen is designed to reduce unscheduled bleeding. The drospirenone POP is not yet widely available.[52]

Irregular bleeding is a common reason for discontinuation of POP. Almost half of POP users experience prolonged bleeding and up to 70% report irregular bleeding or spotting in one or more cycles.[53] Other reported POP side effects include persistent ovarian follicles (simple cysts), worsening of preexisting acne, and mood change (a causal association between POP use and depression is not, however, established).[54]

LOW EFFECTIVENESS METHODS

Condoms

Male condoms protect against STIs including HIV.[55] Typical contraceptive failure rates are in the region of 13% (see Table 121.2) since they rely on correct, consistent use. The female condom is a lubricated polyurethane condom that is inserted into the vagina. It also protects against STIs.

Diaphragm and Cap

These are latex or silicone devices that are inserted into the vagina to prevent passage of sperm through the cervix.[55] They are inserted in advance of sex. Caps fit over the cervix, whereas the diaphragm forms a hammock between the post-fornix and the symphysis pubis. They are usually used in conjunction with a spermicide, commonly nonoxyl-9 (gel, cream, or pessary). Potential users need to be comfortable to self-examine and insert the device correctly. Typical failure rates of about 17% are reported (see Table 121.2). In some women, use may be associated with increased vaginal discharge and urinary tract infections.

Fertility Awareness-Based Methods

Formerly known as "natural family planning" methods, fertility awareness-based contraceptive methods rely on the signs and symptoms that reflect physiological changes during the menstrual cycle to identify the fertile period.[56,57] Intercourse is then avoided or a barrier method used during that fertile time. With ovarian follicular growth, circulating estrogens increase the cervical mucus which becomes thin and stretchy, facilitating the passage of sperm into the uterus. Following ovulation, progesterone secreted by the corpus luteum thickens the mucus, impeding sperm entry. Progesterone secretion results in a 0.5°C rise in basal body temperature (BBT) that identifies the end of the fertile period. By monitoring cervical mucus quality and BBT, motivated women with regular menstrual cycles can identify their fertile window.

An increasing number of electronic devices and phone apps are available that allow users to record cycle length, BBT, or the results of urinary test dipsticks that detect metabolites of LH. As well as recording these data, some apps will also use the information to help predict the timing of ovulation and thus fertile window in future cycles.

Lactational Amenorrhea

Lactation and suckling raise prolactin, disturb the pulsatile release of gonadotrophins, and so inhibit ovulation. The lactational amenorrhea method can be used for contraception with 98% protection from pregnancy if a woman is within 6 months of childbirth, and is fully (or almost fully) breastfeeding and remains amenorrheic.[58]

Sterilization

This is a permanent method of contraception that prevents sperm reaching the oocyte by obstructing the fallopian tubes.[59] It is most commonly performed laparoscopically but may be carried out at laparotomy or at the time of a cesarean section. Laparoscopic sterilization most commonly occludes the fallopian tube with Filshie clips. Follow–up data available for the Filshie clip suggests a failure rate of 2–5 per 1000 procedures after 10 years.[59] Sterilization failure may increase the risk of ectopic pregnancy. Regret rates are particularly high in women under 30 years of age (up to 30% in some studies).[60] Risks of laparoscopic sterilization include failure and injuries to the bowel, bladder, and blood vessels. Women considering sterilization should be advised that there are subsequent changes in the menstrual bleeding pattern are not due to the tubal occlusion, but due to advancing age or stopping hormonal contraception.[61] There is epidemiological evidence suggesting that bilateral salpingectomy may protect against developing high–grade serous ovarian cancer.[62] It is postulated that this may be because some epithelial cancers may originate in tubal epithelium.

Emergency Contraception

EC is defined as any drug or device used after intercourse to prevent pregnancy. When contraception has not been used or fails, the use of EC can substantially reduce a woman's risk of an unintended pregnancy. The WHO lists oral EC as an essential medicine.[63] EC is extremely safe, and, therefore, countries should have legislation and health policies that facilitate easy access to oral EC. The recommended methods of EC that are in common use include the Cu-IUD and the oral methods LNG and ulipristal acetate (UPA).

Estimates of effectiveness of EC are made from clinical trials comparing the number of observed pregnancies after EC with expected pregnancy rates in the absence of EC (based on likelihood of conception at the time of the menstrual cycle when sex occurred).[64] In recent clinical trials of LNG and UPA, the observed pregnancy rates have been low (1%–2%) and expected pregnancy rates have been calculated at around 5%.[65] One might therefore conclude that oral EC prevents around one-half to two-thirds of pregnancies.[65,66]

Availability of oral EC varies widely across the world, and access to EC is often restricted due to myths about its mechanism of action. The most common is the belief that EC is a form of abortion, rather than a contraceptive, contrary to scientific evidence.[65] Myths also exist that improving access to EC will lead to more STIs or unintended pregnancies. However, here is ample evidence that this is not the case. Adolescents can have difficulty negotiating safe sex, and it is therefore important that they also have good access to EC.

The oral EC methods UPA, a progesterone receptor modulator, and LNG, a progestogen, both work by delaying or inhibiting ovulation, until sperm are no longer viable (presumed lifespan of sperm is 5 days). UPA is licensed to be used within 120 hours of sexual intercourse and LNG within 72 hours. In a meta-analysis of comparative clinical trials, UPA oral EC was shown to be more effective than LNG.[66] This is attributed to the ability of UPA to delay ovulation even after the onset of the LH surge, whereas LNG is no longer able to delay ovulation once the surge (ovulatory trigger) has commenced.[67]

Biomedical studies have demonstrated that the EC dose of LNG or UPA does not exert significant effects on a secretory endometrium or prevent blastocyst implantation *in vitro*.[68–70] LNG and UPA use is not associated with any higher risk of miscarriage, ectopic pregnancy, pregnancy complications, or adverse effects on children conceived after exposure.[71–73]

The type and frequency of reported side effects are similar with both UPA and LNG.[65] There are no absolute contraindications to oral EC, and repeat administration in the same cycle is safe. A Cochrane review of EC reported that women who had further episodes of sex in the same cycle after EC had a 4-fold increased risk of pregnancy.[74] It is, therefore, clearly important that an ongoing method of effective contraception is commenced following EC.

In clinical trials, women with obesity were at higher risk of pregnancy after EC compared with women with a normal BMI,[75] and that in this group the risk of pregnancy was greater amongst those receiving LNG than those using UPA. Pharmacokinetic studies support this finding and have demonstrated that the EC dose of LNG takes a longer time to reach steady-state levels in women with obesity; however, this is not the case for UPA.[76,77]

Cu-IUD is by far the most effective method of EC. The effect of the device on the endometrium is thought to prevent implantation if fertilization has occurred.[12] A systematic review of 42 studies with more than 7000 women calculated that the pregnancy rate was just 1 in 1000 when a Cu-IUD was used for EC.[78] In addition, it has a longer timeframe of use after sex than oral EC. Most guidelines advise that it can be inserted up to 5 days after unprotected sex or 5 days after the earliest estimated date of ovulation, but some studies suggest that it can be inserted much later than this.[79,80] It is an underutilized method of EC as it requires an invasive procedure, and both access to the method and the availability of a healthcare professional trained in insertion.

Non-Contraceptive Benefits of Contraception

Many women will use contraception for over 30 years. Additional health benefits beyond pregnancy prevention offer significant advantages and influence acceptability. Hormonal methods in particular confer non-contraceptive benefits,[81] the commonest being reduced menstrual blood loss (Table 121.5). The 52–mg LNG–IUD is highly effective for management of heavy menstrual bleeding and is more cost–effective than other medical therapies and endometrial ablation.[80] It reduces the pain of endometriosis and adenomyosis.[81] There is evidence that the 52–mg LNG–IUD prevents and causes regression of endometrial hyperplasia and protects the endometrium against the effects of tamoxifen among women with breast cancer.[81]

TABLE 121.5 **Non-Contraceptive Uses and Benefits of Hormonal Contraception**

Method	Management of Condition	Potential Health Benefit
Levonorgestrel intrauterine device	Heavy menses Adenomyosis Endometriosis	Reduced risk of endometrial cancer
Combined hormonal contraception	Heavy menses Irregular menses Dysmenorrhea Hirsutism and acne Premenstrual syndrome	Reduced risk of ovarian cancer Reduced risk of endometrial cancer
Progestogen-only injectable	Heavy menses Endometriosis Dysmenorrhea	Reduced risk of endometrial cancer

There is good evidence that CHC pills can help reduce menstrual bleeding, acne and hirsutism, and symptoms of premenstrual syndrome.[81] The progestogen-only injectable is effective in managing the pain of endometriosis and, given the high incidence of amenorrhea, is also used for treating heavy menstrual bleeding.[81] Hormonal contraception can protect against certain cancers, the most important being the significant reduction in ovarian and endometrial cancer associated with use of the CHC pill.[44] DMPA confers a high degree of protection against endometrial carcinoma and should theoretically also protect against ovarian cancer.[81]

KEY POINTS

- Hormonal contraception can have significant non-contraceptive benefits.

SUMMARY AND FUTURE DIRECTIONS

Although there is a range of hormonal and non-hormonal methods of contraception and delivery systems, the search for new sophisticated methods should continue. Unintended pregnancy rates remain high globally, and current methods are limited by side effects, accessibility, acceptability, or convenience to the user. Additionally, it seems only natural that with advances in our understanding of reproductive biology, women should benefit from new methods of contraception that can be taken more flexibly, have fewer side effects, or confer greater non-contraceptive benefits.

Summary, 2042

KEY POINTS

- Menopause is associated with multiple potentially debilitating symptoms including, but not limited to, vasomotor symptoms (VMS), urogenital symptoms, mood changes, sleep disturbances, and decrease in bone density.
- Hormone therapy (HT) remains the most effective treatment modality for severe menopausal symptoms.
- The current recommendation is to use HT in the lowest effective dose for the shortest time needed to control symptoms.

MECHANISMS OF MENOPAUSE AND THE TRANSITION

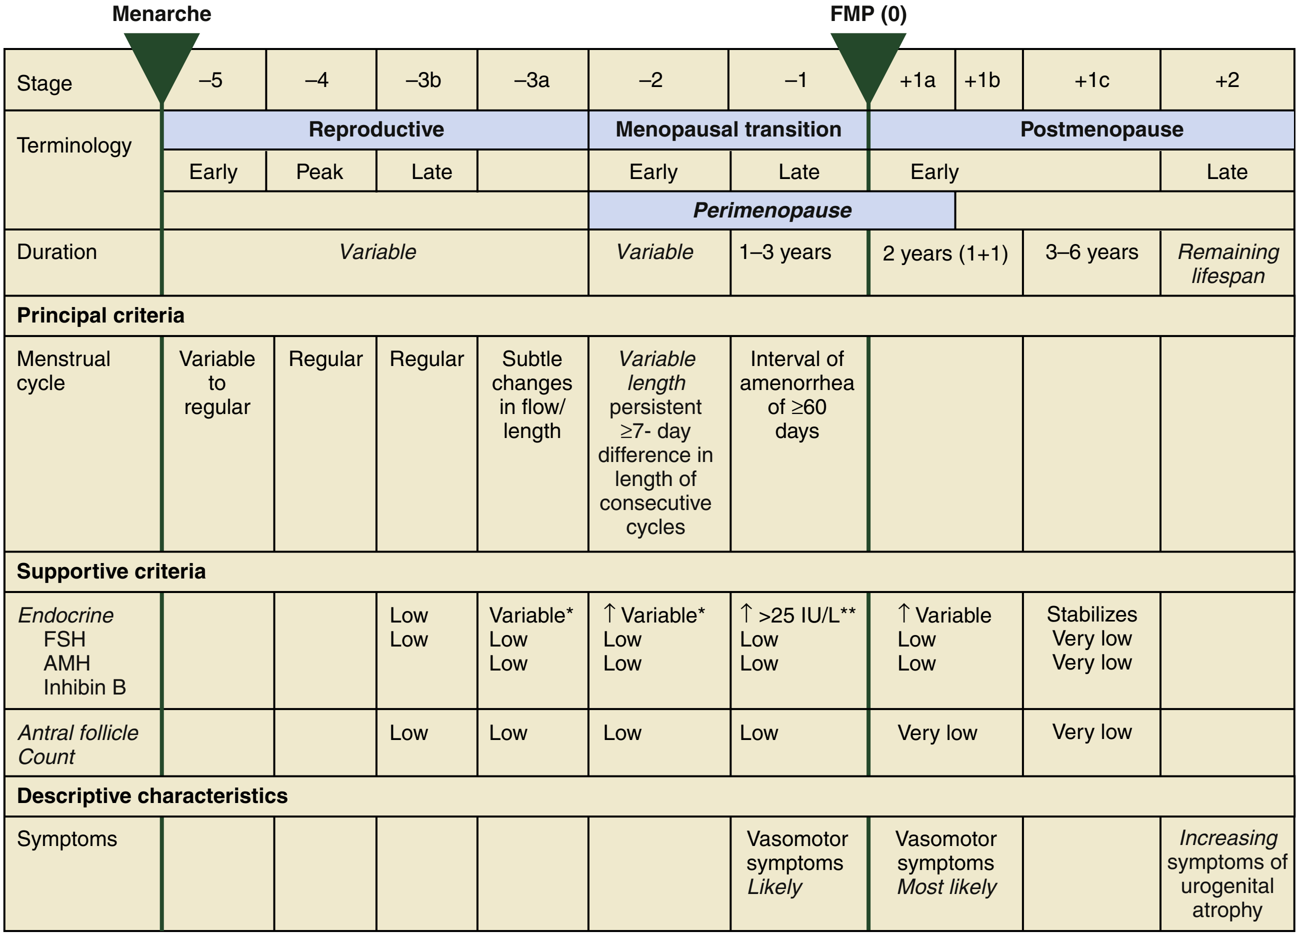
Why do human females among almost all other species survive long after menopause? In 1997, Kristen Hawkes first proposed the grandmother hypothesis of menopause,[1] an evolutionary explanation of the menopause, which supports the idea that the fitness of a population is maximized if women stop reproducing and instead help to raise their grandchildren. Continued investment in already existing children and grandchildren could increase average lifetime reproductive success to a larger degree than a woman's increasingly risky own reproduction as she grows older. Women's attitudes toward menopause range from neutral to positive, and ethnic groups within the United States vary only slightly in their attitudes toward menopause and aging.[2] Although menopause is widely viewed in a negative fashion with an excessive focus on adverse symptoms, it is important to remember that it can be a positive milestone for women.

STAGING REPRODUCTIVE AGING

The Staging Reproductive Aging workshops (STRAW) in 2001 and 2011 provided nomenclature to help standardize research and clinical care in the field.[3] The revised STRAW+10 Staging System (Fig. 122.1) is described in the following sections.

Late Reproductive Stage (Stage –3)

This stage marks the time when fecundability begins to deteriorate and a woman may begin to notice changes in her menstrual cycles. It is further subdivided into two substages (–3b and –3a). In stage –3b, periods remain regular without a change in follicle-stimulating hormone (FSH) levels; however, anti-Müllerian hormone (AMH) and antral



Menarche

FMP (0)

Stage	−5	−4	−3b	−3a	−2	−1	+1a	+1b	+1c	+2

* Blood draw on cycle days 2–5 ↑ = elevated

** Approximate expected level based on assays using current international pituitary standard[67–69]

Figure 122.1 Working model of the female reproductive life span, including but not limited to the menopausal transition. The final menstrual period (FMP) is indicated at time 0, and the menopausal transition (stages –2 through 0) encompasses the onset of increased menstrual irregularity and/or skipped menses up to the FMP. Note that intermittent elevations in early follicular phase follicle-stimulating hormone (FSH) are detectable before the onset of any clinical sign of the transition (stage –3a), and that the FMP is not defined until 1 year without menses has elapsed. *AMH,* Anti-Müllerian hormone. (From Harlow SD, Gass M, Hall JE, et al. Executive summary of the Stages of Reproductive Aging Workshop + 10: addressing the unfinished agenda of staging reproductive aging. *Fertil Steril.* 2012;97:843–851.)

follicle counts (AFC) are declining. In stage –3a, shorter cycles begin and FSH levels becomes more erratic.

Menopausal Transition

Stages –2 (early) and –1 (late) encompass the menopausal transition, which is defined by menstrual cycle and further endocrine changes. Stage –2 is defined by a persistent difference in the menstrual cycle length of 7 days or more between consecutive cycles. It also includes variable early follicular phase FSH levels and lower AMH and AFC compared with prior stages. Stage –1 is manifested by the occurrence of amenorrhea of 60 days or longer. FSH levels are sometimes elevated into the menopausal range and sometimes within normal limits for earlier reproductive years. This stage is estimated to last 1 to 3 years. The menopausal transition ends with the final menstrual period (FMP).

Menopause

The anchor point of menopause (Stage 0) is defined after 12 months of amenorrhea following the FMP and reflects a near-complete but natural decrease in ovarian hormone secretion. AMH is typically undetectable by the FMP; and AMH levels, if the assay is sufficiently sensitive, can be used to predict the FMP, especially for women aged 48 and older.[4]

Postmenopause

Stages +1 (early) and +2 (late) encompass the postmenopause. Stage +1 is further divided into stages +1a, +1b, and +1c. Stage +1a indicates the end of the 12-month period of amenorrhea required to define that the FMP has occurred. Stage +1b includes the remainder of the period of rapid change in FSH and estradiol levels. Stages +1a and +1b together are estimated to last about 2 years. Menopausal symptoms are most likely to occur during this stage. Stage +1c represents the period of stabilization of high FSH and low estradiol levels that is estimated to last 3 to 6 years. Stage +2 represents the period in which further changes in reproductive endocrine function are more limited and processes of somatic aging predominate. The duration of this stage varies since it ends with death.

Body mass index (BMI)
Depression

EPIDEMIOLOGY (TABLE 122.1)

Age of Menopause

The Study of Women's Health Across the Nation (SWAN), a multicenter multiethnic, community-based cohort study of women and the menopausal transition, reported the overall median age at natural menopause to be 52.5 years, after adjustment for other factors.[5] Studies performed outside the United States suggest that Africans,[6] Black Americans,[7] and Hispanics of Mexican descent[8] experience menopause at an earlier age than White women, as opposed to Japanese[9] and Malaysian[10] women, who report a similar median age of menopause to women of European descent. However, findings from a recent analysis of SWAN found that there were no significant differences in the age of natural menopause in women of different racial backgrounds living in the United States, when adjusted for other known demographic factors that influence the age at FMP.[5] Women who are separated, divorced, or widowed have an earlier menopause than women who are married, as do women who smoke or who report difficulty paying for the basic necessities of life.[5] Early menopause is defined as an FMP at or before 45 years of age and late menopause is defined as an FMP that occurs after 54 years of age. Early menopause is present in about 12% of women.[11] Approximately 3% of women experience hypergonadotropic amenorrhea or primary ovarian insufficiency (POI) before 40 years of age.[11] In SWAN, the median age at FMP was significantly older in women who did not smoke, reported better health at baseline, had more education, had higher baseline weight, or reported prior use of oral contraceptives.[5,12] Age at natural menopause for parous women has been reported to occur significantly later than that for nulliparous women.[5,12] A trend of increasing age at menopause with increasing number of live births has also been observed. The proposed mechanism by which parity and use of oral contraceptives may result in later age at natural menopause involves reducing ovulatory cycles earlier in life and thus preserving the oocyte pool for a longer period of time.[5]

Population-Level Determinants of Menopause

Women are born with a finite number of oocytes and go through progressive follicular loss throughout their lifespan. The primary drivers of the menopause transition are alterations in follicle number as well as follicle dynamics. AMH, a transforming growth factor-β superfamily glycoprotein, is produced by granulosa cells of developing primary, secondary, and early antral follicles and has emerged as a marker of ovarian reserve as well as timing of future menopause.[4,13] Nair et al.[13], from a heterogenous population-based sample using premenopausal women from CARDIA Women's Study, found that AMH is independently associated with age at natural menopause. A 0.5 ng/dL AMH reduction correlated with higher risk of menopause ($P < .001$) in fully adjusted discrete-time hazard models, and AMH appears most valuable in recognizing women at risk of menopause in the proximate future.[13] These findings were confirmed and refined further using the SWAN study cohort, with the observation that AMH was a better predictor for menopause than FSH, and AMH measurements could help in estimating when a woman will undergo her FMP.[4] The likelihood of a woman with an AMH < 10 pg/mL would experience her FMP within the next year ranged from 51% at < 48 years old to 79% at ≥ 51 years old. The likelihood of a woman with an AMH > 100 pg/mL would not experience her FMP within the next year ranged from 97% in women < 48 years old to 90% in women ≥ 51 years old.[4] Thus, both a low and high AMH level can be informative for clinical management. The rate of change in AMH may provide further valuable information about the timing of menopause, in that women in the PENN Ovarian Aging Study who had evidence of a more rapid decline were found to be more likely to undergo menopause sooner than those who displayed a lower rate of a decline in serial AMH measurements over time.[14]

Genetic factors have been proven to contribute to the onset of menopause as evidenced by studies involving family history and twin registries. Heritability estimates from twin and family studies for age at natural menopause range from 44% to 63%.[15,16] The association of menopause with heritability has led to many genome-wide association studies (GWAS) that have identified loci for age at menarche and age at natural menopause. To date, 44 genetic loci have been identified for age at natural menopause, but these likely only account for a small portion of overall heritability.[17] Many of these genes are linked to premature menopause (see below) and have been found to play a fundamental role in genome stability and DNA repair.[17]

Determinants of Early Menopause and Primary Ovarian Insufficiency

Single gene mutations, chromosomal deletions, and genetic variants have been shown to influence the timing of menopause, and many of these genetic alterations are associated with early menopause (less than age 45) and POI (less than age 40). The blepharophimosis gene, located on chromosome 3, X-chromosome deletions such as *POF 1* and *POF 2* genes, and mutations in the forkhead transcription factor FOX have been shown to predispose women to an earlier menopause or POI. POI and early menopause share the same genetic features and appear to represent variable expression of the same disease.[17] Fragile X syndrome premutation carriers are prone to premature menopause. The *PvuII* polymorphic allele for estrogen receptor alpha (ERα) has been associated with a slightly earlier age at natural menopause.[18] DNA mismatch repair and other genome maintenance genes and immune modulators are associated with POI as well as being determinants of age at natural menopause.[19] Several of the genes identified to date as responsible for POI and early menopause appear to play a critical regulatory role in primordial follicle activation (see below).

Environmental toxicants may also play a role in early menopause. Current smokers tend to experience menopause at an earlier age (1 to 2 years) than nonsmokers,[5] and may have a shorter menopausal transition.[12] Polycyclic hydrocarbons in cigarette smoke are believed to be toxic to ovarian follicles[20] and may lead to their loss, and thus an earlier menopause in smokers. Irradiation and chemotherapy with alkylating cytotoxics are iatrogenic causes of earlier menopause.[21] Evidence suggests that galactose consumption through the ingestion of high-lactose dairy foods may be a dietary risk factor, and that galactose metabolism, as measured by galactose-1-phosphate uridyl transferase, is a genetic risk factor for early menopause.[22]

Women with a history of medically treated depression have a 20% increased rate of entering perimenopause sooner than women with no depression history after adjustment for age, parity, age at menarche, education, cigarette smoking, and body mass index (BMI).[23]

PATHOPHYSIOLOGY OF MENOPAUSE

Ovarian Follicle Depletion—Current State of Knowledge

The basis of reproductive senescence in women is oocyte/follicle depletion in the ovary. The most massive wave of atresia (follicle loss) that a woman ever experiences happens before she is born. Developmentally, a woman attains her peak oocyte complement at 20 weeks' gestational age. Between 20 and 40 weeks' gestation, the total oocyte count drops from a mean of about 6 to 8 million to 1 to 2 million. By the onset of puberty, germ cell mass has been reduced to 300,000 to 500,000 units. Subsequent reproductive aging consists of a steady loss of oocytes through atresia or ovulation and does not necessarily occur at a constant rate. Atresia is an apoptotic process. During the 35 to 40 years of reproductive life, 400 to 500 oocytes will be selected for ovulation. By menopause, only a few hundred follicles will remain.[24] The relatively wide age range (42 to 58 years) for menopause in normal women seems to indicate that initial oocyte endowment in women is highly variable, or that the rate of oocyte loss varies greatly. The concept that women are endowed with a finite oocyte number that can only be lost and never replenished has been challenged by several studies and is an active area of investigation. Current evidence suggests that mammalian females may generate new oocytes during adult life through the activity of germline stem cells.[25,26] Whether or not human females can regenerate oocytes from oogonial stem cells is highly controversial. Current research directed towards repopulating the human ovary with mesenchymal stem cells is underway, but convincing medical evidence has not yet been forthcoming.

Follicular Growth Activation and Atresia

Developing follicles can be divided into gonadotropin-independent preantral follicle growth and gonadotropin-dependent antral follicle growth (Fig. 122.2). Primordial follicle growth activation (PFGA) occurs when dormant individual follicles are recruited to a growth phase that can result in the development of a preovulatory follicle hosting an immature oocyte. The rate of PFGA is a key factor of ovarian aging. c-Kit/Kit ligand (KL) signaling was one of the initial pathways identified as a PFGA regulatory mechanism. Interruption of this pathway results in heightened arrest of primordial follicles and a decrease in the amount of preantral and antral follicles.[27] A second key regulatory molecule is FoxO3. *FoxO3* knockout mice exhibit a full commitment of primordial follicles to growth early in life that results in the exhaustion of the entire primordial follicle pool by 2–3 months of age. Other central negative regulators of PFGA include phosphatase and tensin homolog (Pten), protein kinase Akt, and mechanistic target of rapamycin (mTOR). High Pten activity downregulates Akt resulting in low downstream mTOR activity; this interaction culminates in impeded cell cycle progression. Absence of negative regulators such as *Pten*, *FoxO3*, and mTOR in mouse models results in vastly accelerated PFGA and early life depletion of the primordial follicle pool.[27] Further understanding of factors that regulate entry into the growing follicle pool is likely to inform treatment targets to prevent early or premature menopause, as many of the genes and gene pathways identified herein are associated with POI and early menopause.

Ovarian and Pituitary Hormones

Concurrent with the loss of ovarian follicles as a woman transitions to menopause are hormonal changes in the hypothalamic-pituitary-ovarian axis. FSH is an indirect marker of follicular activity; as follicle numbers decline, FSH levels increase.[28] In the late reproductive years, initial elevations in FSH are most prominent in the early follicular phase of the menstrual cycle but are intermittent, i.e., they do not occur in every cycle, and they are clinically silent.[28] The rise in FSH appears to be the result of a decline in ovarian inhibin B, a dimeric protein secreted by the growing granulosa cells that surround the oocyte. Inhibin serves to selectively inhibit FSH by binding to receptors on the anterior pituitary gonadotrophs.[28] As the pool of growing follicles shrinks with the overall decline in follicle numbers that occurs with aging, inhibin production is decreased. Circulating estradiol is stable or even elevated during the earlier menopause transition, because the dominant follicle still matures monthly and secretes over 90% of the estradiol produced at midcycle; closer to the FMP, a decline in estradiol can be clearly observed.[28,29] The decline in inhibin B precedes the increase in FSH and the decline in estradiol that occur later in the

Figure 122.2 Ovarian follicles at various stages of development. Follicular growth can be divided into gonadotropin-independent and gonadotropin-dependent phases. Primordial follicles represent the ovarian reserve pool from which all other follicles are derived, and the rate of primordial follicle growth activation (PFGA) is a key factor of ovarian aging. c-Kit/Kit Ligand (KL) signaling is a key regulatory pathway identified in activating primordial follicle growth, and interruption of this pathway results in heightened arrest of primordial follicles and a decrease in the amount of preantral and antral follicles. Other central negative regulators of PFGA include forkhead transcription factor 3 (FoxO3), phosphatase and tensin homolog (Pten), protein kinase Akt, and mechanistic target of rapamycin (mTOR). Absence of these negative regulators results in vastly accelerated PFGA and early life depletion of the primordial follicle pool. *AMH,* Anti-Müllerian hormone. (From Santoro N, Johnson J. Diagnosing the onset of menopause. *JAMA.* 2019;322:775–776.)

transition.[29] AMH, produced by preantral and antral follicles, inhibits initial follicular recruitment and inhibits FSH-dependent growth and selection of preantral and small antral follicles.[30] As the follicular pool decreases in patients approaching menopause, AMH levels will also decrease which can contribute to more rapid activation and depletion of primordial follicles.

Although circulating FSH and estradiol vary near menopause, steroidogenic enzymes are completely absent in the postmenopausal ovary after all functional follicles are lost.[31] Between 20 and 40 years of age, concentrations of total testosterone fall by about 50%.[32] This age-related decline does not change further during the transition years. Similarly, dehydroepiandosterone (DHEA) and its sulfate, DHEAS, decline with age.[33] Because circulating sex hormone-binding globulin (SHBG) decreases across the menopausal transition, free androgen levels rise, as indicated by a small increase in free androgen index (T ÷ SHBG × 100).[34] Androstenedione, which remains relatively stable during the transition, is converted to estrone in extraglandular tissue. This accounts for almost all the circulating estrogen after menopause. When ovulation stops, concurrent with a woman's FMP, serum progesterone levels are invariably low.

CLINICAL PRESENTATION

The "Core Four" Symptoms: Hot Flashes, Vaginal Dryness, Adverse Mood, and Poor Sleep

Impending menopause is clinically evident when a woman observes menstrual cycle changes. A normal menstrual cycle ranges from every 21 to 35 days. Anovulatory cycles become more common as women progress through the menopause transition, and cycle lengths become increasingly variable. By the late menopausal transition, that ultimately ends with FMP, amenorrhea of 60 days or longer occurs.[3] These menstrual cycle changes are related to the increase in overall symptoms. Entry into the early menopause transition is accompanied by generally mild but increased symptoms, and by the late transition symptoms usually peak, and thereafter most will gradually subside (except for vaginal dryness, which will not improve without treatment). It is sometimes difficult to differentiate symptoms or clinical complaints that are truly associated with menopause from those due to aging. Hot flashes, night sweats, and vaginal dryness are most clearly tied to the menopausal transition, and there is some positive evidence of a menopausal link for sleep disturbance. Mood symptoms, such as anxiety and major depression, have been tied to the menopausal transition.[35]

Vasomotor Symptoms (Hot Flashes and Night Sweats)

Hot flashes are considered to be a hallmark symptom of the menopausal transition, and approximately 60% to 80% of menopausal women experience hot flashes at some point during the menopausal transition.[36] The extent to what genetic factors play a role in who will experience VMS is unknown, but recent GWAS studies have shown that genetic variations in tachykinin receptor 3 *(TACR3)* may contribute to the risk of VMS.[37] Hot flashes are commonly defined as transient periods of intense heat in the upper arms and face, which often are followed by flushing of the skin and profuse sweating.[38] Many hot flashes are followed by chills and can be accompanied by palpitations and a sense of anxiety. Almost two thirds of women seek medical attention, usually those who are more symptomatic, with VMS and adverse mood being the biggest motivators.[39] Hot flashes negatively affect quality of life for women by causing sleep disturbances, which often result in fatigue, irritability, forgetfulness, acute physical discomfort, and negative effects on work.[39] The natural history of hot flashes has been examined in a longitudinal sample of women from SWAN; the median total duration of hot flashes was 7.4 years, with a median persistence of 4.5 years past the FMP. Women with onset of bothersome hot flashes earlier in the transition tended to have a longer total duration. Median hot flash duration was longest for Black American women (10.1 years).[40]

Although the etiology of hot flashes is not entirely clear, studies suggest that estrogen levels play a role in inhibiting the thermoregulatory center and expression of VMS. KNDy neurons, located within the arcuate nucleus of the hypothalamus, project to thermoregulatory areas in the median preoptic nucleus that express neurokinin 3 receptors (NK_3R). The median preoptic nucleus is vital for heat dissipation via cutaneous vasodilation. ERα is required for estrogen negative feedback and is located on KNDy neurons. A decrease in E_2 levels seen in menopause stimulates KNDy neurons to active NK_3R on the median preoptic nucleus which alters the thermoregulatory response giving rise to hot flashes.[41]

Vaginal Dryness

Vaginal dryness, due to decreased estrogen exposure, is another common symptom associated with the menopause transition. Transudative fluid leaked from capillaries across the vaginal epithelial cells is responsible for vaginal lubrication, and estrogen is a major contributing factor for this process. In particular for menopause, low estrogen levels results in atrophic epithelial cells, and thus a decrease in transudative fluid.[42] In SWAN participants, the prevalence of vaginal dryness increased from 19.4% among all women at baseline (ages 42–53 years) to 34.0% at the ages 57–69 years at baseline,[43] and vaginal dryness was most prevalent in Hispanic women.[44] Early perimenopausal women reported greater pain with intercourse than premenopausal women,[45] and a decline in sexual function was observed 20 months prior to the FMP.[46] Over 75% of the middle-aged women in the SWAN study reported that sex was moderately to extremely important to them, underscoring the clinical importance of evaluating this complaint

Adverse Mood

Data from SWAN showed that in a large sample of middle-aged women, during 10 years of follow-up, women who had low anxiety at baseline were significantly more likely to develop high-anxiety symptoms at perimenopause or postmenopause than at premenopause, independent of multiple risk factors, including upsetting life events, financial strain, fair/poor perceived health, and VMS. However, among women who started the study with high anxiety, menopausal stage was not associated with an increase in anxiety whether or not VMS were included in the analyses. In addition, SWAN and other cohort studies have clearly shown that the late perimenopause is a period of increased risk for depressive symptoms as well as clinical and subclinical depressive disorders.[35]

Sleep Disturbances

Poor sleep is associated with natural menopause, and the highest rates of sleep disturbances are reported in late perimenopausal women. There are many variables that contribute to sleep difficulty during menopause rather than a single primary determinant.

While age and VMS are contributing factors to poor sleep, SWAN data implies that the menopausal transition independent of age is linked to self-reported sleep difficulty, and subgroup analyses limited to women without VMS continue to find a relationship between the perimenopause and diminished sleep quality. Many additional contributing factors that were associated with sleep difficulty included depression, anxiety, quality of life, self-perceived health, current smoker, sedentary lifestyle, and arthritis.[47] In another population-based study of perimenopausal women that included 14 years of follow-up, a high prevalence of poor sleep was reported in middle-aged women; premenopausal baseline sleep status and simultaneous hot flashes strongly and regularly predicted poor sleep in the menopause transition.[48]

Other Symptoms

Menstrual migraines peak during the transitional years, as do often unrecognized hot flashes around menses.[49] In the early menopause transition, breast soreness-tenderness is significantly more common, but as the menopause transition progresses, more hypoestrogenic symptoms such as hot flashes, vaginal dryness, and night sweats occur with greater frequency.[50] Neuromuscular symptoms have been found to be stable throughout the menopausal transition, suggesting that other events in a midlife woman's life (i.e., life stress and acute and chronic illnesses) account for the common complaint of joint pain.[51]

KEY POINTS

- Menopause is associated with multiple potentially debilitating symptoms including, but not limited to, vasomotor symptoms (VMS), urogenital symptoms, mood changes, sleep disturbances, and decrease in bone density.

REPRODUCTIVE AND SOMATIC AGING

Hypothalamic-Pituitary-Ovarian Axis

Reproductive aging is confounded by somatic aging. All women do not age at the same rate. Menopause has been regarded historically as a primary ovarian event, with associated changes in pituitary gonadotropin secretion occurring secondary to the decline in ovarian sex steroid and protein production. However, increasing evidence suggests that aging is associated with dynamic changes in the hypothalamic and pituitary components of the reproductive axis that are independent of changes in gonadal hormone secretion. Using gonadotropin free α-subunit as a surrogate marker of gonadotropin-releasing hormone (GnRH) pulse frequency in postmenopausal women, Hall et al.[52] demonstrated a 35% decline in GnRH pulse frequency between the fifth and eighth decades of life, providing evidence of slowing of hypothalamic GnRH pulse generator activity. Other studies in which LH was used as a marker for GnRH secretion have shown variable results. Santoro et al.[53] did not observe a different rate of LH secretion in postmenopausal women who were compared with young women with premature ovarian failure, but older women had less overall organization of their LH secretion, and LH was much more readily suppressed by exogenous estradiol. Taken together, there appears to be an overall decline in hypothalamic-pituitary organization and output in association with aging per se apart from menopause.

Somatotropic Axis

The "somatopause" refers to the age-related drop in growth hormone (GH) and it begins prior to the menopause. The 24-hour GH secretion decreases in women before the onset of estrogen deficiency, and insulin-like growth factor-1 (IGF-1) levels in adults progressively decline with age.[54] Because IGF-1 is a cofactor for FSH action, additional gonadal compromise may be imposed by reduced somatotropic axis function.[55] Animal studies demonstrate the necessity of interactions between estrogen and IGF-1 for reproductive and menstrual functioning, suggesting direct mechanisms by which somatopause may hasten reproductive aging.[56] The known association of increased levels of physical activity with elevated IGF-1 levels in premenopausal women raises the possibility that decreased physical activity associated with aging hastens natural somatopause and may also hasten reproductive aging.[57] The somatotropic axis may be amenable to modulation using relatively simple modalities. One small study of progesterone supplementation in postmenopausal women observed a restoration of more youthful GH secretion. Progesterone has been shown by others to prevent sleep disturbances and to positively modulate GH, thyroid-stimulating hormone (TSH), and melatonin secretion in postmenopausal women.[58] Estrogen also modulates the somatotropic axis. Women with POI have reduced circulating IGF-1 compared with age-matched eugonadal women, supporting age- and estrogen-dependent changes.[59] Body composition changes, including an increase in body fat in the visceral/abdominal compartment and a decrease in lean body mass, as well as adverse changes in lipoproteins, a relative increase in insulin resistance, and a reduction in aerobic capacity, are thought to be secondary to changes in the somatotropic axis.[60]

Thyroid

As with other endocrine systems, aging is associated with significant changes in the anatomy of the thyroid gland and modifications in the physiology of the hypothalamic-pituitary-thyroid axis. Subtle changes in the hypothalamic-pituitary-thyroid axis suggest decreased hypothalamic stimulation of thyroid function with aging.[61] The TSH nocturnal surge may be lost with increasing age.[62] Moreover, thyroid hormone clearance decreases with age, which explains the reduced dosing needs for daily replacement of thyroxine in hypothyroid older adults.[63] Progesterone supplementation in postmenopausal women has been found to decrease TSH levels, implying that loss of endogenous progesterone is associated with the age-related rise in TSH.[58]

Adrenal

With aging, minimal and mean cortisol plasma concentrations increase, with no alteration noted in pulsatile frequency, and the diurnal amplitude of cortisol and adrenocorticotropic hormone relative to the 24-hour mean of hormones shows an age-related decline.[64] In addition, the evening cortisol quiescent period is shortened in older adults, suggesting an increasingly impaired circadian function with aging. Despite maintenance of corticosteroid secretion, DHEAS levels decline with age,[65] while testosterone levels are preserved.[33] However, DHEAS levels are not consistently lower in younger women with POI,[66] suggesting that these changes are not completely estrogen dependent. Declining DHEAS in menopausal women has been associated with bone loss[67] and a higher risk for cardiovascular mortality.[68] However, during the late menopausal transition, DHEAS rises transiently. During this transient rise in DHEAS, higher DHEAS was positively associated with depression in one cohort study.[69] The complexities of age- and hormone-dependent changes in adrenal function in women to date are incompletely understood.

Bone

In relation to bone and aging around the menopausal transition, the late menopausal transition is clearly the point in time at which menopause-associated bone resorption begins. Results from SWAN showed that bone mineral density (BMD) loss began 1 year before the FMP and decelerated (but did not cease) 2 years after the FMP (termed the transmenopause), at both the lumbar spine (LS) and femoral neck sites.[70] SWAN has also observed that in premenopausal and early perimenopausal women, higher FSH concentrations were positively associated with greater bone turnover before the last menstrual period, as assessed by higher serum osteocalcin and urinary N-telopeptide of type I collagen concentrations.[70] Serum FSH was inversely correlated with BMD, and BMD tended to be lower in women in the late perimenopause or early postmenopause versus those in the early perimenopause.[70] Finally, SWAN found that more sport and home physical activity, compared with work and active living activity, were statistically significantly associated with greater BMD,[70] suggesting the importance of preserving activity in middle-aged women.

Cognition

Cognitive function declines with age. Leisure activity may mitigate those effects. In a prospective, cohort study, Verghese et al.[71] found that reading and playing board games were associated with reduced risks for dementia and Alzheimer's disease. Combined clinical and functional MRI assessment of cognition has found age-independent effects of menopause on cognition, suggesting that at least some contributions to cognitive decline may have a hormonal basis.[72] This is particularly evident in short-term memory and learning, which have been shown to decrease during the late menopausal transition, but come back to near-premenopausal levels after menopause.[73] The PENN Ovarian Aging study also showed a decrement in verbal memory throughout the menopausal transition, independent of age.[74]

Epidemiological and observational studies support a cognitive benefit for hormones, but clinical trials have not supported these findings. For example, women in the Wisconsin Registry for Alzheimer's Prevention who used hormonal contraceptives had higher cognitive scores than nonusers, and the association was stronger with the duration of use.[75] In contrast, the Women's Health Initiative (WHI) memory study demonstrated a detrimental effect of estrogen + progesterone on verbal memory and a trend for positive impact on figural memory,[76] whereas estrogen alone was associated with overall worse cognition, especially among women with impaired cognitive function at baseline.[77] When the data were pooled between the estrogen + progesterone and estrogen alone trials, and the end points of dementia and mild cognitive impairment were assessed, HT overall increased the risk for dementia.[78] Given the hierarchy of evidence favoring clinical trials over observational data, HT should not currently be given with the expectation that it will prevent cognitive decline. To reconcile the divergent findings between the observational studies and randomized clinical trials, a "critical window" hypothesis has been advanced that posits that the effects of HT depend upon the timing of initiation with respect to age and the menopausal transition. While this hypothesis may be correct, a recent review strongly suggests that a definitive test of this hypothesis may not be feasible.[79] The Kronos Early Estrogen Prevention Study (KEEPS) included an exhaustive cognitive battery of tests on > 700 recently menopausal women who were randomized to transdermal or oral estrogen, both with intermittent progesterone, or to placebo and observed an overall neutral effect of hormones on cognition.[80] Henderson et al.[81] found similar neutral findings in their RCT, with a total of 567 healthy women randomly assigned to oral 17β-estradiol 1 mg/day or placebo within 6 years of menopause or 10+ years after menopause. There were no differences in executive function, verbal memory, or global cognition when estradiol was initiated within 6 years of menopause or if begun 10+ years after menopause.

Cardiovascular

The aging process is associated with predictable anatomic and physiologic alterations in the cardiovascular system. A gradual increase in the circumference of all four cardiac valves occurs with age.[82] Histologic changes detected in the vasculature include increased intimal thickness, elastin fragmentation, and increased collagen content of the arterial wall. Finally, the natural history of heart disease is adversely affected by age.[83] Atherosclerosis progression is especially prominent in late postmenopausal women. HT to prevent cardiovascular disease in menopausal patients has been extensively studied, but the data remain controversial. The WHI demonstrated a negative overall risk/benefit ratio of HT for cardiovascular protection in menopausal women; however, when the data were analyzed post-hoc by decade (50–59, 60–69, and 70–79 years), a small benefit was observed in the youngest group of women aged 50–59, HT appeared risk-neutral in women aged 60–69, and only women aged 70–79 had evidence of harm. Thus, the "timing hypothesis" has again been invoked to explain how HT may have multiple beneficial effects when administered during the early period after menopause, but not during the late postmenopausal period. The Early versus Late Intervention Trial of Estradiol (ELITE) study, a single-site RCT of 643 healthy postmenopausal women, stratified the sample according to time since menopause (early postmenopause as < 6 years or late postmenopause as ≥ 10 years). Women were randomly assigned to either oral 17β-estradiol or placebo (with intermittent progesterone or placebo progesterone). The ELITE study found that oral estradiol therapy initiated within 6 years after menopause was associated with a decreased development of subclinical atherosclerosis (measured as carotid artery intima-media thickness [CIMT]) compared with placebo but not when it was initiated ≥ 10 years after menopause.[84] The KEEPS studied > 700 menopausal women who were within 3 years of their FMP who were randomized to transdermal or oral estrogen, both with intermittent progesterone, or to placebo and did not find a difference in progression of CIMT, but also did not find any evidence for harm of HT.[80]

Some data suggest that women with menopause symptoms have a worse cardiovascular profile[85] and a recent study suggests that severe VMS may be related to increased epigenetic aging.[86] However, data from the Rancho Bernardo cohort study of 867 postmenopausal women indicates the opposite, in that women who suffer more severe hot flashes and especially night sweats had fewer cardiovascular events.[87] A lack of association between menopausal symptoms and subclinical atherosclerosis was confirmed by Wolff et al.,[88] who found that, among recently menopausal women screened for KEEPS, neither circulating estradiol nor menopausal symptoms predicted the degree of subclinical atherosclerosis. In SWAN, women with either surgical or natural menopause demonstrated decreased physical activity.[89] This is another factor that could mediate cardiovascular risk.

Estrogen-Dependent Disorders

Abnormal uterine bleeding is common during the menopausal transition, and largely attributable to the increase in anovulatory cycles and the appearance of anatomic disorders. In the Seattle Midlife Women's Health Study, the most common subjective menstrual cycle changes prior to the menopause transition included a lighter menstrual flow (32%), a heavier menstrual flow (29%), a shorter duration of flow (24%), and a longer duration of flow (20%).[90] When compared to perimenopausal women with no menstrual complaints, subjective reports of heavy flow in perimenopausal women were associated with higher levels of estradiol throughout the menstrual cycle.[91] Besides anovulatory cycles, common causes of abnormal uterine bleeding in perimenopausal women include leiomyomata and adenomyosis, emphasizing the importance of correct diagnosis to inform treatment.[92]

Leiomyomata uteri are the most common benign neoplasia of the uterine musculature in women.[93] They are clinically troublesome throughout a woman's reproductive years and typically regress and become clinically quiescent after menopause. However, for some women, the erratic estrogen levels that accompany the early menopausal transition lead to leiomyomata growth, necessitating intervention. It has also been hypothesized that local dysregulation of growth factors within leiomyoma leads to increased vasculogenesis and precipitates bleeding.[94] Polyps can also present with abnormal uterine bleeding in the transition. Relatively little is known about the natural history of these two common conditions throughout menopause. One longitudinal study of women, enrolled at a mean age of 44, indicated that 70% of women with polyps, more than twice the number of women without polyps, reported abnormal uterine bleeding.[95] The behavior of leiomyomata was more variable, with some large increases in size observed in asymptomatic women, but a general regression in size as women aged.

The menopausal transition is associated with the development of stress urinary incontinence.[96] This relationship does not appear to be attributable to estrogen withdrawal, as Waetjen et al.[97] recently found that estradiol levels had no association with the development or worsening of incontinence in women transitioning through menopause in SWAN.

DIAGNOSIS

Despite the population trend of elevated FSH and decreased estradiol with progression through the transition, measurement of FSH, inhibin, or estradiol provide at best an unreliable guide to the menopausal status of an individual woman.[29] Although there is accumulating evidence supporting AMH as a stronger predictor of the FMP than age, AFC, or ovarian volume, an ultrasensitive ELISA is required to provide a reliable index of ovarian aging in the clinical setting, and confirmation of current evidence is needed before recommending AMH as the "menopause test."[4] For most clinical circumstances in women who present with perimenopausal complaints, the most rational approach to diagnosing menopause can be based on an assessment of menstrual cycle patterns and of the longitudinal symptoms. Hormone profiles correlate well with symptoms and cycle features.[98] Thus, if a woman is > 45 years old and has had a recent disruption in her menstrual pattern and symptoms suggestive of transient hypoestrogenemia, it is likely that she has entered her menopausal transition.[55] That being said, the clinician should take care to rule out other pathologies that can be masked by common complaints associated with the menopausal transition. At minimum, a screening TSH level should be performed, as menstrual irregularity may be the only manifestation of thyroid dysfunction.[99]

Many women experience a loss of "wellness" and dysphoric mood during the menopausal transition; these syndromes should be formally distinguished from the more severe and life-threatening risk that clinical depression may pose. Cohen et al.[100] reported that women with no lifetime history of depression, who enter the menopausal transition earlier, have a significant risk for a new onset of major depression as compared with women who remain premenopausal. Analysis of women participating in SWAN revealed that 15.8% of participants with no history of major depressive disorder developed symptoms of major depression over the course of 7 years. Lifetime history of an anxiety disorder and a very stressful life event prior to depression onset also predicted a first episode of major depression.[101]

Atypical hot flashes can be due to non–estrogen-related causes, including new-onset diabetes with autonomic dysfunction, carcinoid, pheochromocytoma, and medication side effects.[102] Women who appear to be entering the menopausal transition earlier than 40 years of age should have a more extensive workup, including screening appropriate for patients with POI.[103]

TREATMENT

Hormone Therapy Overview

It is important to separate short-term and long-term therapeutic goals with patients when discussing treatment options during and after the menopausal transition because short-term (<5 years) and long-term (≥5 years) benefits and harms differ.[104,105] It is challenging for both physicians and patients to interpret the literature, which is often based on aggregate epidemiologic, observational, or clinical trial data, and to apply it to the individual to counsel appropriately. The role of short-term therapy for symptom relief is considerably less complicated because the benefits are immediate and often large.

Some women go through their menopausal transition without notice, others are severely affected, and most have symptoms that are somewhat bothersome. Distinguishing symptoms related to the menopause transition versus those related to the normal aging process is a helpful first step in determining the usefulness of HT. In general, VMS, sleep disturbances, and vaginal symptoms show the strongest and most consistent association with the transition into menopause, and mounting supportive evidence suggests that depression and sexual dysfunction may be independently related to the menopause as well.[106] Choosing the best treatment option for an individual woman involves knowledge of the risks and benefits of each treatment.

The North American Menopause Society (NAMS) describe the comprehensive benefits compared with risks of HT for both treatment of menopause-related symptoms and its consideration for longer-term use based on the time since the FMP.[106] According to the statement, "HT remains the most effective treatment for VMS and the genitourinary syndrome of menopause (GSM) and has been shown to prevent bone loss and fracture. The risks of HT differ depending on type, dose, duration of use, route of administration, timing of initiation, and whether a progestogen is used. Treatment should be individualized to identify the most appropriate HT type, dose, formulation, route of administration, and duration of use, using the best available evidence to maximize benefits and minimize risks, with periodic reevaluation of the benefits and risks of continuing or discontinuing HT. For women aged younger than 60 years or who are within 10 years of menopause onset and have no contraindications, the benefit-risk ratio is most favorable for treatment of bothersome VMS and for those at elevated risk for bone loss or fracture. For women who initiate HT more than 10 or 20 years from menopause onset or are aged 60 years or older, the benefit-risk ratio appears less favorable because of the greater absolute risks of coronary heart disease (CHD), stroke, venous thromboembolism (VTE), and dementia."[106] NAMS as well as other organizations that have issued guidelines on HT (the American College of Obstetricians and Gynecologists and the Endocrine Society) endorse non-oral estrogen to minimize the risk for VTE.[105]

KEY POINTS

- Hormone therapy (HT) remains the most effective treatment modality for severe menopausal symptoms.

Vasomotor Symptoms

Behavioral techniques can be beneficial for mild-moderate hot flashes, but none are evidence-based. Encouraging patients to wear layered clothing that can be added or removed easily can help a woman maintain control of her core body temperature. Changes in dietary habits such as avoiding spicy foods and reducing caffeine and excess alcohol intake, which can cause flushing, can be beneficial. Patients should be told that regular physical activity, a balanced diet, and stress reduction (particularly paced breathing) may be of additional help in decreasing vasomotor flushing.

HT remains the most effective pharmacologic option for the treatment of VMS. More than 40 RCTs of oral and transdermal estrogen have reported a reduction in the severity of VMS, and estrogen was effective in doses lower than the usual 0.625 mg of equine estrogen or equivalent. Transdermal estradiol, transdermal estradiol spray, as well as gels, vaginal rings, and intranasal 17β-estradiol spray are all approved by the Food and Drug Administration (FDA) with demonstrated efficacy in reducing hot flashes. A systematic review of 32 included trials comparing conjugated equine estrogens (CEE) versus 17β-estradiol (oral and transdermal) for reducing hot flashes found them to be comparable in effectiveness.[107]

To optimize compliance and patient satisfaction, selection of the most appropriate regimen of HT (dose, route of administration, and schedule) for the needs of each individual is important. The risk for endometrial hyperplasia and cancer, associated with unopposed estrogen use in perimenopausal and postmenopausal women who have a uterus, is decreased by supplementing the patient with progestogen. Progestogen can be administered orally, transdermally, or vaginally, or even intrauterine, via a levonorgestrel-impregnated intrauterine device (LNG-IUD).[108]

The largest systematic review and meta-analysis to date of double-blind, placebo-controlled RCTs of non-hormonal therapies available for the treatment of VMS showed supportive evidence for the efficacy of selective serotonin reuptake inhibitors (SSRIs), clonidine, and gabapentin in reducing the frequency and severity of menopausal hot flashes.[109] On average, SSRIs provide a 60% reduction in hot flash frequency and severity, but carry significant side effects.[110] Gabapentin, at doses between 300 and 900 mg/day, reduced hot flashes by as much as 45% in two double-blind, placebo-controlled RCTs, with a chief limiting side effect of sedation.[109] Both oral and transdermal clonidine may be beneficial for some patients, but can be associated with postural hypotension.[109] Depot medroxyprogesterone acetate (MPA),[111] oral megestrol acetate,[112] and micronized progesterone at a 300-mg nightly dose are effective in the treatment of severe VMS.[113]

The tissue-selective estrogen complex which combines a selective estrogen receptor modulator (SERM) with estrogen is a relatively new treatment for menopausal symptoms. A combination of a daily dose of 20 mg of the SERM bazedoxifene (BZA) with 0.45 mg or 0.625 mg of CEE is a non-progestogen therapy that has been approved for the prevention of osteoporosis and treatment of VMS. The SMART trial, a double-blinded RCT, showed a low incidence (<1%) of endometrial hyperplasia with BZA/conjugate estrogen (CE), and the BZA/CE group showed significantly greater increases in LS and total hip BMD than placebo.[114] This new form of treatment can be considered in patients with progestin intolerance or those with breakthrough bleeding unresponsive to hormonal manipulation.

On the horizon for treatment of VMS are NK3R antagonists which are currently in clinical trial. NK3R activation stimulates the thermoregulatory center in the hypothalamus which contributes to VMS of menopause. Early data has had favorable results showing promise as a future non-hormonal treatment for VMS of menopause.[115]

Urogenital Symptoms (GSM)

Treatment of vulvovaginal atrophy should focus on relieving atrophic anatomic changes resulting from low estrogen levels. Over-the-counter vaginal lubricants and moisturizers are commonly used as a first-line treatment of vaginal atrophy–related symptoms.

Estrogen by any route, whether oral, transdermal, or vaginal, improves urogenital symptoms. Topical estrogens (cream, tablet, ring, or insert) avoid the higher circulating levels of estradiol found with systemic preparations, and appear to be safe for long-term use.[116] Topical estrogen can relieve sexual dysfunction if dyspareunia is the underlying deterrent.

Data regarding the influence of HT on urinary incontinence symptoms are mixed. A Cochrane Database meta-analysis, which covered a total of 19,313 incontinent women among whom 9417 were treated with HT in 33 studies, reported worsening urinary incontinence symptoms for systemic HT. However, topical vaginal estrogen was associated with improvement in urinary incontinence primarily by reducing urinary urge symptoms.[117]

SERMs have been studied as treatments for vaginal atrophy. Ospemifene at a 60-mg dose was effective and well tolerated for vaginal dryness and dyspareunia and has no demonstrable proliferative effect on the endometrium.[118]

The prevalence of vaginal dryness from participants in the SWAN study ranged from 30% to 40%,[43] which is similar to most studies. One of the main consequences of vaginal dryness is dyspareunia which can contribute to a decrease in sexual desire over the menopause transition.[119,120] However, the relationship between sexual dysfunction and hormone levels, specifically estrogens and androgens, is relatively weak, although consistent across studies. The most dramatic change in androgen levels is seen after surgical menopause rather than natural menopause. RCTs of testosterone have provided evidence that low sexual desire can be improved by use of supraphysiologic androgen supplementation.[121,122] Although short-term safety appears reassuring, long-term safety data are not available, there is a lack of consensus who represents the ideal candidate for therapeutic intervention, and there are no FDA-approved formulations of testosterone appropriate for women at the present time.[123]

A prospective, phase III RCT suggested a significant benefit of vaginally administered DHEA on sexual desire, arousal, orgasm, and pain at sexual activity.[124] Daily intravaginal administration of 0.50% (6.5 mg) DHEA reduces the percentage of parabasal cells, increases the percentage of superficial cells, and reduces vaginal pH, all consistent with improved vaginal health.[125]

Women who present with specifically sexual complaints should undergo a thorough evaluation into their exact nature and potential causes, including medication usage, psychological stressors, and comorbidities. Cognitive behavioral therapy has demonstrated effectiveness in clinical trials, but at present the two neuroactive, FDA-approved compounds for treatment of low sexual desire in women, flibanserin and bremelanotide, are not approved for use in postmenopausal women.

Sleep Disturbances

Sleep disturbances are often treated in a multifactorial manner, as HT alone might be insufficient for improving sleep quality in perimenopausal women. Cognitive behavioral interventions, such as stimulus control, sleep hygiene education, and relaxation training can be very helpful in treatment of insomnia. Empiric HT, along with behavioral techniques, may provide short-term support, with the understanding that sleep should improve after the menopausal transition.[126,127]

Adverse Mood

Depressive and/or worsening anxiety symptoms are experienced among 15%–50% of women during the menopausal transition, and fluctuations in hormones are thought to contribute. Several studies have evaluated the effectiveness of HT on menopausal mood symptoms. A recent review evaluating HT and mood in perimenopausal and postmenopausal women concluded that estrogen was effective in improving mood in perimenopausal women, but the progestogenic component in combined HT could potentially offset the beneficial influence of estrogens by inducing adverse mood symptoms. HT is generally considered to be useful along in mild-to moderate depression, but in more severe cases of depression, a combination of antidepressant and HT must be considered.[128] The ancillary Cognitive and Affective Study (KEEPS-Cog) of the KEEPS examined the effects of up to 4 years of HT on cognition and mood in recently postmenopausal women and found that women treated with oral CEE plus micronized progesterone had a decrease in anxiety and depression symptoms over the 48 months of treatment compared with those taking placebo.[129] Transdermal estradiol at a dose of 100 mcg/day for 12 months prevented clinical depression and reduced depressive symptoms in perimenopausal and postmenopausal women.[130]

Other Common Issues

Menstrual Irregularities. Menstrual irregularities are common during the menopausal transition and are used to mark its progression. Overall, menstrual bleeding tends to become initially more frequent, and then becomes progressively less frequent and lighter as women go from the early to the late transition.[131] Women who report persistent, heavy bleeding require a gynecologic evaluation for anatomic pathology, as uterine polyps, fibroids, or adenomyosis may be present and require surgical management. The unpredictability of bleeding episodes can present an inconvenience for women. Management options include cycling with oral contraceptive pills (OCPs) as long as there are no contraindications (i.e., smokers, migraines with aura[132]). Birth control pills (or patches or rings) are effective for regularization of withdrawal bleeding and can reduce mood lability, while also providing contraception. Women who use hormonal contraception during the menopausal transition may experience adverse symptoms during the pill-free interval of 7 days, and limiting or eliminating the pill-free interval may result in improved symptom profiles.[133] Another option includes adding a low dose of transdermal (i.e., 25 to 50 mcg) or oral estradiol during the pill-free week. In women who do not need contraception, HT can be considered. With combined continuous administration of HT, breakthrough bleeding may occur. With cyclic regimens, women will continue to experience monthly bleeding but breakthrough bleeding may be minimized. In women whose chief complaint is menstrual irregularities, LNG-IUD can decrease menstrual flow as long as there is no uterine pathology.[134] Estrogen-only HT can be used with an LNG-IUD.

Complementary and Alternative Medicine in the Treatment of Menopausal Symptoms

Estimates on the prevalence of the use of complementary and alternative medicine (CAM) in women aged 45 to 54 years are 40% or more, based on the SWAN cohort, with many women using more than one method. Ethnic differences are seen in their usage, with Black American women less likely to use CAM, and usage of specific therapies also differs significantly by ethnic background.[135] Some popular treatments are listed below with limited data supporting their use.

In one small (n = 51) study of soy/isoflavone supplementation, women given a soy protein supplement with 40 mg of protein and 76 mg of isoflavones had a 45% reduction in VMS, compared with 30% in the placebo group.[136] It is important to note that soy supplementation is required to achieve the high levels of isoflavones observed in participants in the latter study; Western diets do not normally contain foods rich in these substances. Although black cohosh continues to be marketed in various forms, a large, well-conducted RCT did not demonstrate efficacy.[137] Evening primrose oil (gamma linolenic acid [GLA]) was not found to be superior to placebo in the treatment of menopausal VMS.[138] Finally, an RCT of 4.5 g of dong quai daily versus placebo observed a 25% reduction in hot flashes.[139] A review of the literature related to specific forms of CAM found the overall evidence to be mixed, of low quality, and insufficient to allow specific recommendations.[140] However, given the relatively large placebo effect size seen in most RCTs for hot flashes, clinicians and patients may wish to balance the practicalities of cost versus potential for harm when considering such treatments.

Long-Term Use for Prevention of Chronic Conditions

Bone. Many factors may increase a woman's risk for bone fracture. Non-modifiable risk factors include age, family history, personal history of osteoporotic fracture, and early menopause. Modifiable risk factors include weight (increased risk in thin women), excess alcohol consumption, current smoking, low calcium intake, vitamin D deficiency, sedentary lifestyle, and low bone density. Based on the National Academy of Science, Engineering and Medicine (NASEM) recommendations released in 2011, calcium supplementation should be given up to a dose of 1000 mg/day in women aged 19 to 50 years and 1200 mg/day in women aged > 50 years who are not taking hormones. Ideally, calcium should be taken via consumption of calcium-rich foods; if supplementation is required based on dietary intake, calcium supplements should be taken with a meal to optimize absorption. The vitamin D recommended daily allowance is 600 IU, although individuals aged > 70 years may need more. NASEM recommends a serum vitamin D level no lower than 20 ng/mL (50 nmol/L) for good bone health because that is the level required by 97.5% of the population; however, routine screening of vitamin D levels is not recommended.[141]

Weight-bearing exercise stimulates osteoblasts to form new bone.[142] In menopausal women, weight-bearing exercise for 22 months led to a 6.1% increase in bone density of the LS[143]; the benefits of exercise have been demonstrated into the ninth decade of life and persist for as long as it is continued.[144] Because lifestyle modifications have been shown to improve bone density in young women and to prevent fracture in older women, they are inexpensive and safe treatment recommendations and should be included in every routine health maintenance examination.

Pharmacotherapy is appropriate for women who are at high risk for fracture in the future and in women with established osteoporosis. The fracture risk assessment tool (FRAX), developed in collaboration with the WHO, can be used to predict a 10-year risk for osteoporotic fracture.[145] FRAX has been widely used to aid clinical decision making regarding treatment initiation when the patient's bone density indicates osteopenia. Treatment should be considered when there is a 3% risk for hip fracture and/or a 20% risk for a major osteoporotic fracture, in the next 10 years. Clinical risk factors used in FRAX include, age, sex, BMI, previous fragility fracture, parental hip fracture, current smoking status, corticosteroid use, alcohol intake ≥ 3 units (a unit of alcohol is equivalent to a glass of beer [285 mL], an ounce [30 mL] of spirits, or a medium-sized glass of wine [120 mL]) per day, rheumatoid arthritis, and other secondary causes of osteoporosis (Table 122.2).[146] The list of available preventive and treatment options is presented in Table 122.3.

Estrogen has both a preventive and therapeutic role for hypoestrogenic premenopausal women with osteoporosis because such women are young enough that they may build new bone if their estrogen deficiency is corrected. After menopause, however, estrogen's antiresorptive

TABLE 122.3 Agents Used in Prevention/Treatment of Osteoporosis

Agent	Prevention/Treatment	Site of Action
Bisphosphonates	Prevention + treatment	Vertebrae and hip
Selective estrogen receptor modulators	Prevention + treatment	Vertebrae
Calcitonin	Treatment (>5 years postmenopause)	Vertebrae
Parathyroid hormone	Treatment	Vertebrae and hip
RANK ligand inhibitor	Treatment	Vertebrae and hip
Estrogens	Prevention	

action will only prevent further bone loss, as demonstrated by many RCTs. No HT product currently has government approval for the treatment of osteoporosis; however, most are approved for osteoporosis prevention. Observational studies and RCTs have demonstrated reductions in fractures of the vertebrae and possibly the hip in women on HT. A meta-analysis of 22 trials of estrogen reported an overall 27% reduction in non-vertebral fractures, while taking into account that the quality of individual studies varied.[147] The Heart and Estrogen/Progestin Replacement Study (HERS) and HERS II found no reduction in hip, wrist, vertebral, or total fractures with HT, but the follow-up interval was relatively short.[148] The WHI is the first RCT to demonstrate reduction of hip fracture risk with estrogen use[149]; risk reductions were also reported for vertebral and other osteoporotic fractures. The US Preventive Services Task Force concluded that good evidence suggests that HT prevents bone loss, and fair to good evidence indicates that it reduces fractures.[150] Women experiencing an early menopause who require prevention of bone loss are probably best served by the administration of HT or oral contraceptives, rather than bone specific treatments, until they reach the median age of natural menopause (51.4 years), at which time treatment needs may be reassessed.[106]

For postmenopausal women with established osteoporosis without a symptom indication for HT, non-hormonal modalities are available. Alendronate, a bisphosphonate that is a powerful antiresorptive agent and reduces fractures in menopausal women with osteoporosis, has been approved by the US FDA for the prevention (5 mg daily) and treatment (10 mg daily or 70 mg weekly) of osteoporosis. Risedronate is more potent and has fewer upper gastrointestinal side effects than alendronate; it reduces the incidence of fracture in osteoporotic women. Raloxifene is the only SERM approved for long-term treatment in the prevention of osteoporotic fractures in postmenopausal women. It has been demonstrated to reduce vertebral fractures.[151] Denosumab is a human monoclonal antibody to the receptor activator of nuclear factor-κB (NF-κB) ligand, which binds to the receptor activator of NF-κB on the surface of osteoclasts blocking proliferation and differentiation of the osteoclasts. Approved in 2010 for treatment of postmenopausal women with osteoporosis who are at high risk for fracture, it is administered subcutaneously every 6 months.[152] Finally, recombinant parathyroid hormone, administered subcutaneously, daily, is approved for the treatment of osteoporosis in postmenopausal women who are at high risk for fractures, and can increase BMD substantially.[153]

Cardiovascular Disease. Observational studies have long suggested that combined HT is beneficial for the primary prevention of heart disease.[154] The WHI, a primary prevention trial of 16,608 healthy postmenopausal women after 5.2 years of daily HT or placebo, initially reported a small but significantly increased risk for nonfatal heart attacks. Although CHD mortality was not increased, the risk for heart disease was 29% higher for women taking combined HT than for those on placebo.[149] The WHI findings do not support the use of HT for primary prevention of heart disease in women.

The HERS indicated that women with known CHD who were randomized to CEE and MPA had a 52% increased risk for myocardial infarction during the first year of use and experienced increased CHD deaths during the first 3 years of use.[155] After 6.8 years of follow-up in HERS II, no difference in primary or secondary CHD events was reported among estrogen users.[156] Thus, for secondary prevention of heart disease, no clinical benefit is derived from HT. Furthermore, the American Heart Association has long recommended discontinuing treatment after an acute event in a woman who is currently using HT.[157]

Since the publication of the two major primary and secondary prevention trials, multiple observational cohorts and smaller RCTs have been performed to attempt to reconcile the discrepancy between the apparent benefit of HT in cohort studies and a neutral to harmful outcome in RCTs. Unfortunately, the divide has only deepened with time, with further observational studies such as the Danish Osteoporosis Prevention Study supporting a benefit of HT,[158] despite no clear benefit demonstrated from randomized clinical trials.

The "timing hypothesis" seeks to explain this discrepancy by theorizing that HT has multiple long-term beneficial effects when initiated before or during the early period after menopause, but not during the late postmenopausal period (i.e., more than 10 years after FMP). The ELITE study, a single-site RCT of 643 healthy postmenopausal women, stratified the sample according to time since menopause (early postmenopause as < 6 years or late postmenopause as ≥ 10 years). Patients were randomly assigned to either oral 17β-estradiol or placebo (with intermittent progesterone or placebo progesterone). ELITE found that oral estradiol therapy initiated within 6 years after menopause was associated with a decreased development of subclinical atherosclerosis (measured as CIMT) than placebo but not when it was initiated ≥ 10 years after menopause.[84] At the same time, KEEPS, a multicenter RCT of 727 women, was performed to assess the effect of HT in women who started within 3 years of FMP. Treatment arms included (1) oral conjugated equine estrogens (O-CEE) 0.45 mg/day, (2) transdermal estradiol (t-E2) 50 mcg/day, and (3) placebo. Active arms received cyclical micronized progesterone 200 mg/day for 12 days/month, with a progesterone placebo for the placebo arm. After 48 months of follow-up, O-CEE and t-E2 had no adverse effects on atherosclerosis progression or coronary calcium. O-CEE and t-E2 had neutral effects on blood pressure and mainly favorable or neutral effects on CHD biomarkers. These findings support a lack of harm, and imply the potential for benefit to early intervention with HT for symptomatic women, but they are a far cry from supporting widespread preventive use of HT.

Aside from heart disease, HT may play a role in recurrent thrombotic events. The WHI reported an increased risk for stroke after 5 years of HT use[149] and, in agreement with previous studies, a higher risk for thromboembolism in the first year of HT use, which diminishes thereafter to approximately a 2-fold increased risk.[149] Follow-up analysis of the WHI that examined both coronary and venous thromboembolic events showed that the increased risk for both events in the combined HT group subsided over the 2.4-year postintervention follow-up period.[159] Taking all of the data into account, guidelines on HT have evolved in their recommendations to include the case for "extended use." The American College of Obstetrics and Gynecologists,[105] the NAMS,[106] and the American Heart Association[160] continue to appropriately recommend against the use of HT for primary or secondary prevention of cardiovascular disease. Because cardiovascular disease is a more common cause of morbidity and mortality for women than are osteoporosis and cancer combined, efforts to identify patients at risk and recommendations on lifestyle modifications, diet, and other pharmacotherapy (i.e., beta blockers, aspirin, angiotensin-converting enzyme inhibitors, statins) are more beneficial and probably less harmful than HT for long-term treatment. However, for women who remain symptomatic and are unable to utilize non-hormonal alternatives to HT, longer-term use can and should be considered using shared decision making that takes into account the patient's perceptions of benefit.

Cognition. Similar to the data on cardiovascular disease and HT, observational studies demonstrate a benefit of hormones, whereas RCTs demonstrate a neutral to negative effect. Thus, the timing of initiation of HT may be relevant for both cardiovascular and cognitive outcomes. While this hypothesis may be correct, a recent review by Maki[79] strongly suggests that a definitive test of this hypothesis may not be feasible. KEEPS included an exhaustive cognitive battery of tests on > 700 recently menopausal women randomized to transdermal or oral estrogen, both with intermittent progesterone, or to placebo, and found an overall neutral effect of hormones on cognition.[80] KEEPS is in the process of repeating the cognitive battery on participants from the original cohort and may be able to address the timing hypothesis. Henderson et al.[81] found similar neutral findings in their RCT, with a total of 567 healthy women randomly assigned to oral 17β-estradiol 1 mg/day or placebo within 6 years of menopause or 10+ years after menopause. There were no differences in executive function, verbal memory, or global cognition when estradiol was initiated within 6 years of menopause or if begun 10+ years after menopause.

Primary Ovarian Insufficiency and Early Menopause. POI can result from genetic factors, medical conditions, iatrogenic causes, or idiopathic factors. All patients diagnosed with POI (excluding iatrogenic causes) should be evaluated with a karyotype, adrenal antibodies, *FMR1* premutation, pelvic ultrasound, and bone density.[161] Patients with idiopathic POI have a higher prevalence of autoimmune disorders, and all should be screened regularly for thyroid dysfunction, diabetes, and adrenal insufficiency. Ongoing screening should continue even when initial screening is negative as these conditions can present later. Other conditions such as pernicious anemia, myasthenia gravis, rheumatoid arthritis, and systemic lupus erythematous are associated with POI, and should be screened with onset of symptoms.[103] HT is particularly beneficial for patients with POI or early menopause that occurs from either natural or surgical causes. These patients are at increased risk for osteoporosis, adverse cardiovascular effects, neurological disease, impaired sexual function, and psychiatric conditions, and the risk of poor outcomes increases with earlier age of loss of ovarian function.[162] Estrogen replacement can prevent many of these conditions or reduce symptom severity,[162] and it should be initiated immediately upon the diagnosis of POI and continued until the natural age of menopause for the highest benefit.[161] HT should attempt to mimic physiological estradiol levels with estradiol-progestin preferred over OCPs due to a higher risk of VTE and less proven benefits of bone health in OCPs. It is important to remember that younger patients with POI have a 5%–10% chance of spontaneous conception, and patients should be counseled appropriately about this risk. Those not interested in pregnancy should be on some form of contraception since HT alone does not prevent pregnancy.[161]

Cancer Risks and Mitigation of Risk With Hormone Therapy

Breast Cancer. In the WHI study, an additional 8 breast cancer cases per 10,000 women taking continuous combined CEE + MPA per year was observed, with a HR of 1.24 (95% CI 1.01-1.53) after a median 5.6 years of randomized treatment.[163] Somewhat surprisingly, a reduced risk of breast cancer was observed in women who had a hysterectomy in the CEE-alone arm.[164] The combined lack of cardioprotection and potential risk of breast cancer associated with HT led to widespread discontinuation of its use. Unfortunately, the reassuring message of reduced risk of breast cancer in association with estrogen-only therapy was essentially unheard by the public. Yet, the findings raise fundamental questions about the biology of breast cancer and how hormone exposure contributes to risk. Women who were HT naïve when randomized in the WHI had an overall similar breast cancer incidence whether they took CEE+MPA therapy or placebo for up to 11 years of follow-up; women who had previously taken HT had an overall lower incidence of breast cancer when they were randomized to placebo.[165] The most recent WHI data containing more than 20 years of median follow-up confirms that women randomized to CEE+MPA had a higher long-term risk of breast cancer, but no increase in breast cancer mortality, and that women randomized to CEE alone had a lower risk of both breast cancer and breast cancer mortality.[166] Two more recent RCTs that initiated HT within 6 years of FMP, with a primary outcome being the effects of HT on cardiovascular disease, showed no increased risk of breast cancer compared with placebo; however, these trials were not sufficiently powered to provide definitive data for a breast cancer outcome.[84,158] The Collaborative Group on Hormonal Factors in Breast Cancer's recent meta-analysis found that all forms of HT, excluding vaginal estrogen, were associated with an increased risk of breast cancer, and this risk progressively increased with the duration of HT use and was higher for estrogen plus progestin than estrogen alone. These excess risks were detectable even during years 1–4 of use (estrogen-progestogen RR 1.60, [95% CI 1.52–1.69]; estrogen-only RR 1.17, [1.10–1.26]), and increased incrementally with longer duration of use (years 5–14 estrogen-progestogen RR 2.08, [2.02–2.15]); estrogen-only RR 1.33, [1.28–1.37]).[167] The French E3N-EPIC cohort study found an increased risk of breast cancer in postmenopausal women on HT compared with non-users (RR 1.2 [1.1–1.4]), with most risk attributable to HT containing synthetic progestins compared with micronized progesterone, the RRs being 1.4 [1.2–1.7] and 0.9 [0.7–1.2], respectively.[168] For women without a uterus who do not need a progestin, the overall data favor that HT with estrogen alone is risk neutral to minimal. However, for women who require a progestin to prevent endometrial hyperplasia, breast cancer risk appears to increase with duration of use, and this risk may be mitigated by use of micronized progesterone, but currently there are no randomized clinical trials to support this notion. Breast cancer risk is a serious adverse effect and therefore counseling is recommended to be conservative (i.e., reliant on the best available RCT data) and to involve shared decision making. Although the overall risk of breast cancer attributable to menopausal HT with E+P equates to less than 1 additional case per 1000 woman-years of use,[169] risk accumulates with duration of use and is one of the principal drivers of the dictum: "lowest possible dose for shortest possible time."

KEY POINTS

- The current recommendation is to use HT in the lowest effective dose for the shortest time needed to control symptoms.

Other Cancers. Unopposed estrogen is a well-known risk factor for endometrial hyperplasia and endometrial cancer, and the major method to protect the endometrium in women taking HT with an intact uterus is the addition of progestin. Multiple studies have found an increased risk of endometrial cancer among users of ET only compared with age-matched controls,[170] but this risk does not accrue to women using vaginal estrogen alone.[116] Concomitant estrogen plus progestin (or BZA) is required for women with a uterus who are taking systemic HT. Progestin may be given either continuously or sequentially. Sequential use may be more palatable for women who have adverse effects from progestin use, but it will result in continued menstruation. Sequential combined estrogen plus progestin therapy is also less effective in eliminating the risk of endometrial cancer compared with continuous combined estrogen plus progestin, which decreases endometrial cancer risk below that of never users.[170]

In regards to ovarian cancer risk, several meta-analyses[171,172] have shown an increased risk of ovarian cancer associated with HT use. The pooled RR of ovarian cancer was 1.29 (95% CI 1.19–1.40), and increased risk was only found for the two common types, serous and endometrioid tumors. A recent prospective Swedish population–based matched–cohort study included all women aged ≥ 40 years having used systemic HT between 2005 and 2012 compared with non-users. These investigators found that current estrogen plus progestin HT use correlated with a moderately higher risk of ovarian cancer (OR = 1.38, 95% CI 1.18–1.62), with no increased risk among past users, and a reduced risk was observed for estrogen-only use (OR = 0.25, 95% CI 0.22–0.29).[173] These findings are in direct contradiction of those of the WHI, in which E alone but not E+P, was associated with increased risk of ovarian cancer. Current data regarding association of HT and ovarian cancer is therefore somewhat unclear. Incorporation of a woman's background risk of ovarian cancer is recommended to be part of the risk/benefit discussion of menopausal HT for symptomatic women.

Risk of VTE in patients taking HT is another potential risk, and has been evaluated in many studies, including the WHI. Women randomized to combined E+P HT had double the risk of VTE compared with those randomized to placebo; this risk fell to background levels shortly after discontinuation of HT. Many observational studies have reported similar results in women taking oral estrogen, but no elevated risk of VTE has been reported in patients taking transdermal estrogen.[106] Lower doses of estrogen, and the use of oral estradiol may reduce or avert the increased risk of VTE,[114] and use of vaginal estrogen has not been shown to increase the risk of VTE.[116]

SUMMARY

In conclusion, menopausal HT remains the most effective treatment modality for severe menopausal symptoms. In addition, it protects against bone resorption and improves vaginal atrophy. It is beneficial for adverse mood and may be helpful for sleep problems, particularly during the transition. Current recommendations are to use the lowest effective dose for the shortest time needed to control the symptoms. Long-term outcomes of women from the WHI who have now been followed for over 20 years[174] confirm the overall safety of this intervention for a mean period of use of 5 to 7 years. Ongoing work will help increase understanding of the mechanisms by which menopausal changes cause symptoms, refine our ability to identify women at risk for more severe and prolonged symptoms, and target hormonal and non-hormonal treatments that will be most effective for maintaining the vigor of women traversing this reproductive milestone.

KEY POINTS

- This chapter reviews current knowledge on the evaluation of infertility, with emphasis on the balance between timing and extent of diagnostic procedures.
- Current treatment options for specific diagnostic categories are discussed, as is the management of the large category of unexplained infertility, for which the importance of the right balance between assisted reproduction technology and expectant management is acknowledged.
- Recent developments in assisted reproduction are outlined.

INTRODUCTION

Infertility is defined as the inability to conceive within 1 year of regular unprotected intercourse. *Fecundability* is the probability of achieving a pregnancy within a given menstrual cycle, and *fecundity* is the capacity of a couple to achieve a live birth.[1] One in every six couples visits a physician because of an unfulfilled wish for children. The 1-year period is chosen arbitrarily and is based mainly on assessment of the likelihood for pregnancy without medical intervention (Fig. 123.1). Infertility should be viewed as a problem of the couple; therefore, medical attention should focus on both partners of a couple. Chances are roughly similar for finding some form of reproductive dysfunction in the male as in the female. Abnormalities may also be found in both the male and the female partner. Still, in a considerable number of couples, no obvious abnormalities will be found during the initial infertility workup, and it is not always clear whether an observed abnormality is indeed causally related to reduced fertility. Notably, single individuals and same-sex couples seek fertility services to fulfill their procreative goals. They may also have infertility, warranting infertility evaluation if pregnancies have not been achieved in a 1-year period. As age of the female partner is a major contributor to infertility, shorter time periods for couples or individuals to pursue infertility evaluation and treatment are recommended (see below).

Primary (as opposed to secondary) infertility involves individuals (or couples) with no previous pregnancy. Hence, for a given couple—depending on the individual reproductive history—infertility can be primary for one, and secondary for the other. Decreased fertility (referred to by some as subfertility) of a given individual may be compensated for by enhanced fertility of the partner, and the clinical challenge is to assess chances for pregnancy, either spontaneously or after infertility treatment, of a given couple.

Overall, the proposed management algorithm may include distinctly different options, ranging from expectant management without intervention, to causal therapy for those with distinct forms of infertility, to assisted reproduction as an empirical approach, to increasing chances for offspring in unexplained infertility.

KEYPOINTS

- Infertility is an ill-defined condition, with often no obvious causal explanation.

HISTORY

Infertility care has witnessed rapid growth since the early 1960s. The first two decades were dominated by the possibilities of endocrine diagnosis and treatments and the introduction of reproductive surgical procedures. Gonadotropin and steroid hormone assays were developed for widespread clinical use, and the synthetic antiestrogen clomiphene citrate (CC) and urinary gonadotropins (human menopausal gonadotropin [hMG]) obtained from postmenopausal women containing excreted pituitary follicle-stimulating hormone [FSH] and luteinizing hormone [LH]), and subsequently recombinant hormones became available for stimulating gonadal function in both females and males.

Initial surgical approaches in the female involved wedge resection of polycystic ovaries, microsurgery of endometriotic pelvic disease and uterine myomas, adhesions, and tubal disease[2] and, more recently, by endoscopic pelvic surgery and operative hysteroscopy on uterine anomalies, endometrial abnormalities, submucous myomas, and adhesions. Surgical approaches in the male were dominated by varicocele correction to improve sperm quality, although most of these initial surgical approaches have not proven efficacious after rigorous assessment.[2,3] Yet, the surgical recovery of sperm from the epididymis (percutaneous epididymal sperm extraction) or testis (testicular sperm

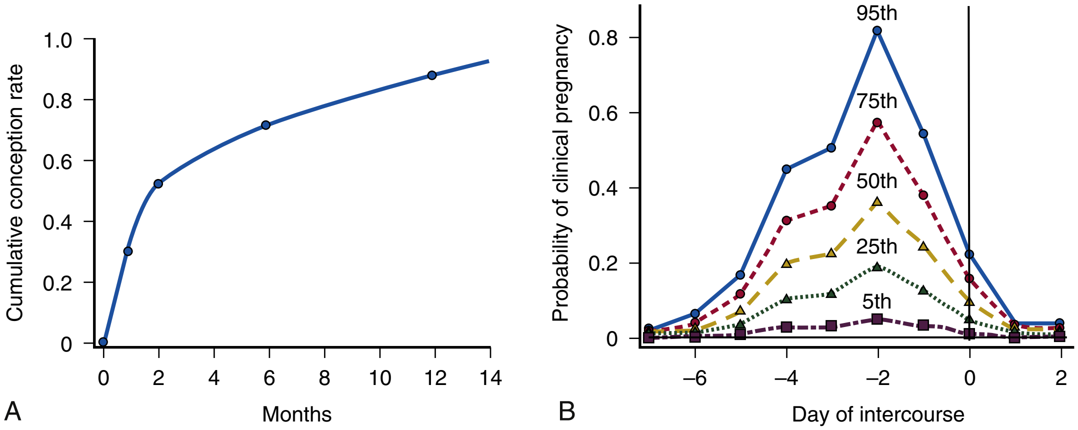

Figure 123.1 A, Cumulative conception rates during the first 12 months of unprotected intercourse. B, Probability of a clinical pregnancy relative to the day of intercourse. *Day 0* depicts the day of the serum luteinizing hormone surge. *Individual lines* depict 5th to 95th percentiles of the total population. (A, from Taylor A. ABC of subfertility: the extent of the problem. *BMJ.* 2003;327:434–436. B, from Evers JL. Female subfertility. *Lancet.* 2002;360:151–159.)

extraction) has greatly changed the perspective of the azoospermic male due to obstructive and spermatogenic causes.

The past two decades have been dominated by the development of assisted reproductive technology (ART), intrauterine insemination (IUI), *in vitro* fertilization (IVF) in 1978,[4] and intracytoplasmic sperm injection (ICSI) in 1992.[5] These novel therapeutic strategies, combined with complex ovarian stimulation (OS) protocols, created new possibilities for infertile couples and individuals. Recent decades have focused on improved methods of embryo cryopreservation which have enabled the large-scale use of single-embryo transfer in IVF, thereby reducing rates of multiple pregnancy and associated medical risks and cost.[6] Other major advances include: mild stimulation protocols using lower doses of drugs, resulting in best embryos to transfer in a given cycle[7,8]; vitrification of oocytes (from stimulated ovaries), which opened the field for oocyte banking for egg donation programs, fertility preservation for cancer treatment patients, and pregnancy postponers[9]; *in vitro* maturation and cryopreservation of oocytes from unstimulated ovaries, which currently lacks sufficient efficiency and safety to allow for large-scale application[10]; and cryopreservation of ovarian tissue, for example, cancer patients before undergoing gonadotoxic chemotherapy and subsequent transfer into the abdominal cavity, once a pregnancy is desired. Currently, over 100 babies have been born worldwide following this procedure.[11] Finally, embryo selection for transfer has been aided by cleavage or blastocyst stage embryo biopsy to detect transmitted hereditary disease (preImplantation genetic testing for disease) such as Huntington's disease, cystic fibrosis or polycystic kidney disease, or embryo aneuploidies (preImplantation genetic testing for aneuploidies).[12] Overall, these advances have enabled millions of children born to infertile couples and individuals, although the cost of IVF, ICSI, TESE, and other technologies can be prohibitive, along with disparities of availability of fertility services in certain regions across the globe, still leaving challenges to be addressed.

KEYPOINTS

- In vitro fertilization and related technologies have been the significant steps forward in infertility management.

EPIDEMIOLOGY

In the general population, the highest chance of pregnancy occurs in the first cycle of unprotected intercourse. The maximal probability for a clinical pregnancy is ~30% per cycle, and chances for pregnancy are highest when intercourse takes place 2 days before ovulation[13] (see Fig. 123.1). The likelihood of pregnancy slowly decreases in subsequent cycles, generating a cumulative chance for pregnancy of 60% within three cycles, 70% within six cycles, and ~90% within 1 year[14] (see Fig. 123.1). Very fertile couples are likely to achieve a pregnancy within the first few cycles, whereas others will conceive within 12 months (Table 123.1). Moreover, a considerable proportion of couples will still conceive spontaneously after the 1-year period or even later (Figs. 123.2 and 123.3). The 1-year arbitrary cutoff period is to define infertility and justify an infertility workup, as the chance of finding an exclusive cause like severe male factor or tubal obstructive pathology is realistic. Infertility occurs in ~10% to 15% of the population.

TABLE 123.1 Estimated Spontaneous Cumulative Pregnancy Rates in Normal Fertile and Infertile Couples*

	Monthly Fecundity Rate (%)	CUMULATIVE PREGNANCY RATE (%)			
		6	12	24	60
Superfertile	60	100			
Normally fertile	20	74	93	100	
Moderately subfertile	5	26	46	71	95
Severely subfertile	1	6	11	21	45
Infertile	0	0	0	0	0

*Rates over a given period of time, under conditions with different monthly fecundity rates. The data indicate that women with moderate fertility, which applies to many in their 30s, may have a considerable chance (≈50%) of not having achieved a pregnancy within 1 year's time. From Evers JL. Female subfertility. *Lancet.* 2002;360:151–159.

Multiple societal tendencies interfering with normal fertility have been described, especially (1) early sexarche and promiscuous sexual behavior (resulting in increased chances for tubal disease due to sexually transmitted disease), (2) postponement of pregnancy and consequently an increased proportion of women older than 30 years of age with already decreased natural fertility (due to diminished ovarian reserve) when offspring is desired, (3) female lifestyle factors (especially obesity and resulting ovarian dysfunction), and (4) environmental and toxic agents (e.g., cigarette smoking inducing accelerated follicle pool depletion). Consequently, more couples will not conceive spontaneously within 1 year of unprotected intercourse and, therefore,

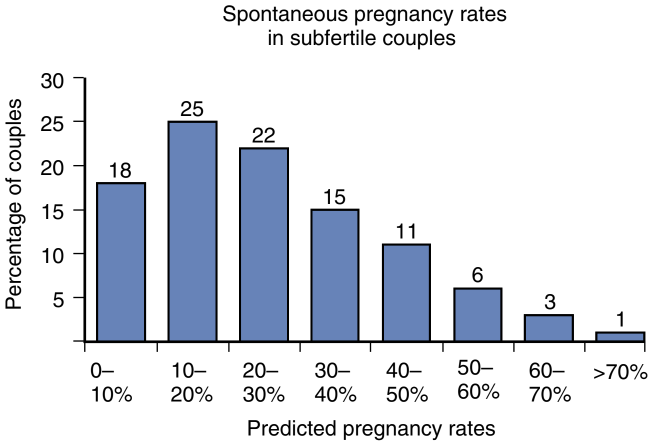

Figure 123.2 The distribution of the probability to become pregnant among untreated infertile couples within the year after intake for infertility workup (defined as having had at least 1 year of unprotected intercourse). (Data from Eimers JM, te Velde ER, Gerritse R, et al. The prediction of the chance to conceive in subfertile couples. *Fertil Steril.* 1994;61:44–52.)

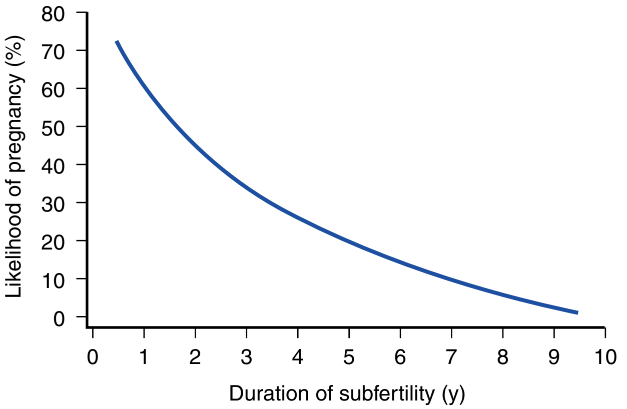

Figure 123.3 The likelihood of pregnancy in couples relative to the duration of their infertility. Note the considerable chance to conceive within the first 3 years of unprotected intercourse. For instance, the probability for a couple to become pregnant in the course of the second year of trying is still 50%. (Data from Evers JL. Female subfertility. *Lancet.* 2002;360:151–159.)

will visit a healthcare professional for infertility care. It appears that the prevalence of infertility in the Western world has remained unaltered over the past 50 years or may even have reduced,[14–16] although more couples have been seeking access to infertility services.[17]

KEYPOINTS

- Postponing family building creates higher risks of infertility occurring, in relation to the female age.

PATHOGENESIS AND CLINICAL FEATURES

According to textbooks, the female factor accounts for approximately 35% of infertility, the male factor for 35%, and in about 30% of cases, both male and female factors are involved. In female infertility, approximately 30% to 40% involve ovulatory dysfunction, 30% to 40% involve tubal and pelvic pathology, and 30% are attributed to "unexplained" causes, of which advanced reproductive age may be the most important contributor.[18] Clinical data supporting these figures are not robust. However, differences among populations and different referral characteristics may exist. Overall, a full workup of the infertile couple will yield a cause leading to infertility in approximately 23% (bilateral tubal obstruction, amenorrhea, azoospermia); in the remainder, only factors that will reduce the probability of conception (i.e., subfertility) are identified of which female age is the factor with the highest impact.[19]

Couples who suffer from infertility usually do not have associated complaints or symptoms. Exceptions include abnormal or absent menstrual bleeding, a history of pelvic inflammatory disease, ruptured appendix, or maldescent of one or both testes. The general rule that the more tests conducted, the more likely it is that at least one test will be abnormal by chance also holds true for infertility. It may not be easy to identify a disease state that is causally related to reproductive failure in a given couple or individual. Classic examples include conditions such as endometriosis or uterine leiomyomas, which were widely believed to induce infertility, until it was found that both these conditions are also prevalent in the general, fertile population.

Similar findings apply to male infertility. Poor sperm quality (by World Health Organization [WHO] criteria) was widely believed to be the cause of infertility in many cases, until more recent studies demonstrated that diminished sperm quality is often observed in males with children.[20,21] Although criteria for defining abnormal sperm have been revised repeatedly, the predictive power of sperm quality assessment should be viewed with caution in an infertile population. A clear effect upon pregnancy rates has been demonstrated only in males with severely reduced sperm density, or azoospermia.[22]

Several classes of disease conditions that may underlie female infertility can be identified, notably ovulatory dysfunction, mechanical dysfunction, ovarian aging, and unexplained infertility.

Ovulatory Dysfunction

Changes in ovarian function usually are presented by extended bleeding intervals (oligomenorrhea) or absence of bleeding (amenorrhea). Amenorrhea is usually associated with a hypoestrogenic status, whereas bleeding in oligomenorrhea may represent occasional ovulation or breakthrough bleeding due to continued estrogen exposure. In primary amenorrhea, with or without disturbed sexual maturation, one should consider rare conditions involving abnormal gonadal or uterine development due to (inherited or spontaneous) gene mutations (Chapter 117).

Ovulatory dysfunction can be classified into three categories based on FSH and estradiol (E_2) hormone assays in peripheral blood.[23] Low FSH and E_2 indicate a central origin of the abnormality at the level of the hypothalamus or pituitary gland. Hence, ovaries fail to function normally owing to insufficient stimulation by pituitary gonadotropins (WHO group 1). In contrast, the combination of high FSH and low E_2 concentrations indicates that the primary defect is at the ovarian level (WHO group 3, i.e., premature ovarian insufficiency [POI]), with the ovaries failing to produce estrogens despite maximal stimulation by endogenous FSH. The third group of oligo/anovulatory patients (WHO group 2) is represented by FSH and E_2 levels within the normal range constituting approximately 80% to 85% of all women presenting with ovulatory dysfunction. This heterogeneous group especially includes polycystic ovarian syndrome (PCOS) also characterized by clinical or biochemical androgen excess and/or polycystic ovaries (see Chapter 117).[24]

Luteal-phase insufficiency (short luteal phase) as an expression of ovulatory dysfunction has long been believed to be an important factor in infertility, occurring in up to 14% of infertile patients. However, controlled studies conducted to establish its role in infertility or the value of any treatment in improving pregnancy rates are currently still lacking.[25]

Anatomic Dysfunction

Normal functioning of the reproductive tract is important for fertility. Uterine abnormalities, including congenital uterine malformations,

malformations due to fetal exposure to diethylstilbestrol, fibroids (in particular, the submucosal or cornual myomas), polyps, and adhesions related to previous intrauterine procedures, are associated with infertility or early miscarriage.[26]

Normal fertility may also be affected by pelvic adhesions (especially involving the ovaries and fallopian tubes) caused by pelvic inflammatory disease, complicated appendicitis, or intraabdominal surgery. Abnormal tubal function may be due to isthmic or terminal occlusion or phimosis of the fimbriae due to salpingitis. Peritubal adhesions may interfere with normal tubal motility and, hence, with gamete and zygote transport. Severely damaged tubes may fill with fluid, giving rise to hydrosalpinges.

Endometriosis (see Chapter 125) is a topic of continued controversy related to disease conditions associated with infertility. It is the ectopic localization of the endometrial tissue, most commonly in the pelvis; retrograde menstruation may be the important causal factor, but metaplastic errors during Mullerian tube development may also contribute to endometrial tissue in the myometrium or rectovaginal septum.[27] Severe forms of endometriosis give rise to adhesions, cyst formation, and reduced fertility. In addition, abdominal discomfort, specifically dysmenorrhea, chronic pelvic pain, and dyspareunia are frequent complaints. Limited data suggest that minimal and mild disease are prevalent in the general population, without a clear relation to infertility or pain. Moreover, positive effects on subsequent fertility of intervention studies using hormonal medication or surgical procedures are still questionable.[28,29]

Uterine myomas (see Chapter 126) occur in 1% to 2.5% of infertile patients without other evident cause of infertility,[30] and removal has long been thought to improve subsequent pregnancy chances. A recent meta-analysis has shown that infertility patients with uterine cavity-distorting fibroids have poorer reproductive outcomes than infertile patients without fibroids, and removal therefore may be considered justified despite a lack of comparative trials. Cases with intramural myomas may have a poorer prospect for pregnancy occurring, but the absence of quality studies prevents advocating their removal.[31] Subserosal fibroids are not associated with fertility issues.[32]

As with many other factors associated with infertility, comparative data on the frequency of similar abnormalities in a matched, fertile population are lacking. In addition, randomized follow-up studies of pregnancy rates comparing intervention versus expectant management are rare, so the efficacy of treatment is uncertain.

Ovarian Aging

In many societies, increased participation of females in extended education and careers has resulted in postponement of childbearing to a later age. An increased proportion of women make their first attempts to conceive when they are beyond 30 years of age, when natural fertility starts to decrease, and with a major subsequent decline in fertility after 37 years of age.[33] Beyond 41 years of age, chances of having a spontaneously conceived baby have decreased on average to close to zero.

At around 20 weeks' gestation, in the female fetus, initial germ cell mitosis is arrested, and the primordial follicle pool reaches its maximum size of around 8 million per ovary (see Chapter 122). Thereafter, this stock of resting primordial follicles is gradually depleted (by the onset of growth of follicles), falling to 2 million at birth and 0.5 million at menarche (first menstrual period), with final exhaustion of the pool with the last spontaneous menstrual period. Thus, only a small proportion (~10% to 15%) of the initial primordial follicle pool is present at the time that many women consider conceiving their first child.

Menopause, which marks the definitive end of the reproductive life span, occurs at the average age of 51, with a range from 40 to 60 years of age (see Chapter 122). This indicates that exhaustion of the follicle pool takes 50% more time (60 years rather than 40 years) in some women than in others. The association between chronologic age and ovarian aging therefore may be complex. Indirect evidence indicates that a fixed time interval exists between the transition from normal fertility into decreased and finally into absent fertility (sterility).[34] Some women at 35 years of age may already have severely compromised fertility due to poor-quality oocytes. These women may also present with an earlier than average menopause, although the relation between the quantitative and qualitative aspects of the ovarian ageing process are far from elucidated. For other women of identical age (35 years), natural fertility is still completely normal or may even be above normal. The latter group of women is often believed to experience menopause at a later age, although the evidence is minimal. The clinical challenge is to assess the reproductive aging status in terms of fecundability of a given woman at a given age, which will help to predict her pregnancy chances more accurately than will chance assessment based on chronologic age alone. This may help the clinician in counseling the patient regarding expectant management or therapeutic strategies.[34] Studies on genetics of cell cycle and immune system maintenance may potentially identify relevant factors in this context. "Early" ovarian aging can be linked to genetic as well as environmental factors (see Chapters 122 and 137).

The mechanisms underlying reduced natural fertility in relation to ovarian aging have not yet been fully elucidated. It has been clearly established that the size of the cohort of growing follicles is diminished, and this coincides with an increased proportion of chromosomally abnormal oocytes. The latter is exemplified by increased rates of aneuploid (e.g., trisomy 21) pregnancy, increased rates of early pregnancy loss (most likely based on an aneuploid conceptus), and increased numbers of aneuploid oocytes and embryos with increasing female age.[35] Changes in follicle cohort size can be assessed by transvaginal ultrasound or by hormone estimates in the peripheral blood (see later). Unfortunately, as explained in the aforementioned, assessment of average oocyte quality on an individual basis so far has not proven feasible.

Unexplained Infertility

The indicated percentage of infertility of unknown origin is ~30% but may be higher depending on the criteria applied. The reported incidence is very much dependent on the extent of the infertility evaluation, characteristics of the population studied, female age, and the reported incidence of other "known" factors related to infertility. Again, a clear-cut causal relationship between an abnormal condition as established during initial evaluation and infertility is often absent. A clear tendency towards less diagnostic evaluation resulting in an increased proportion of infertility remaining "unexplained" can be observed. This implies that several factors are known that do not per se exclude the possibility of achieving a pregnancy (e.g., mild or moderate semen abnormalities, a suboptimal or negative postcoital test, mild-stage endometriosis, elevated basal FSH or low age-specific anti-Müllerian hormone [AMH], or subtle uterine abnormalities like fibroids), but they only contribute to a reduction in monthly fecundity. In assessing the remaining chances for success in these unexplained infertile couples or individuals, key factors such as female age, a previous pregnancy, duration of the current infertility status, and semen quality have been identified as crucial factors for the individualized estimates of pregnancy chances.[36,37]

On the other hand, many processes are involved in natural fertility that cannot be tested properly in a routine clinical setting. These involve oocyte maturation and fertilization, embryo transport through the tube and uterine cavity, chromosomal constitution of embryos, apposition and implantation of embryos, and, finally, endometrial receptivity, including regulation of endometrial maturation by steroids produced by the corpus luteum,[38] and gene expression variation indicative of changes in the window of implantation.[39]

Moreover, many pregnant women, under natural conditions or in an infertile population, may miscarry very early, before the occurrence of her expected, regular menses.[38]

KEYPOINTS

- The true key causes for female infertility are uterine/tubal pathology and oligo-/an-ovulation. However, age related limitations at the level of the oocyte may comprise a contribution of yet unknown magnitude.
- Female age effects on fertility are likely to be related to oocyte quality. An individual specific test to assess average ovulated oocyte quality is urgently needed.

EVALUATION OF THE FEMALE IN THE INFERTILE COUPLE

The extent to which basic infertility testing should be performed is extensively debated in the current era, dominated by ART. Consequently, marked differences exist with regard to the numbers and types of tests performed.[40] Tests are time-consuming and costly, and some are not performed without risks or high patient burden. According to some clinical investigators, results may have little bearing on ART outcomes. In a commercial environment where patients have to pay for services, "customers" may prefer to spend their money on treatment with some chance for pregnancy than on diagnostic procedures that will have no impact on their chances to conceive.

Many tests are not clearly standardized, and therefore reproducibility is limited. The usefulness of infertility tests should be based on the proper evaluation of (1) sensitivity (the capacity of a test to detect abnormalities), (2) specificity (the chance that an abnormality is actually present if the test yields an abnormal result), (3) invasiveness, complexity, and cost of the test, and, finally, (4) the clinical utility of the test in terms of how result will influence the management or treatment options for the infertile couple or individual. Indeed, few studies have been undertaken to evaluate the practical value of tests despite their widespread use in clinical practice.[41]

During the initial consultation, the physician should take a full medical history from both partners. Relevant information includes duration of infertility, past sexual development, children from current or previous relationships, general health and use of medication, current or past smoking or use of drugs, including alcohol, obstetric history, previous surgery, family history, abdominal or menstrual discomfort, and sexually transmitted diseases. Moreover, the clinician should counsel a couple regarding timing of intercourse and fertility chances, the use of LH detection tests, the effects of lifestyle factors (such as excessive smoking, alcohol intake, caffeine consumption, and exercise), food intake and obesity, and occupational exposures. A general physical examination usually is advised, with focus on height, weight, and blood pressure.[17,42,43]

Diagnostic tests that may be performed for the evaluation of infertile couples include assessment of the normal menstrual cycle, assessment of anatomic factors, and assessment of ovarian aging status.

Assessment of the Normal Menstrual Cycle

Regular menstrual periods strongly suggest normal ovulatory cycles. Ovulation and normal corpus luteum function can be assessed in different ways.[25] However, the tests are not optimal in terms of accuracy and reproducibility, or in the detection of a meaningful and treatable disease condition relevant to infertility.[44] Applications for mobile phones are being developed and marketed successfully aiming to monitor the fertile period more closely, which can be used both to improve pregnancy chances when desired but also to avoid pregnancy as a means of contraception. These programs improve over time, also by applying artificial intelligence using big data sources.

Menstrual Period Chart. This represents the simplest way to document the menstrual cycle pattern. The days of onset and cessation of menses should be recorded on a calendar for several months, or may be kept in one of several apps.[45] A normal menstrual cycle ranges between 25 and 35 days, with a median duration of 28 days.

Basal Body Temperature Chart. Progesterone produced by the corpus luteum has many effects on the central nervous system, including changes in the body temperature set point. Consequently, daily assessment of basal body temperature (BBT) can be used to document a persistent increase in temperature (typically from 36.6°C to 37.1°C) and therefore can provide "proof" of ovulation. A rise in temperature indicates that ovulation and corpus luteum formation have taken place. The length of the second half of the cycle should be at least 10 days. Daily temperature assessments should be performed at the same time during the early morning before the activities are begun. Although performing these tests for several months can be quite stressful to women, it may be helpful for the couple to be aware of the day of ovulation, so they can time intercourse to achieve optimal pregnancy chances. However, the BBT is notoriously unreliable for the timing of ovulation, and LH surge tests and menstrual and fertile period apps are taking over fast.[45]

Urinary LH Surge. When LH concentrations are high in serum during the midcycle surge, sufficient quantities are excreted into urine to allow its detection. Kits are commercially available for use at home. On average, LH appears in the urine around 12 hours after onset of the LH surge in the blood, and this can accurately predict ovulation (see Chapters 117 and 120). This method may help with optimal timing of intercourse, although evidence for a beneficial effect upon pregnancy rates has so far not been found.[45,46]

Transvaginal Ultrasonography. The preovulatory, Graafian follicle usually attains a diameter of around 20 mm (ranging from 16 to 24 mm) before rupture and subsequent release of the oocyte. Rupture of the follicle can be established by visualizing the disappearance or decrease in size of the dominant follicle by transvaginal ultrasound. This method usually is reserved for monitoring of OS during infertility therapy or for proper timing of a postcoital test or midluteal phase progesterone assay (see the following section).

Progesterone Assay. Appropriate timing of the assessment of progesterone serum concentrations is crucial and should always be checked in retrospect, especially in women whose cycle length may vary. A level > 2 ng/mL indicates ovulation, although levels between 6 and 25 ng/mL are considered normal and are associated with chances for pregnancy. Some investigators advocate that multiple hormone assays should be performed around the midluteal phase to document insufficient corpus luteum function. The luteal phase may be reduced in length, or insufficient quantities of progesterone may be produced during the luteal phase. However, the exact role of these variations in terms of female fecundity remains a matter of debate.[47]

Assessment of Anatomic Dysfunction

Some type of mechanical factor relevant to infertility is reported to occur in 10% to 30% of infertile couples. Several methods exist to establish abnormalities at the level of the uterus, fallopian tubes, or ovary/ampulla complex relevant for *in vivo* oocyte pickup. Until recently, diagnosis of mechanical abnormalities by hysterosalpingography (HSG) during the early infertility workup and by laparoscopy later in the evaluation has been the standard procedure for each patient. Currently, the tendency is toward the use of less invasive screening tests to identify women at high risk for tubal disease and the performance of more invasive diagnostic procedures only in those women at increased risk for such abnormalities.[48] The question remains as to what extent any mechanical deviation from normal truly contributes to the infertility. The clinician should take this reservation seriously, especially in cases of minor abnormalities of the uterine cavity and of presumed unilateral tubal damage.

History Taking. The guidelines of the National Institute for Clinical Excellence (NICE) in the United Kingdom advise clinicians to use the past medical history in the woman to decide whether invasive diagnostics should be applied to assess the presence of tubal pathology (especially previous deliveries, previous pelvic inflammatory disease, or previous pelvic surgery) enables the identification of such couples.[49] The addition of *Chlamydia* antibody testing will further enhance the correct identification of couples at such low risk for anatomic dysfunction that invasive diagnostics can well be avoided.

Transvaginal Ultrasonography. Today, transvaginal ultrasonography (TVS) is standard in the infertility workup, as it is simple, highly informative and allows for a test with low patient burden. With its use, several relevant abnormalities can be assessed. These comprise uterine cavity abnormalities such as thin endometrium lining, endometrial polyps, submucous myoma, and intrauterine adhesions. Secondly, the status of the myometrium can be assessed allowing for the detection of intramural or subserous myomas, adenomyosis, or congenital anomalies such as a uterine septum, a bicornate or a didelphys uterus. Only pathologic conditions of the fallopian tubes, e.g., hydrosalpinx, can be diagnosed by TVS, due to the presence of intraluminal fluid trapped in a terminally occluded salpinx. Finally, ovarian imaging will reveal information on the presence of cysts (dermoid, endometriosis), polycystic ovarian morphology, as well as the total antral follicle count (AFC), which may indicate the ovarian reserve status. In typical cases of dysmenorrhea, indirect signs of adhesions based on endometriosis can be identified between the rectum and uterus and uterus and bladder.

Screening by *Chlamydia* Antibody Testing in Serum. *Chlamydia trachomatis* represents the most common sexually transmitted pathogen in the Western world, with a reported prevalence of infection of around 5% to 10%. Most of these infections are asymptomatic, but ~10% can cause pelvic inflammatory disease.[50] *Chlamydia* acts as an immunogen that gives rise to antibody formation. Immunoglobulin G (IgG) antibodies remain in the circulation for years and therefore can be used as a marker for past infection. IgG concentrations are reportedly elevated in 30% to 60% of women from infertile couples. The capacity of IgG antibody levels to predict tuboperitoneal disease (as assessed by laparoscopy) has been evaluated prospectively, with acceptable receiver operator characteristic (ROC) curves and the use of titers between 16 and 32.[51] In infertile couples with a relatively good fertility prognosis based on the Hunault prediction rule,[52] a workup strategy starting with history taking and screening for *Chlamydia* antibodies is an effective approach,[53,54] and for many women with only a low risk, performance of more invasive tubal patency evaluating procedures can be prevented.

Hysterosalpingography. HSG represents the radiographic visualization of the endocervical canal, uterine cavity, and lumina of the fallopian tubes. Both oil- and water-based contrast media are used. The oil-based medium may provide the advantage of a minor subsequent increase in spontaneous pregnancy chances,[55,56] whereas the water-based medium is faster and less painful and results in improved visualization of abnormalities. Abnormal uterine features include filling defects (related to submucous fibroids, polyps, or intrauterine adhesions), and abnormal shape (congenital uterine anomalies such as unicornuate, bicornuate, or septate uterus, uterus didelphys, fetal exposure to diethylstilbestrol, or intrauterine adhesions). In addition, unilateral or bilateral tubal occlusion, with or without hydrosalpinges, may be diagnosed. The occurrence of peritubal adhesions may be suspected on the basis of an abnormal intraabdominal distribution pattern of the contrast medium (pocketing, especially noted on the post-filling x-ray).

The HSG procedure should be planned during the follicular phase of the menstrual cycle to avoid an unexpected early pregnancy. The procedure can be quite painful, and an ascending infection with acute salpingitis is the most significant complication, occurring in ~1% to 2% of patients. Preventive antibiotic prophylaxis should be advised in all patients for whom tubal pathology has been diagnosed or suspected. HSG is reasonably accurate in diagnosing tubal occlusion; abnormal results are associated with reduced fecundity rates, especially if abnormalities are double-sided.[57,58] An important drawback of this procedure remains the subjective nature of the evaluation, which renders the reproducibility of this test rather poor.

Hysterosalpingo Contrast Sonography (HyCoSy). Hysterosalpingo contrast sonography (HyCoSy) is a simple and well-tolerated outpatient ultrasound procedure and requires the use of a contrast agent to visualize patency of the fallopian tubes. With a small balloon catheter as filling device and using a transvaginal ultrasound, the contrast agent is instilled into the uterine cavity. The contrast medium may be an agitated saline/air mixture or a non-iodinated contrast agent (ExEm Foam). The contrast flow from the uterine cavity into the fallopian tubes can be visualized by the operator and allows judging rapid passage through the length of the fallopian tubes, indicative of tubal patency. Although HyCoSY may be a promising alternative for HSG with regard to accuracy and effectiveness, proper assessment studies are yet to appear.[59]

Laparoscopy. This procedure is considered the gold standard for the diagnosis of tubal disease and intraabdominal disorders such as endometriosis and adhesions that interfere with normal fertility.[57,58] Some authorities believe that laparoscopy should be performed before unexplained infertility is diagnosed. More recent data suggest that the added value of such a procedure in women without a history suggestive of tubal disease and a normal HSG is very limited.[60]

Laparoscopy involves the intraabdominal inspection of the internal genital organs after abdominal insufflation with CO_2 of a patient under general anesthesia. Next to the reproductive organs, the appendix should be inspected for infection and the perihepatic region for adhesions suggestive of past chlamydial infections (Fitz-Hugh-Curtis syndrome). In experienced hands, risks associated with this technique are minimal. Attention should be focused toward standardizing the evaluation of the abdominal and pelvic cavities.

Other Techniques. Recently introduced, more sophisticated techniques that can be used to visualize intrauterine, intratubal, or intraabdominal abnormalities include ultrasound imaging of the uterine cavity after fluid lavage and endoscopic techniques such as saline infusion sonography, hysteroscopy, salpingoscopy, falloposcopy, transvaginal hydrolaparoscopy, and microlaparoscopy.[61] Although some of these techniques have seemed promising, with their focus on reduced patient discomfort and costs, the usefulness of these tools in a standard infertility workup remains to be established.

Assessment of Cervical Mucus–Sperm Interaction

In humans, semen is deposited in the posterior fornix of the vagina, and the cervix via its mucus secretion is believed to play an important role in allowing sperm to enter the uterine cavity. Several functions of cervical mucus include protecting sperm from the acidic milieu in the vagina, allowing the sperm to enter the cervix, supporting energy requirements for sperm motility, and filtering morphologically abnormal sperm. Before ovulation, cervical mucus is produced in large quantities, allowing easy sperm access at the most appropriate moment during the menstrual cycle. The prognostic performance of cervical mucus tests, the incidence of cervical factor infertility ("cervical hostility"), and the validity of treatment options to correct disturbed cervical mucus–sperm interactions remain poor.

Postcoital Test. This test, which involves appraisal of the presence of motile sperm in cervical mucus, after intercourse during the late follicular phase of the menstrual cycle, was originally described in 1866 by Sims and was reemphasized in 1913 by Huhner (reviewed in ref 62). There is no agreement regarding the preferred interval between intercourse and the test, nor the cutoff between a normal and an abnormal test result. The threshold is 1–5 spermatozoa per high-power magnification (i.e., 10 × 40) field. A systematic review of 11 well-designed studies indicated that the discriminating ability of the postcoital test is poor, regardless of the applied criteria for normality.[62,63] A subsequent systematic prospective evaluation indicated that inclusion of a postcoital test in routine evaluation of new couples only results in additional interventions.[62] Several national and international bodies (such as the American Society of Reproductive Medicine, the European Society of Human Reproduction, and the Royal College of Obstetrics and Gynaecology) currently advise against performing the postcoital test in routine infertility evaluation. In addition, earlier tests used to evaluate the quality of the cervical mucus, along with several *in vitro* tests of interactions between cervical mucus and sperm, have been abandoned.

Assessment of Ovarian Aging

It is well established that the female partner's age is the most prominent factor in determining chances of spontaneous pregnancy[33] or after infertility therapy (such as insemination with donor sperm[64] or with *in vitro* fertilization–embryo transfer [IVF-ET]).[65] As discussed previously, however, chronologic age has limitations in that the degree of ovarian aging varies considerably among women in the same age group. This is true for the quantitative aspects of ovarian reserve, expressed by the AFC and AMH levels. Some 35-year-old women may be normally fertile (i.e., have the fecundity of a 25-year-old), and expectant management may be the most appropriate option. In contrast, natural conception chances may already be severely compromised in other women of the same age (with fecundity of a 41-year-old), and the clinician would best offer the most effective treatment options without delay.

The major challenge of today is to assess the magnitude of ovarian aging on an individual basis.[66,67] Endocrine and ultrasound changes go along with ovarian aging. Recent efforts have focused on the clinical implications of these changes, applying test systems that aim to predict chances for pregnancy, either spontaneously or after infertility therapy. Some factors indeed may have some capacity to predict fertility chances, although studies on the added value of these tests on top of female age are either scarce or inconclusive as to their value in patient management.

While initial physiologic studies in normo-ovulatory women have emphasized that the length of the follicular phase is shortened with increasing age and with elevated early follicular phase serum FSH concentrations, baseline FSH has limited capacity to predict IVF outcome, independent of chronologic age.[68] In addition, a decreased cohort of AFC can be observed by ultrasound and used as a marker of ovarian aging.[69] However, a meta-analysis on the predictive value of baseline FSH and AFC for IVF outcome concluded that their clinical value in pregnancy prediction is restricted to only a small group of patients.[70]

In recent years, AMH has become the marker of promise in ovarian reserve assessment. Serum levels are proportional to the number of antral follicles in the size range of 1 to 8 mm, and indirectly represent the size of the pool of primordial follicles.[71,72] Compared with AFC and basal FSH, the current AMH test has unfortunately failed to significantly improve prediction of pregnancy after IVF-ET.[73,74]

For the prediction of poor response to OS, especially AMH has proven quite adequate. A poor response may indicate advanced ovarian aging, with inherent reduced prospects for a live birth, but underdosing or decreased sensitivity of the ovary may also play a role. In cases where poor ovarian response is due to exhaustion of the ovarian follicle pool, the prediction of poor response has no therapeutic implications because the prognosis for successful treatment will be poor, regardless of the chosen intervention. It needs to be emphasized, however, that especially in younger patients, oocyte quality may still be quite good in spite of low numbers obtained by OS, even if this is caused by low ovarian reserve status.[75] At the other end of the spectrum, the capacity of these tests to predict excessive response to ovarian hyperstimulation allows treatment schedules to be adjusted in order to mitigate the number of stimulated follicles and thereby limit the risk for ovarian hyperstimulation syndrome (OHSS).[76–78]

Today, initial testing of ovarian reserve may be useful especially for managing high responses,[79–81] as a reduced gonadotropin dose in high responder patients will generate less oocytes with adequate IVF success rates; this approach reduces chances for developing OHSS. However, with the use of gonadotropin-releasing hormone (GnRH) antagonists for LH peak suppression, high responders can also be managed by GnRH agonist trigger of oocyte maturation and a "freeze all" embryos strategy.

From Diagnosis to Prognosis

In many couples, a clear cause for infertility remains unknown with currently available diagnostic tools. Various prospective follow-up studies evaluated whether specific characteristics assessed upon initial evaluation could predict the chance for a spontaneous pregnancy in these couples. Three studies[82–84] identified similar factors predicting pregnancy chances for couples with unexplained infertility. The Hunault prediction model[36,37] based on duration of infertility, female age, previous pregnancies, sperm motility, and referral status for couples with unexplained infertility has been externally validated, demonstrating its accuracy in prognosis assessment.[85] Application of this model[37] to assess chances for spontaneous pregnancy will help counseling couples with unexplained infertility regarding the preferred strategy, i.e., expectant management versus initiation of (empirical) treatment. Today, the option has been further developed to estimate the changes in the prospects for an individual couple over time, thereby facilitating potentially the right timing of initiation of infertility treatment. This approach may reduce overtreatment, in that invasive therapies may be avoided in couples who have a still favorable likelihood of spontaneous pregnancy. Notably, a well-designed cohort follow-up study concluded that 61% of couples achieved pregnancy independent of treatment.[85,86] Similar prediction models have been developed aiming to assess cumulative pregnancy changes throughout an entire IVF treatment.[87]

KEYPOINTS

- The purpose of the infertility work-up in the female is to identify clear causes, such as tubal pathology and/or oligo/an-ovulation.
- Invasive evaluation of uterine-tubal abnormalities is best reserved for cases with a positive history (STDs and pelvic surgery), abnormalities at transvaginal ultrasonography and/or presence of Chlamydia antibodies in the serum.
- Assessment of ovarian reserve status is not meaningful in terms of diagnosis or prognosis in the infertility work-up. Its value stems from the prediction of ovarian response to ovarian hyperstimulation in assisted reproduction technology.

EXPECTANT MANAGEMENT OF THE INFERTILE COUPLE

The chance that a spontaneous pregnancy will occur after unprotected intercourse for 1 year is around 90%[88] (see Fig. 123.1. This cumulative pregnancy rate is highly influenced by female age. When a couple seeks evaluation of infertility, it is important first to rule out causes of absolute infertility (i.e., tubal factor, anovulation, and severe sperm abnormalities). Thereafter, the likelihood of a spontaneous pregnancy should be assessed, before any type of empirical therapy is begun. As mentioned previously, the age of the woman and the duration of infertility are the most important factors affecting the future likelihood of conception (see Figs. 123.3 and 123.4, and Table 123.2). With the use of prognostic models applied in unexplained infertile couples, a predicted chance of > 30% live birth in the year to come may urge physicians to promote expectant management as the first-line treatment, specifically as studies have shown that compared to treatment with mild OS combined with IUI no improvement in live birth rates will be obtained. Whether in such cases direct application of IVF will make a true benefit still remains to demonstrated. Comparing different treatment options in couples with an unfavorable prognosis (< 30% predicted one year live birth) revealed that IVF did not result in improved outcomes compared to IUI with mild stimulation.[89]

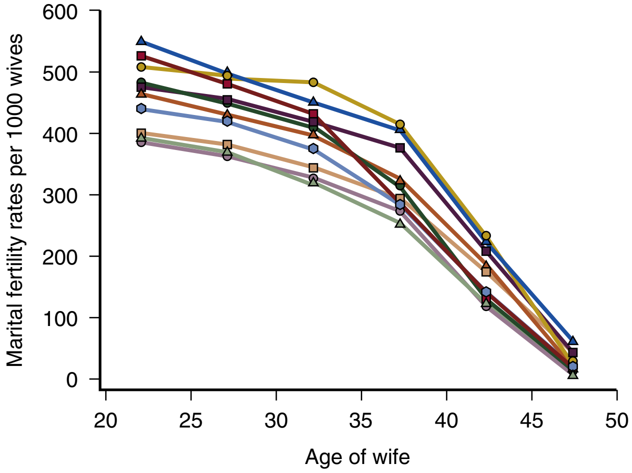

Figure 123.4 **Natural marital fertility rates as a function of age of the woman, indicated for different populations from the sixteenth until the twentieth century (Hutterites, Geneva bourgeoisie, Canada, Normandy, Tunis, Norway, and Iran).** (Data from Menken J, Trussell J, Larsen U, et al. Age and infertility. *Science*. 1986;233:1389–1394; Schwartz D, Mayaux MJ. Female fecundity as a function of age: results of artificial insemination in 2193 nulliparous women with azoospermic husbands. Federation CECOS, *N Engl J Med*. 1982;306:404–406.)

Increasing patient pressure and the financial interests of some infertility centers have prompted starting infertility treatment prematurely. The approach of comparing spontaneous pregnancy chances with chances following intervention may aid in the proper timing to initiate therapy, which may prevent overtreatment. This approach is distinctly different from one that focuses on the highest chances for pregnancy per treatment cycle, which is often used.

The definition of cost-effective infertility care is achieving the desired end point at the lowest possible expenditure of resources.[90] Analysis modeling in the United Kingdom confirmed that IVF is a cost-effective treatment option for severe tubal factor infertility.[91] Initial cost-effectiveness studies also support the use of IUI and mild ovarian hyperstimulation before IVF is initiated, although this may apply only for couples with unexplained infertility who have a 1-year prognosis of at best 30% for an ongoing pregnancy.[92–94] Gradually, a consensus is evolving that a healthy singleton live birth per started treatment should be the preferred end point.[95,96] OS in normo-ovulatory women is inherently associated with multiple follicle development and increased chances for multiple pregnancies and should therefore be applied with great caution. In addition, a systematic evaluation documented that success rates of infertility therapies are often overstated and that the quality of relevant clinical studies is often questionable.[97]

Anovulation usually can be treated effectively with ovulation induction agents (such as CC, the aromatase inhibitor letrozole [LTZ], or exogenous gonadotropins) aimed at restoring normal ovarian function (see Chapter 117). In addition, mechanical factors involving the uterine cavity, tubal function, or oocyte pickup can be restored by endoscopic surgery (such as hysteroscopic myomectomy, adhesiolysis, or fimbrioplasty).

The diagnosis of unexplained infertility can be made only after an appropriate diagnostic infertility workup has established the absence of any detectable abnormalities.[98] Because no consensus has been reached regarding the extent of testing that should be performed during an

TABLE 123.2 Summary of Cochrane Review Concerning the Efficacy of *In Vitro* Fertilization (IVF) for Unexplained Infertility

Comparison	Number of Cases	Ongoing Pregnancy	Rate per Couple	Odds Ratio	95% CI

Overall	118	41%	37%	1.15	0.55–2.42

The table shows that randomized clinical trials demonstrating the efficacy of IVF as first-line therapy in unexplained infertility are scarce and cover only limited numbers of cases. The application of intrauterine insemination (IUI) with or without stimulation as first-line treatment is to be recommended in view of lower costs and patient discomfort.

Data from Pandian Z, Bhattacharya S, Vale L, et al. In vitro fertilisation for unexplained subfertility. *Cochrane Database Syst Rev*. 2005;2:CD003357.

infertility workup, cases of unexplained infertility involve a notoriously heterogeneous group of patients. In many cases of unexplained infertility or male factor infertility, patients undergo empirical treatment to improve pregnancy chances. Assisted reproduction encompasses various techniques used to increase the chances of pregnancy per cycle by basically bringing more gametes closer together. This goal can be achieved by OS, combined with IUI or IVF.

Ovarian Stimulation

Under normal conditions, a cohort of follicles is recruited for ongoing gonadotropin-dependent development during the inter-cycle rise in FSH. During a limited time interval (the "*FSH window*"), FSH concentrations rise above the threshold before declining[99] (see Chapter 118). The aim of OS, with exogenous FSH as the most frequently used drug, is to intervene in mechanisms that regulate single dominant follicle development, in order to mature multiple follicles via generation of multiple oocytes for fertilization *in vivo* (after intercourse or IUI) or *in vitro* (IVF).

OS in IUI cycles can be achieved using CC, LTZ, or exogenous gonadotropins. Medication is usually administered during the early or midfollicular phase (cycle days 2 through 7 or 5 through 9) in daily dosages ranging between 100 and 150 mg for CC and 2.5–5 mg for LTZ. Exogenous gonadotropins are used in a fixed dose, starting with 50–75 IU/day on day 2 to 3 of the cycle. Depending on the number of dominant follicles > 12 mm that develop, this dosage can be adjusted in a subsequent cycle, using steps of 25–37.5 IU. The use of GnRH agonist cotreatment to avoid a premature LH rise generally is not recommended in IUI cycles.

Along with a possible beneficial effect on the ongoing pregnancy rate, OS may lead to multiple pregnancies and OHSS, both of which should be considered preventable complications of treatment (Fig. 123.5).[100] When multiple oocytes are released *in vivo*, the number of oocytes fertilized cannot be controlled, and a marked increase in multiple (especially higher-order multiple) pregnancies has occurred over the past two decades.[101,102] Development of more than two dominant follicles has been shown to enhance the rate of multiple pregnancies, without a gain in overall ongoing pregnancy rates.[103] The results of OS are often combined with those of IUI, and few studies allow differentiation between the independent effects of the two.[102–104] Specifically, when judging the efficacy of these two treatment components, several factors need to be considered. The infertility diagnosis (unexplained, male, or cervical factor), the age of the female, and the prognosis level for spontaneous pregnancy according to the Hunault model will all affect the decisions on which treatment modality to apply. Currently, initiating treatment in couples with unexplained or moderate to mild male factor infertility and a 1-year prognosis of ≥ 30% is not advocated. If treatment is indicated, IUI in natural cycles will increase conception rates in couples with cervical factor infertility, preventing exposure to multiple pregnancy risks. In unexplained, but even in mild male factor infertility (total motile sperm count > 10 million) or minimal endometriosis, applying only IUI in the natural cycle may not be sufficiently effective over expectant management,[104] implying that only the combination with OS will clearly benefit over timed intercourse. The combined use of IUI and OS with exogenous gonadotropins or CC for unexplained infertility may bypass various subtle barriers, such as minimal sperm abnormalities, sperm–cervical mucus interaction, and the timing of sperm delivery, and may further enhance fertility through the ovulation of more than one follicle. Notably, success in these treatment modalities is further affected by female age such that applying IUI with OS may be omitted in women aged > 40 years.

The procedures during the treatment itself may be also considered as to their role in the achieved efficacy. OS should lead to the release of two to three oocytes maximally to maintain the proper balance between success and complications. Because of low cost and ease of administration, the antiestrogen CC could be recommended as first-choice medication for OS, although gonadotropins have appeared to be more effective.[105] It should be noted that limited or even absent efficacy has been suggested recently[106] for any drug (CC, gonadotropins, or aromatase inhibitors) that is used as monotherapy without IUI in unexplained infertility.[107] In stimulated cycles, the additional use of GnRH antagonists or agonists for LH peak suppression have shown not to be cost-effective, while the use of luteal support with vaginally applied progesterone may be of benefit but is awaiting larger trials to demonstrate a true effect.

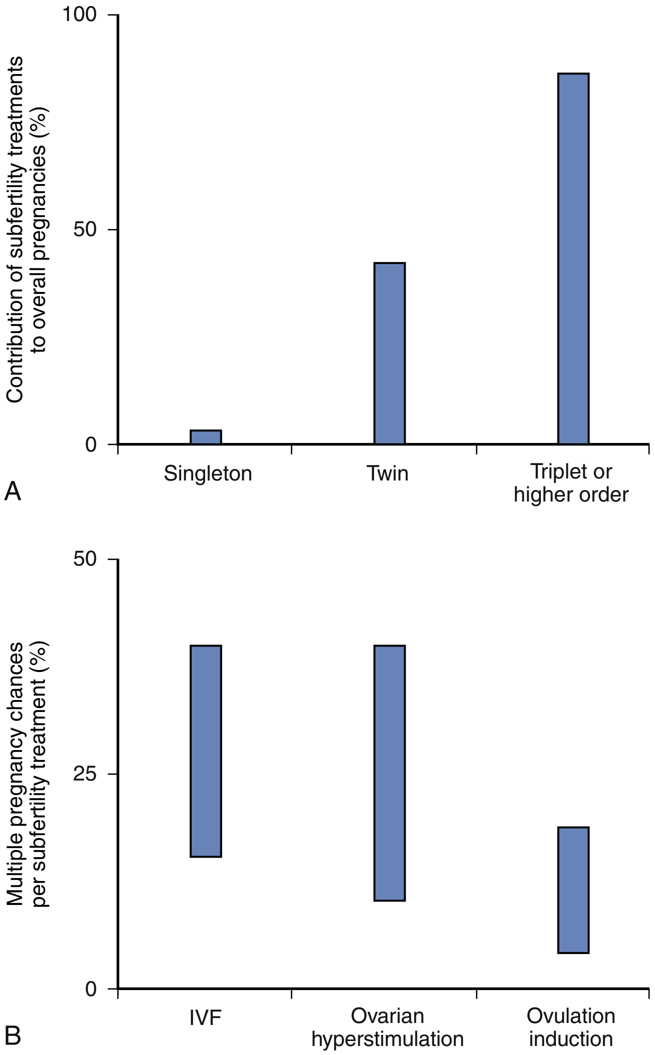

Figure 123.5 Contribution of infertility treatments to overall pregnancies (**A**) and reported frequency of multiple pregnancy in relation to *in vitro* fertilization (IVF), ovarian hyperstimulation, and ovulation induction (**B**). The graphs show that assisted reproduction contributes considerably to the rate of multiple pregnancies in society and affects singleton rates only minimally. Also, ovarian (hyper)stimulation without access to the choice of how many embryos may be implanting contributes heavily to the totals of multiples pregnancies from infertility treatments. (Data from Fauser BC, Devroey P, Macklon NS. Multiple birth resulting from ovarian stimulation for subfertility treatment *Lancet.* 2005;365:1807–1816.)

In case the total number of motile sperm inseminated is < 5 million, IUI treatment will hardly lead to pregnancies and is best abandoned. With sufficient sperm quantity, acceptable cumulative ongoing pregnancy rates after six cycles of IUI with OS can be obtained, with the highest yield in the first three cycles and stable cycle rates up until the ninth cycle. Timing of the insemination using LH surge detection in natural cycles is preferred over the use of human chorionic gonadotropin (hCG) triggering, and generally a time interval of 12 to 36 hours is optimal, depending on the triggering mode applied.

Intrauterine Insemination

IUI refers to placing sperm, after a washing procedure in the laboratory, in the uterine cavity just before ovulation. The rationale for IUI combined with OS is to increase gamete density at the site of fertilization (i.e., the fallopian tube). Hence, the classic indications for IUI are male (erectile and ejaculatory) or female (vaginismus) sexual dysfunction and cervical hostility. IUI combined with mild OS has been applied in couples suffering from male factor and unexplained infertility.

Renewed interest in IUI reflects the evolution of better washing techniques (i.e., gradient or swim-up) to improve the quality of the initial sperm sample by removing prostaglandins, infectious agents, and antigenic proteins, and nonmotile cells (leukocytes) or immotile and immature spermatozoa and thus decreased cytokines and lymphokines and subsequent reduction in free oxygen radicals.[108] IUI is usually performed within 30–36 hours after hCG administration or 20–28 hours after the LH surge.[109] It is performed using a small flexible catheter through which a small volume (0.3 to 0.5 mL) of culture medium containing the washed spermatozoa is delivered into the uterine cavity. When IUI is used to manage fertility problems, single rather than double insemination should be used.[110]

IUI combined with OS in the treatment of infertility remains a topic of ongoing debate. A recent literature review has made clear that treatment with IUI with OS as well as IUI alone probably results in a higher cumulative live birth rate than expectant management in couples with a low prognosis for natural conception. IUI in a stimulated cycle may outperform IUI in a natural cycle.[104] Pregnancy chances as such may increase, but inherent associated risks include a considerable chance of multiple pregnancies, additional costs, and increased patient discomfort and chances for complications.[103]

A large retrospective analysis in a single European center, which assessed 1878 pregnancies attained through IUI combined with gonadotropin stimulation, reported a 16% twin and a 6% higher-order multiple pregnancy rate[111] (see Fig. 123.5). Also, a 2-year follow-up in a US infertility center involving 3347 OS cycles found a high multiple pregnancy rate, with an overall pregnancy rate of 30%.[112] Reducing the risk for a multiple pregnancy may result from restricting the number of dominant follicles allowed at the time of ovulation trigger. From a nationwide survey in the Netherlands, twin rates appeared to be as low as 9% per pregnancy, albeit at the cost of some reduction in the overall chance of ongoing pregnancy.[89,113,114]

Although births resulting from assisted reproduction represent only 1% of all live births in the United States, they now account for 35% of twin births and for more than 40% of triplet and higher-order multiple births.[101] The adverse impact of multiple births on perinatal morbidity and mortality has been clearly documented and should lead to management of the infertile couple that increases chances for pregnancy without causing complications that have lifetime consequences.[115,116]

Cost-effectiveness analyses so far have led to the conclusion that IUI, with or without OS, should precede IVF.[93,117] These assessments were made, however, before the advent of current approaches to minimize costs and minimizing complications in IVF through minimal OS and transfer of a reduced number of embryos.[95]

As pregnancy chances per cycle remain low, it can be calculated that the number needed to treat for patients to benefit from any additional intervention is high. For instance, when the combination of FSH and IUI is compared with IUI alone, 31 treatment cycles are required before there would be one more singleton live birth.[118] Offset against the additional pregnancy are the added costs of medications and of frequent ovarian response monitoring. When costs related to multiple pregnancies are also taken into consideration, the conclusion seems justified that widespread use of OS with exogenous gonadotropins combined with IUI should be discouraged. The real question remains whether society (especially patients, physicians, and health insurance companies) considers the high rate of multiple pregnancies an acceptable price to be paid for increased pregnancy chances per cycle. Thus, current international guidelines (NICE) recommend the use of IUI in the natural cycle as standard first-line treatment for couples with unexplained or mild to moderate male factor infertility, although the efficacy of such treatment clearly may be doubted. As the risk for a multiple pregnancy may become reduced by applying CC or LTZ as an OS agent, the widespread use of FSH OS in IUI treatment may need to be reconsidered. Recent and currently ongoing studies will provide answers to the preferred treatment modality.[119] Beginning treatment with CC/IUI will result in pregnancy in nearly one fourth of the couples, with minimal risk for multiple births. With IVF procedures using a high proportion of single-embryo transfer, eliminating gonadotropin/IUI will result in pregnancies with the lowest possible risk for multiple births. Compared with conventional infertility treatment, an accelerated approach to IVF after the initial CC/IUI treatment results in a shorter time to pregnancy with fewer treatment cycles, and cost savings.[120]

In Vitro Fertilization

IVF involves OS, oocyte retrieval, fertilization of oocytes *in vitro* (either spontaneously or by ICSI), and subsequent transfer of embryos into the uterine cavity. Aspects of IVF relevant to infertility management are discussed here.

IVF was originally designed for treatment of bilateral tubal occlusion, but currently the "tubal factor" represents only a small proportion of indications for IVF. At present, it is applied most often in cases of mild to moderate male factor and unexplained infertility. A meta-analysis of five relevant trials in unexplained infertility confirmed that no difference in pregnancy rates could be observed when IVF was compared with IUI, with or without ovarian hyperstimulation in treatment-naïve infertile couples (odds ratio: 1.96; 95% CI: 0.88–4.36).[102,121] This implies that first-line treatment may best be carried out using mild OS combined with IUI across a series of 6–9 cycles. The next step would then be IVF, although the added benefit has not been exactly assessed. Two separate studies indicated that initial treatment with IVF is not cost-effective when compared with a conventional treatment algorithm.[121–123]

Many advances in IVF, such as improved cryopreservation programs, blastocyst culture, techniques of the embryo transfer, and the widened application of GnRH antagonists cotreatment may have improved the efficiency over the past decade, along with improved safety by applying single-embryo transfer and better OHSS management.[124]

Tubal occlusion can give rise to hydrosalpinges. In women undergoing IVF, the presence of hydrosalpinges is associated with early pregnancy loss and poor implantation due to altered diminished endometrial receptivity. Thus, salpingectomy or at least occlusion of the isthmic part of the tubes should be offered before IVF when hydrosalpinges are present.[125]

Similarly, endometriosis-associated infertility reduces pregnancy rates. IVF represents an effective means of bypassing the hostile peritoneal environment and anatomic distortion associated with this disease. Pretreatment with GnRH agonists immediately before IVF initiation appears to be beneficial. It is uncertain whether only a specific subset or all patients with endometriosis would benefit from this approach; the use of endometrial implantation markers may be helpful in this regard.[28,126]

The incidence of multiple gestations in IVF is easier to control than OS with or without IUI, because in case of IVF the occurrence of multiples is primarily dependent on the number of embryos transferred. Increased emphasis is being directed toward decreasing the number of embryos for transfer and, therefore, diminishing the chances of (higher-order) multiple pregnancies. In a comparison of conventional maximal OS and replacement of two embryos, the application of milder OS with single-embryo transfer resulted in the same number of ongoing pregnancies leading to term life birth after a 1-year treatment period. Although on average one additional treatment cycle was required, the long-term medical costs and patient burden were the same.[96,127]

KEYPOINTS

- In unexplained infertility with a prognosis for spontaneous ongoing pregnancy of over 30% for the subsequent year, expected management is justified as infertility treatment is not likely to yield better prospects for the couple.
- In couples with unexplained infertility and a prognosis below 30% for the subsequent year, and in couples that have applied a period of 6-12 month of expected management without achieving an ongoing pregnancy, mild ovarian stimulation combined with intra uterine insemination is the preferred first line treatment.
- In vitro fertilization and related technology is considered the last resort in treatment of couples with unexplained infertility. It is however the first line treatment in couples with a clear cause such as tubal pathology. In couples with oligo-/an-ovulation, failed treatment by ovulation induction may be a justified indication to apply in vitro fertilization and related technology.

SUMMARY AND FUTURE DEVELOPMENTS

Infertility represents a serious health issue and is considered as a disease by WHO. Notably, most people worldwide have insufficient access to infertility and fertility care. Postponement of pregnancy beyond 30 years of age, as is observed in the Western world, is giving rise to an increased demand for infertility services, because more couples will fail to conceive spontaneously within 1 year of unprotected intercourse. The major clinical challenge remains to assess the reproductive aging status of a given woman. This will help to predict her pregnancy chances more accurately compared with assessment based on chronologic age alone. The use of multivariate models may further improve the prediction capacity of initial screening for a given couple. The duration of infertility and a woman's age constitute the most important predictors of chances for achieving a spontaneous pregnancy. This approach should help when couples are counselled regarding the likelihood of success of expectant management, or whether (empirical) treatment should be initiated.

The diagnosis of unexplained infertility can be made only after a proper diagnostic infertility workup has established the absence of any abnormalities. Because no consensus exists regarding the extent of testing that should be performed, unexplained infertility represents a notoriously heterogeneous group of patients. This condition may include couples with undiagnosed infertility and those with normal fertility for whom pregnancy, purely by chance, has not yet occurred. These patients often undergo empirical treatment to improve pregnancy chances per cycle. The inherent disadvantage of such an approach is decreased interest in the diagnostic workup, which impairs progress in our understanding of the underlying pathophysiology.

When costs and prematurity of newborns related to multiple pregnancies are also taken into consideration, the conclusion is justified that widespread use of OS with exogenous gonadotropins with or without IUI should be discouraged. With IVF, increased emphasis is directed toward decreasing the number of embryos for transfer and, therefore, diminishing the chances of (higher-order) multiple pregnancies. Additional cohort follow-up studies using appropriate end points, such as singleton, term delivered, and live birth rate, are required to elucidate further the optimal approach to empirical treatment of patients with unexplained infertility.

Numerous innovations in ART have emerged and are currently being evaluated for its clinical efficacy and safety. However, the stakes are high and novel technologies are often introduced prematurely in everyday patient care without sufficient scientific proof of safety and efficacy.

The most important recent developments in ART may be listed as follows:

1. Improved vitrification technology, allowing oocytes, embryos, and gonadal tissue to be cryopreserved with increased efficacy.
2. Blastocyst transfer; transition from the transfer of embryos into the uterus after 2 or 3 days of culture toward development up to the blastocyst stage on day 5 or 6 generating improved implantation and ongoing pregnancy rates.
3. Time laps monitoring; embryos are constantly being monitored for development potential in special incubators, using camera images and sophisticated software technology. Its clinical usefulness remains doubtful.
4. PGT-A; preimplantation genetic testing for aneuploidy. Aneuploidy screening can now be performed on a large scale using sophisticated next-generation sequencing of a number of cells removed from an early stage embryo before transfer, so only euploid embryos can be transferred. Potentially, this technology could also improve implantation rates, decrease miscarriage rates following IVF and therefore improve IVF success rates and time to pregnancy. However, again its clinical usefulness remains highly controversial.
5. A GnRH agonist bolus rather than hCG to stimulate final oocyte maturation at the end of the stimulation phase and prior to oocyte retrieval. This approach considerably reduced the risk for OHSS but can only be performed with GnRH antagonist cotreatment during OS.
6. Single embryo transfer; this policy initially developed in Northern Europe and is gradually being applied by the rest of the IVF community. Multiple pregnancies can be prevented by the transfer of one embryo at a time, significantly reducing pregnancy complications and improving perinatal outcomes. Supernumerary embryos can be cryopreserved and individually transferred in subsequent cycles. National data from various countries now demonstrate multiple pregnancy rates following IVF can be < 5%, with similar overall pregnancy rates. At present, in some countries approximately 50% of all children born are from cryopreserved embryos.
7. Freeze all embryos; OS for IVF gives rise to a supraphysiological endocrine milieu during the follicular phase of the cycle. Increasing evidence suggests that this may also impact endometrial receptivity and hence embryo implantation rates may be reduced. For these reasons, increasingly, IVF centers are applying "freeze all" strategies, where only embryos are transferred in subsequent cycles after freezing and thawing. The jury is still out whether this strategy will truly improve IVF outcomes.
8. Widespread use of fertility preservation strategies in oncology patients aiming to preserve their fertility potential once cured from the primary disease. Despite the fact that this technology is more and more available, there still seems much room for growth in the area. Even today, many young cancer patients are not being made aware of this option.

9. Nonmedical oocyte freezing; programs are offered worldwide to cryopreserve oocytes from young potentially fertile women who would like to have children later in life once circumstances are right. It is heavily debated whether this option is actually helping women by increasing their reproductive choices, or whether this development represents yet another example of exploitation of reproductive care.

KEYPOINTS

- Assisted Reproduction Technology as treatment for female infertility has evolved by creating numerous technical improvements in order to make this treatment more effective, safer and more bearable for the patient.
- A special note are the possibilities that this technology offers for fertility preservation strategies as well as the growing role in the prevention of hereditary disease through preimplantation genetic testing of embryos.

  Prevention of Long-Term Complications, 2076
Summary and Future Directions, 2076

In this chapter, we first summarize the normal physiology of androgen production in women. This is followed by a review of the pathogenesis and clinical presentation of disorders leading to androgen excess. Finally, an approach to the diagnosis, differential diagnosis, and therapy of these disorders is provided.

ANDROGEN PHYSIOLOGY AND PATHOPHYSIOLOGY

Androgen Biosynthesis

Androgens (from the Greek word *andre*-, the stem of the word meaning "man") comprise a group of steroid hormones that regulate the developmental process and maintain male and female characteristics by binding to their cognate receptors. Classically, four main androgens have been identified including testosterone, dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), and androstenedione, which are secreted from endocrine glands through similar pathways and are released into the circulation to exert a number of physiological functions (Table 124.1). More recently, other androgens, such as androsterone, have been found to play a key role in male sexual development and female hyperandrogenic disorders. Although androgens are essential during childhood, subsequently, their synthesis is important for pubertal development, sexual life, and improving fertility in males and females. Thus, androgen biosynthesis is regulated both in fetal and pubertal life in males and females.

Pathways of Androgen Biosynthesis. The early steps of steroid synthesis are shared between glucocorticoids, mineralocorticoids, and sex steroids; however, defects in the initial step will definitely affect the final product. Two possible pathways are described for androgen biosynthesis: the "classic" and the "backdoor" pathways[1] (Fig. 124.1). Animal studies, analyses of human tissues, and clinical studies have converged to form a classic model of androgen synthesis in a zone of the primate adrenal cortex called the zona reticularis.

The Classic Pathway of Androgen Biosynthesis. Cholesterol is the main precursor for the formation of all steroid end products, and the first step is transport to the inner mitochondrial membrane. Acute stimulation of androgen biosynthesis is mediated by steroidogenic acute regulatory protein (StAR), which is an active transporter of cholesterol through the inner mitochondrial membrane. Notably, any defect or mutation in StAR is accompanied by severe loss of adrenal steroidogenesis and lack of virilization.[2] StAR mutations, along with all other genetic defects of androgen biosynthesis, are inherited in an autosomal recessive fashion, and both types of genetic male and female individuals can be affected.[3]

The first enzymatic and rate-limiting step for the steroid cascade inside the mitochondrial inner membrane is supported by side-chain cleavage (SCC), a mitochondrial cytochrome enzyme (P450scc) that mediates the conversion of cholesterol into pregnenolone (Preg). Two cytochrome P450 enzymes (P450scc and cytochrome P450c17) are involved. P450scc stimulates the chemical reaction with the help of StAR protein in preparation for steroid hormone biosynthesis in the adrenal glands and the gonads.

In contrast, cytochrome P450c17 is important for cortisol and sex hormone biosynthesis. This enzyme is a qualitative regulator of steroid synthesis which has two distinct activities: 17α-hydroxylase and 17,20-lyase activity. These are essential for synthesis of cortisol, 17-ketosteroids DHEA, and androstenedione, precursors for steroid hormones.

For the production of testosterone through the classic pathway, first, pregnenolone is converted to 17-hydroxypregnenolone (17OH-preg) and then the 17,20-lyase activity of P450c17 converts 17OH-preg to DHEA, supported by cofactors P450 oxidoreductase and cytochrome

TABLE 124.1 Major Types of Androgen Source, Functions, and Metabolism in Women

Androgen Types	Site of Production	Production Rate/Day (mg)	Adrenal (%)	Ovarian (%)	Functions
Testosterone	Ovarian stroma, adrenal zona reticularis	0.1–0.4	25	25	Gonadotropin regulation, estradiol precursor, primordial follicle growth
DHEA-S	Peripheral tissue, adrenal zona reticularis	3.5–20	95–100	0–5	Preantral follicle development, androgen precursor, oocyte development
DHEA	Ovarian theca, adrenal zona reticularis	6–8	50	20	Testosterone precursor, anti-aging effect, improve sexual functions, endothelial proliferation
Androstenedione	Ovarian stroma, adrenal zona fasciculata	1.4–6.2	50	50	Testosterone precursor, follicle growth

Figure 124.1 Outlines of classic and backdoor pathway of androgens biosynthesis. Adrenal and gonadal pathways are combined in the figure. The left hand column indicates the Δ5 classic pathway, in which steroids retain the double bond between carbons 5 and 6 in cholesterol's B-ring. The StAR mediates the transport of cholesterol to the inner membrane of mitochondria, where P450 facilitates to cleave off the side chain and resultant pregnenolone (Preg) formation. Δ4 steroids are converted from Δ5 steroid by using 3βHSD2 (HSD3B2) within the adrenal and gonadal tissue. Progesterone (Prog) is converted into 17OH-prog in the zona fasciculate and gonads by P450c17. 17OH-prog and 17OH-preg is converted to androstenedione and DHEA by human P450c17 activity, followed by testosterone production in stepwise manner. DHEA is converted into androstenediol and then androstenedione to testosterone by the activity of 17βHSD3. Right hand side in red arrows indicates the backdoor pathways of adrenal biosynthesis. In alternative backdoor pathway, progesterone is converted into neuroactive steroid, allopregnanolone. Note that in the alternative pathway, 17OH-prog is 5α, 3α reduced and then converted into androstenedione. Androsterone is the principle androgen in fetal circulation which is converted into androstenediol by 17HSD17B3/5 and then further oxidized by HSD17B6 to yield into potent androgen DHT.*5-αRed2,* 5α-reductase type 2; *AKR1C2/4,* aldo-keto reductase family 1, member C2/4; *Aro,* aromates; *DHEA,* dehydroepiandrosterone; *DHT,* dihydrotestosterone; *HSD3B2,* 3β-hydroxysteroid dehydrogenase type 2; *Preg,* pregnenolone; *Prog,* progesterone; *StAR,* steroidogenic acute regulatory protein.

b5. P450c17 is encoded by a single copy gene on chromosome 10q24.3, and mutations within this gene can inhibit either all functions or selectively the 17,20-lyase activity of the resulting protein.[4]

DHEA is a C19 steroid and androgen precursor, which is then either converted to androstenedione (Δ4A) or androstenediol and finally to testosterone by the enzymes 3β-hydroxysteroid dehydrogenase type 2 (HSD3B2) and 17β-hydroxysteroid dehydrogenase (HSD17B3) that exhibit tissue-specific expression. Approximately 50% of testosterone comes from direct secretions from steroid-producing endocrine glands, whereas the remaining 50% is produced by different organs including the adipose tissue, liver, and skin which contain 3β-HSD type 1, 17β-HSD type 5, and P450arom enzymes.

Testosterone is further converted to the most potent androgen, dihydrotestosterone (DHT), by 5α-reductase type 2 (SRD5A2). Two isoforms of 5α-reductase are expressed in different tissues; however, 5α-reductase type 2 is the more abundant form in the gonads. With regard to the degree of androgen action at the androgen receptor (AR), DHT is the most potent androgen followed by testosterone, whereas weak stimulation of AR has been observed by androstenedione and androstenediol.[2]

The Backdoor Pathway of Androgen Biosynthesis. For the synthesis of DHT, an alternative "backdoor" pathway was first discovered in the tammar wallaby pouch young and then was identified in mouse pups.[5] It provided evidence that testosterone is the androgen in the circulation, while DHT exerts its actions locally on genital skin. This pathway bypasses the usual intermediate steroids DHEA, androstenedione, and testosterone. This alternative backdoor pathway diverges from the classic pathway with further conversion of 17-hydroxyprogesterone (17OH-prog) to 17OH-dihydroprogesterone (17OH-DHP; 5α-pregnane-17α-ol-3,20-dione), 17OH-allopregnanolone (17OH-Allo; 5α-pregnane-3α,17α-ol-3,20-dione), androsterone, and androstanediol (3αDiol) to DHT. The stepwise conversion of 17OH-prog to DHT is supported by the enzymes 5α-reductase type 1 (SRD5A1), AKR1C2/4, P450c17, HSD17B3/5, and AKR1C2/4. This novel alternate pathway to DHT thus circumvents the usual steroid intermediates and is thus considered as "the backdoor pathway."

The backdoor pathway plays an important role in a number of hyperandrogenic disorders including PCOS,[6] congenital adrenal hyperplasia (CAH),[7] some virilized female newborns with P450 oxidoreductase deficiency,[8] and mini puberty of infancy.[9]

Regulation of Androgen Secretion

Organ-Specific Androgen Secretion Regulation.

In women, the ovaries and adrenal glands are the prime source of androgen secretion stimulated by luteinizing hormone (LH) and adrenocorticotropic hormone (ACTH), respectively. ACTH is a 39-amino acid peptide synthesized and secreted by the anterior pituitary (Fig. 124.2). Both corticotropin-releasing hormone and arginine-vasopressin work synergistically to regulate the synthesis of ACTH. The secretion and levels of adrenal androgens are controlled by intraglandular paracrine and autocrine mechanisms, rather than direct negative feedback by the pituitary gland.

Circulating androgens are predominantly produced in the ovaries, adrenal glands, and from peripheral tissue conversion. Androgen precursors, including DHEA, DHEAS, and androstenedione, and the active androgen testosterone are the major androgens secreted from the adrenal glands. Two potent bioactive androgens, testosterone and DHT, directly bind to the receptors, whereas DHEA, DHEAS, and androstenedione are pro-androgens that exert androgenic effects after conversion to testosterone and DHT. DHT, the most potent androgen, circulates at very low levels due to its production from local metabolism within tissues.

The synthesis and production of androgens vary by age; for example, DHEAS levels are high in newborns and then precipitously decline until adrenarche, which commences approximately at 6–8 years of age. High levels of DHEA and DHEAS are the hallmark of adrenarche. Increased levels of DHEAS are noted prior to the increase in the circulating concentrations of estrogens and androgens, whose synthesis and increasing blood levels are directly associated with puberty. Circulating levels of DHEAS are high during the second decade of life, and higher levels are noted in males than in females. However, no significant increase in the concentration of cortisol and ACTH has been observed during this period, indicating that adrenarche is not dependent on activation by the pituitary axis. The following sections describe the organs specific for androgen production and metabolism.

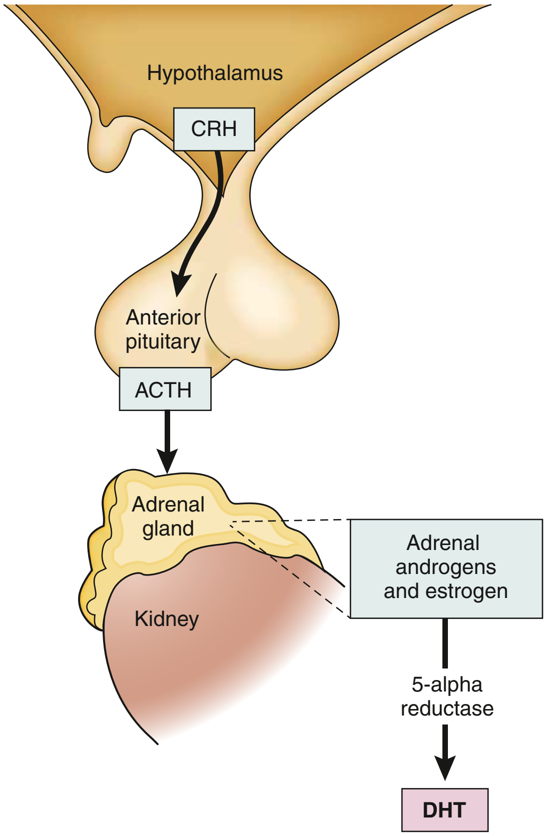

Figure 124.2 Schematic outlines of regulation for androgen secretion by adrenal structure. *ACTH,* Adrenocorticotropin; *CRH,* corticotrpin-releasing hormone; *DHT,* dihydrotestosterone.

Ovary. The principal source of ovarian androgens is theca interna cells and the ovarian stroma of the developing follicles. The mechanism of regulation of androgen secretions is similar to Leydig cell regulation in the testes. The combined activity of LH and follicle-stimulating hormone (FSH) is required to stimulate ovarian steroidogenesis, with LH stimulating the theca-interstitial (thecal) cells to produce androgen precursor for subsequent conversion by ovarian granulosa cells under the action of FSH (Fig. 124.3). In the adult human ovary, progesterone and estradiol are produced from the androgen precursor cholesterol under the control of LH and FSH. The production of progesterone occurs during the luteal phase, while estrogens are produced in the follicular phase. Human granulosa cells convert cholesterol to pregnenolone (due to lack of P450c17) which is further converted into progesterone and then ultimately to androstenedione. Androstenedione secretion from the theca cells represents approximately 50% of circulating androgens in women. Androgenic precursors (especially androstenedione) are produced by thecal cells under LH stimulation and aromatized to estrogen by FSH-stimulated granulosa cell aromatase activity. During the preovulatory phase, the high level of LH inhibits the activity of 17,20-lyase and 17α-hydroxylase, thereby ultimately reducing testosterone and androstenedione concentrations. The growth of antral stage follicles requires stimulation of granulosa cells via FSH action. Increased androstenedione and estradiol secretion accompanies the development of the dominant follicle. Androgens are obligate intermediates for the synthesis of estradiol and play an important role in follicle selection, follicle recruitment, and ultimately follicular growth (see Chapters 118 and 119). Therefore, the overall functional activity of the ovarian follicle structure is highly associated with the level of estradiol. High

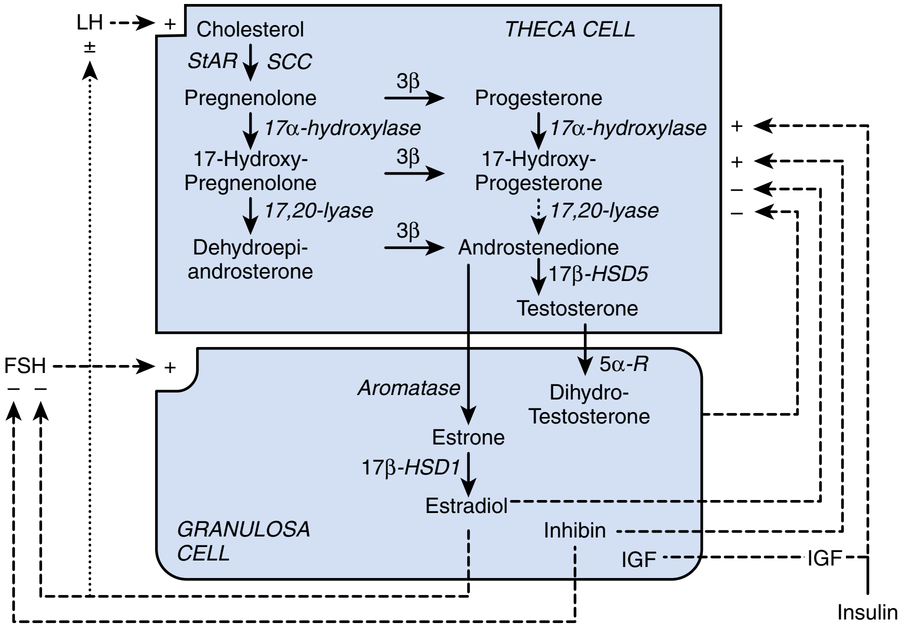

Figure 124.3 Outline of the organization of the major steroid biosynthetic pathways in the small antral follicle of the ovary, depicted according to the two-gonadotropin, two-cell model of ovarian steroidogenesis. Luteinizing hormone (LH) stimulates androgen formation within theca cells via the steroidogenic pathway common to the gonads and adrenal glands. Follicle-stimulating hormone (FSH) regulates estradiol biosynthesis from androgen by granulosa cells. Long-loop negative feedback of estradiol on gonadotropin secretion does not readily suppress LH at physiologic levels of estradiol and stimulates LH under certain circumstances. Androgen formation in response to LH appears to be modulated by intraovarian feedback at the levels of 17-hydroxylase and 17,20-lyase, both of which are activities of cytochrome P450c17. The quantitative importance of androstenedione formation from 17 OH-Prog *(dotted arrow)* in the intact follicle is unknown. Androgens and estradiol inhibit *(minus signs)* and inhibin, insulin, and insulin-like growth factor-1 (IGF-1) stimulate *(plus signs)* 17-hydroxylase and 17,20-lyase activities. Polycystic ovary syndrome as a form of functional ovarian hyperandrogenism due to dysregulation of androgen secretion. *Endocr Rev.* 1995;16:322–353. Copyright © 2007 The Endocrine Society.)

levels of androgens suppress ovulation and cause the development of the histologic and gross anatomic features of the polycystic ovary (PCO, see below).

Ovarian thecal androgen production is regulated by the functional activity of LH. Desensitization in part is mediated by downregulation of the LH receptor binding sites by LH itself (homologous desensitization). The main product obtained from the theca interna and stroma cells of the ovary is androstenedione, which ultimately is transformed into testosterone by the activity of theca and granulosa cells; however, the ability of the granulosa cells to synthesize testosterone is relatively high compared with theca cells. These androgens transport to the granulosa cells by the process of diffusion through the basal membrane of follicles, and inside the granulosa cells, the androgen precursor is aromatized to 17β estradiol by the stimulatory action of FSH on the aromatase enzyme activity. FSH in combination with estradiol increase the division of granulosa cells and ultimately the volume of the antral cavity. Regulation of androgen secretion is a complex process in which different hormones and growth factors are involved that mediate ovarian functional activity that ultimately increases steroidogenesis by activation of P450c17 (see Fig. 124.3). The activity of P450c17 is inhibited by estrogen through a negative feedback mechanism using both paracrine and autocrine routes. These inhibiting activities are balanced by the action of different hormones and growth factors including insulin, insulin-like growth factor-1 (IGF-1), and inhibin that ultimately amplify P450c17 action (see Fig. 124.3 and see Chapter 119).

Adrenal Cortex. The adult human cortex is composed of three layers: the zona glomerulosa (ZG) for mineralocorticoid production, the zona fasciculata (ZF) for glucocorticoid production, and the zona reticularis (ZR) for androgen production. ZG and ZF play an important role during fetal life, while the ZR production of steroid hormones begins slowly after birth and becomes active at adrenarche, approximately at 6–8 years of age. Differentiation of the centripetal progenitor cells into ZR, then ZG, and finally again conversion into ZR cells underlies the development of the adrenal zones. In terms of androgen production, the activity of ZR reaches a maximum at the age of 30 years and then declines thereafter. The activity of ZR is low for HSD3B2 and high for P450C17-20 lyase, and sulfonyl-transferase (SULT2A1), ultimately yielding massive production of DHEA and DHEAS.[10]

Adrenal 17-ketosteroid is an important androgen whose secretion commences in mid-childhood and reaches its maximum at adrenarche. Adrenarche is characterized by a change in the pattern of the adrenal secretory response to ACTH. ACTH elicits cortisol production prior to adrenarche, although both cortisol and 17-ketosteroid secretion begins after adrenarche. Factors contributing to this change at adrenarche are nutritional status, somatic growth, secretion of leptin, insulin, and IGFs; however, further investigation is needed to highlight the role(s) of each of these factors. There are marked increases in the production of 17OH-preg and DHEA that cause increased transformation of DHEAS, the predominant androgen secreted by the adrenal gland. DHEAS is a unique secretory product released from the ZR at 3.5–20

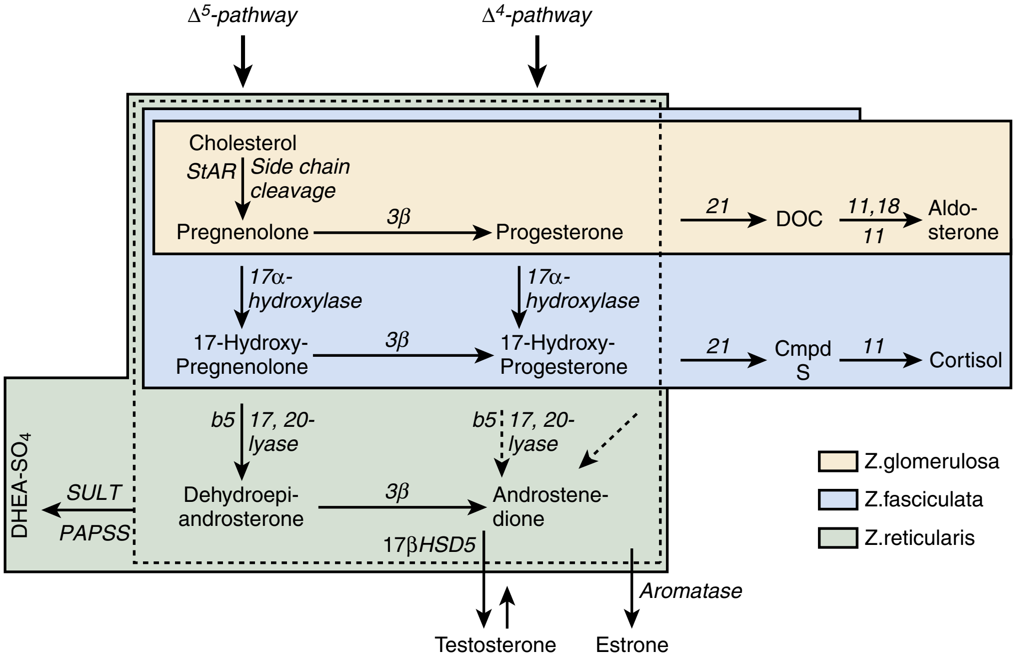

Figure 124.4 Outline of the organization of the major steroid biosynthetic pathways in the adrenal cortex. The area within the dotted square contains the core steroidogenic pathways, of which the *left column* shows the Δ5-pathway and the *right column* shows the Δ4-pathway, also utilized by ovarian theca cells. The *top yellow row* shows the pathway to aldosterone; the *middle blue row* shows the zona fasciculata pathway to cortisol. The *lower green row* shows the zona reticularis steps to DHEA-sulfate (SO_4) and other 17-ketosteroids. The *dotted box* encompasses steps common to all zones and the gonads. *Dotted pathways* are considered to be relatively minor. Cmpd S = 11-deoxycortisol; the 11-deoxy intermediate to aldosterone (deoxycorticosterone) is not shown. The steroidogenic enzymes are *italicized*. Cytochrome P450 enzyme steps are: side-chain cleavage (scc); 17α-hydroxylase/17,20-lyase; 21-hydroxylase (21); 11β-hydroxylase/18-hydroxylase-dehydrogenase (11,18); and aromatase. Non-P450 enzyme steps are steroidogenic acute regulatory protein (StAR); Δ5-isomerase-3β-hydroxysteroid dehydrogenase type 2 (3β); 17β-hydroxysteroid dehydrogenase type 5 (17βHSD5); and sulfotransferase 2A1 (SULT). Clinically relevant electron and sulfate transfer enzymes are, respectively, P450-oxidoreductase (POR), cytochrome b5 (b5), and 3′-phosphoadenosine-5′-phosphosulfate synthase 2 (PAPSS). mg per day in reproductive age women. Changes during adrenarche are highly associated with the development of the ZR and the adrenal zone that produces large amounts of DHEA and DHEAS (Fig. 124.4).[2] The activity of 3β-HSD and cytochrome b5 increases the production of DHEA that is further converted into DHEAS in the adrenal gland by the action of high zonal expression of *SULT2A1*. *SULT2A1* (steroid sulfotransferase or cholesterol sulfotransferase) is highly expressed in the cytoplasm of adrenocortical cells in the reticularis and its substrates include pregnenolone, 17α hydroxypregnenolone, and DHEA. During fetal development, these steroids are used as substrates resulting in high levels of sulfated products that are then transported to the placenta for further biosynthesis. However, the predominant substrate in adults is DHEA which ultimately is transformed into DHEAS. The quantity of DHEAS varies across the life span, however, although it is the dominant androgen released from the adrenal gland. Similarly, in the ovary different factors, including insulin and IGFs, contribute to the production of adrenal steroids in response to ACTH. Infusion of insulin to hyperandrogenic women modestly potentiates the 17-ketosteroid response to ACTH in a manner that is compatible with increases in 17-hydroxylase and 17,20-lyase activities. *In vitro* studies have directly shown that insulin and IGFs upregulate adrenal 17-hydroxylase, 17,20-lyase, and 3β-HSD activities.

Blood Levels and Transport of Androgens

Serum concentrations of androgens and intermediate products in their biosynthesis and metabolism are shown in Table 124.2. Androgens in women are mainly derived from the adrenal gland and ovary. While serum DHEAS levels usually reflect adrenal androgen production, testosterone, androstenedione, and DHEA are secreted by both the ovary and the adrenal gland. Among circulating androgens, testosterone is the most important biologically and clinically because of its relatively high serum concentration and potent effect on target organs.

Androgens exist in the blood in conjugated or unconjugated forms. Over 96% of plasma testosterone binds to carrier proteins including sex hormone-binding globulin (SHBG) and albumin. SHBG is a glycoprotein synthesized in the liver and secreted into the circulation.[11] It has a high binding affinity for testosterone, leading to a small fraction of total testosterone as free and bioavailable. The binding of testosterone to albumin is of much lower affinity, and therefore SHBG concentration is the major determinant of the testosterone remaining free and biologically active in the blood. SHBG serum levels are influenced by metabolic and hormonal factors in various physiological and pathological conditions. Therefore, they not only change (usually decreased) in metabolic diseases such as obesity, type 2 diabetes mellitus, and non-alcoholic fatty liver disease, but also in thyroid disorders, pituitary diseases, and breast and

prostate cancer.[12] Reportedly, tumor necrosis factor (TNF)-α downregulates SHBG in chronic low-grade inflammatory diseases such as obesity and type 2 diabetes mellitus.[13] PCOS is also considered to be a low-grade chronic inflammatory state, and SHBG levels are often decreased in the PCOS patients (see below), which may be due to hyperinsulinemia as well as elevated TNF-α.[14] Therefore, in some PCOS patients whose total testosterone levels are still in the normal range, their serum *bioavailable* testosterone levels are often elevated. This elevation of free or bioavailable testosterone is the best single indicator of hyperandrogenism. However, direct free testosterone assays, such as radiometric or enzyme-linked assays, are not recommended to assess biochemical hyperandrogenism in PCOS.[15] Instead, there has been increasing reliance and standardization of measuring testosterone levels through liquid chromatography with tandem mass spectrometry (LC-MS/MS) due to high sensitivity, accuracy, and precision.

Mechanisms of Androgen Action

Androgens exert their effects by binding to the AR in target cells. The human *AR* gene is located on the X chromosome and encodes a nuclear hormone receptor. After binding to testosterone, AR binds to DNA and results in activation or repression of target genes. However, the biological activity of testosterone is dependent largely on its conversion to DHT. DHT has greater biological activity than testosterone due to its higher affinity for AR.[16] It is primarily formed from testosterone and other precursors by the 5α-reductase activity in peripheral tissues including skin and liver, which largely determines the androgen action. Skin is not only a main site for androgen conversion but also a target organ of androgen, where AR is expressed in the hair follicle and sebaceous gland. In the ovary, androgen stimulates follicle development through binding to its receptor which is expressed in granulosa cells, theca cells, and oocytes.[17] Polymorphisms and skewed X-inactivation of the AR have been associated with sensitivity to androgens. In addition, androgens can also exert effects via rapid non-genomic mechanisms.[18]

KEY POINTS

- The major types of androgen in women are testosterone, DHEAS, DHEA, and androstenedione.
  Androgens in women are biosynthesized via the classic pathway and the backdoor pathway.
- Circulating androgens are predominantly produced in the ovaries, adrenal glands, and from peripheral tissue conversion.
- Androgen exit in the blood in conjugated or unconjugated forms.
- Over 96% of plasma testosterone binds to SHBG and albumin.

CLINICAL MANIFESTATION OF ANDROGEN EXCESS

Cutaneous Manifestations

Hair follicles are associated with sebaceous glands to form pilosebaceous units (PSUs) (Fig. 124.5). Hair is categorized as either *vellus* or *terminal*. Vellus hair is fine, soft, and not pigmented, whereas terminal hair is long, coarse, and pigmented. Growth of the hair follicle of PSUs is controlled by an as yet uncharacterized induction factor(s) elaborated by the dermal papilla. Androgen promotes sebum production and induces transformation of vellus to terminal hair. In target areas, androgens cause the prepubertal PSUs to differentiate into either a sexual hair follicle (in which the vellus hair transforms into a terminal hair) or into a sebaceous gland (in which the sebaceous component proliferates and the hair remains vellus). Anti-androgens reverse this process, causing PSUs to revert toward the prepubertal state. The effect of androgens on PSUs varies by body location and largely depends on local concentrations of active androgen (testosterone and DHT) and abundance of ARs.

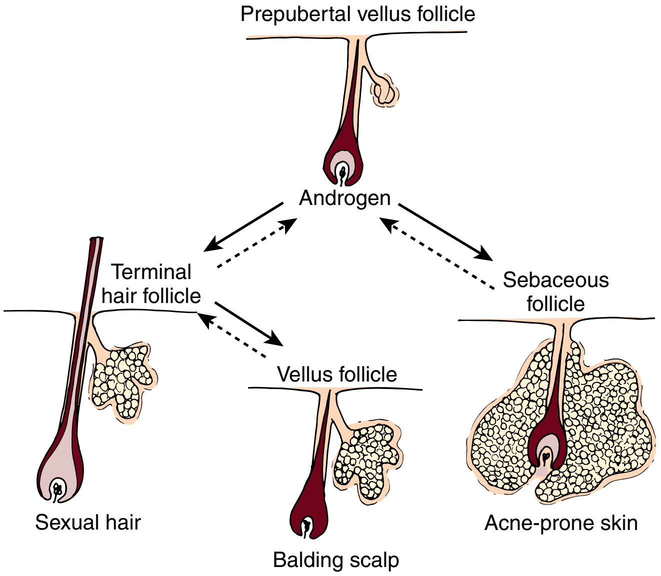

Figure 124.5 **Role of androgen in the development of the pilosebaceous unit.** *Solid lines* indicate effects of androgens, and *dotted lines* indicate the effects of anti-androgens. Hairs are depicted only in the anagen (growing) phase of the hair cycle. In conjunction with other regulatory factors, androgens cause the prepubertal pilosebaceous unit in androgen-dependent areas to differentiate into either a sexual hair follicle, in which the vellus hair transforms into a terminal hair, or into a sebaceous follicle, in which the sebaceous component proliferates and the hair remains vellus. In balding scalp *(bottom center),* terminal hairs not previously dependent upon androgen regress to vellus hairs under its influence. (Reproduced with permission from Deplewski D, Rosenfield RL. Role of hormones in pilosebaceous unit development. *Endocr Rev.* 2000; 21:363-392. Copyright ©2000 The Endocrine Society.)

Hirsutism is defined as excessive male pattern hair growth in women and is the most common clinical diagnostic criterion of hyperandrogenism. Hirsutism must be distinguished from *hypertrichosis*, i.e., excessive growth of androgen-independent hair which is vellus, prominent in nonsexual areas, and most commonly familial or caused by metabolic disorders (e.g., thyroid abnormalities, anorexia nervosa) or medications (e.g., phenytoin, minoxidil, or cyclosporine). The clinical presence of hirsutism is usually determined by a scoring scale of hair growth in nine body areas, i.e., the modified Ferriman-Gallwey (mFG) scale (Fig. 124.6). There are significant ethnic and racial differences in the definition of hirsutism. In adult White American and Black women, hirsutism is defined by a total score of 8 or more on the mFG scale. Thus, it is normal for these women to have a few sexual hairs in many "male" areas (upper lip and chin). Notably, scores ≥2 to 3 in Han Chinese and Thai women, and ≥9 to 10 in Mediterranean, Hispanic, and Middle Eastern women are excessive.[19] However, there are limitations in this scale, mainly due to the subjective nature of assessment, interobserver variance, and problems in evaluating women who had cosmetic therapies.

Acne and male pattern balding (androgenic alopecia) are other cutaneous manifestations of androgen excess.[20] Acne is characterized by increased sebum production and obstructed sebaceous follicle by keratinization of epithelial cells. Androgenic alopecia in women can display both a male pattern and a female pattern of hair loss. The male pattern is characterized by hair loss mainly in the sagittal scalp accompanied by recession of the frontal hairline and can be associated with virilizing levels of circulating androgens. The female pattern of androgenic alopecia is characterized by progressive thinning of the crown area of the scalp and is often characterized clinically by the Ludwig

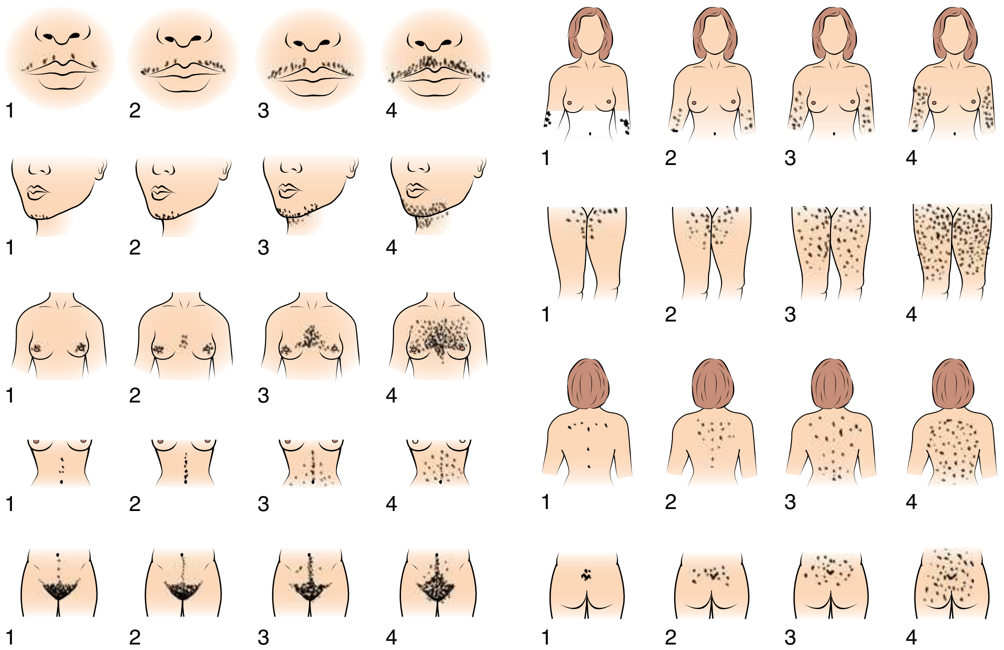

Figure 124.6 **Hirsutism scoring scale of Ferriman and Gallwey.** The nine body areas possessing androgen-sensitive pilosebaceous units are graded from 0 (no terminal hair) to 4 (frankly virile) and the sum totaled. Normal hirsutism score is less than 8 in adult White American and Black women. (Modified with permission from Hatch R, Rosenfield RL, Kim MH, Tredway D. Hirsutism: implications, etiology, and management. *Am J Obstet Gynecol.* 1981;140:815–830.)

scale.[21] Androgenic alopecia is largely the result of conversion of terminal hair to sebaceous follicles under the impact of androgen excess. The mechanisms for the different PSUs' response to androgen are still unclear. The cutaneous signs vary with the degree of androgen excess and are also dependent on the sensitivity of the PSUs to androgens. Some hyperandrogenic patients have hirsutism or acne alone, others both, yet others neither ("cryptic hyperandrogenemia").

Elevated serum total or bioavailable testosterone concentration underlies half of the cases of mild hirsutism, and most women with a 2-fold or greater elevation of androgen levels have some degree of hirsutism.[22] Moderately severe hirsutism or cystic acne is even more likely to be hyperandrogenic. However, the amount of sexual hair and sebaceous gland development seems to depend as much upon the factors determining sensitivity of the PSUs to androgens as it is upon the serum androgen level itself. At one end of the normal spectrum are women whose PSUs seem "hypersensitive" to normal blood free androgen levels; this seems to account for "idiopathic" hirsutism and acne. At the other end of the spectrum are women whose PSUs are relatively insensitive to androgen, accounting for "cryptic" hyperandrogenemia (hyperandrogenism without skin manifestations).

Polycystic Ovary and Polycystic Ovary Morphology

Polycystic ovary morphology (PCOM) describes a state of excessive numbers of small antral follicles (2–9 mm in diameter) present in the ovaries. With advances in sonography, antral follicles can be easily and precisely counted, although the threshold in the number of follicles for the diagnosis of PCOM is still controversial and is subject to the ever-greater resolution of transvaginal ultrasonography.[23] An ovary containing ≥ 12 antral follicles or an ovarian volume of ≥ 10 mL is diagnostic for PCOM by the Rotterdam criteria.[24] PCOM is tightly associated with androgen excess in patients with PCOS, CAH, and in prenatally androgenized nonhuman primate models, suggesting a causal relationship. Exposing rhesus female fetuses to high intrauterine concentrations of testosterone induces features of PCOM. The AR is highly expressed in preantral follicles and early antral follicles, declines with follicle development, and is nearly absent in preovulatory follicles. Although the precise mechanisms are not known, androgen excess promotes initiation of primordial follicle growth and accelerates progression of primordial follicles to primary and early antral follicles.[25] Meanwhile, androgen excess may also reduce atresia of early antral follicles. These two effects combine and lead to excess numbers of small antral follicles and PCOM on ultrasonography. Additionally, androgen excess also stimulates hyperplasia of the ovarian cortex and stroma in studies of female-to-male transsexuals with excessive androgen exposure.[26]

The large number of small antral follicles produce excessive amounts of anti-Müllerian hormone (AMH), which counteracts the action of FSH on follicle development. Together with the accompanying dysfunctions in secretion of gonadotropins and altered intraovarian paracrine factors, the development of early antral follicles arrest and oligo-/an-ovulation occurs in PCOS (see below).

Metabolic Dysfunction

The effect of androgen on metabolism differs between males and females due to sex-specific activation of ARs in peripheral tissues and in the central nervous system. In men, androgen deficiency contributes to metabolic disturbance. However, in women androgen excess has adverse effects on metabolic homeostasis. Androgens widely act on peripheral metabolic organs and tissues, such as the adipose tissue, liver, skeletal muscle, and pancreas.[27] Androgen excess alters the pattern of fat distribution by promoting visceral fat accumulation. Abdominal obesity is closely correlated with hyperandrogenism, as evidenced by studies in women with PCOS, female-to-male transsexuals, and in androgenic animal models.[27] Abdominal adiposity in turn is an important risk factor for metabolic syndrome and cardiovascular disease (CVD).[28] Androgen excess also has a deleterious impact on glucose uptake and metabolism by adipocytes and skeletal muscle cells, which consequently impairs insulin sensitivity. Insulin resistance is the central pathophysiology of type

TABLE 124.3 Causes of Androgen Excess in Women

- Functional Gonadal Hyperandrogenism
  - Primary functional ovarian hyperandrogenism (common form of polycystic ovary syndrome)
  - Secondary polycystic ovary syndrome
  - Virilizing congenital adrenal hyperplasia
  - Ovarian steroidogenic blocks
  - Syndromes of severe insulin resistance
  - Acromegaly
  - Epilepsy ± valproic acid therapy
  - Disorders of sex development
  - Pregnancy-related hyperandrogenism
- Functional Adrenal Hyperandrogenism
  - Primary functional adrenal hyperandrogenism (uncommon form of polycystic ovary syndrome)
  - Congenital adrenal hyperplasia and related adrenal steroid metabolism disorders
  - Other glucocorticoid-suppressible hyperandrogenism
  - Prolactin excess
  - Cortisone reductase deficiency
  - Glucocorticoid-nonsuppressible functional adrenal hyperandrogenism
  - Cushing's syndrome
  - Glucocorticoid resistance
- Peripheral Androgen Overproduction
  - Idiopathic hyperandrogenism
  - Obesity
  - Portohepatic shunting
  - Androgenic drugs
- Tumoral Hyperandrogenism

2 diabetes. In women with PCOS, studies suggest that PCOS subtypes with hyperandrogenism have an increased risk of metabolic syndrome, insulin resistance, and hyperlipidemia compared with other subtypes.[29]

KEY POINTS

- The common clinical manifestations of androgen excess include hirsutism, polycystic ovary, and metabolic dysfunction.
- Mild hirsutism is unrelated to hyperandrogenemia in half of cases.
- Hirsutism, acne vulgaris, and male pattern balding are variably expressed in women with androgen excess.

COMMON ANDROGEN EXCESS DISORDERS

Polycystic Ovary Syndrome

Most women with androgen excess have ovarian hyperandrogenism as demonstrated by the results of ovarian vein catheterization, long-term administration of gonadotropin-releasing hormone (GnRH) agonists, dexamethasone suppression testing, or the acute ovarian steroidogenic response to the administration of a GnRH agonist or human chorionic gonadotropin (hCG).[30] The causes of gonadal androgen excess are listed in Table 124.3.

PCOS is the most common endocrine disorder in reproductive age women, with a prevalence between 5.5% and 19.9%.[31] Variance in reported prevalence may be due to the inconsistent diagnostic criteria and reflect the impact of ethnic origin, race, and environmental factors that can modify expression of the PCOS phenotype.[31] Since its first description in 1935 by Stein and Leventhal, diagnostic criteria for PCOS have evolved. Three international conferences have developed diagnostic criteria based on various combinations of otherwise unexplained clinical or biochemical evidence of hyperandrogenism, evidence of anovulation, and a PCO: National Institutes of Health (NIH) conference diagnostic criteria (1992), Rotterdam consensus criteria (2004), and Androgen Excess-PCOS Society (AE-PCOS) consensus criteria (2009).[24,25,32]

These criteria must be adapted to age, as adolescents display a high prevalence of physiologic anovulation and polycystic appearing ovaries.[31] Endocrine Society clinical guidelines suggest the criteria of persistent hyperandrogenism and oligomenorrhea.[33]

Reproductive Abnormalities. The signs of PCOS usually begin around menarche and persist thereafter. Anovulatory symptoms (oligomenorrhea, dysfunctional uterine bleeding, and/or infertility) occur in about 75%, and the remainder may have subclinical anovulation with eumenorrhea (phenotype 3).[31]

About 60% to 80% of PCOS patients have elevated levels of circulating androgens. DHEAS levels are elevated in about 25% of PCOS women and occasionally may be the sole abnormality of hyperandrogenemia.

The vast majority of PCOS patients have FOH, which can be identified after functional challenge. About 90% of PCOS women have elevated testosterone after adrenocortical function is suppressed by dexamethasone, and two thirds have a characteristic 17OH-prog hyperresponsiveness to GnRH agonist–induced endogenous gonadotropin release in the absence of evidence of a steroidogenic block.[34] *In vivo* and *in vitro* challenges with LH or the LH analog hCG result in markedly elevated 17OH-prog responses, and, to a lesser extent, elevated androgens, in PCOS versus non-PCOS women.

Functional adrenal hyperandrogenism (FAH) is also common in PCOS. Approximately 30% to 50% of patients with PCOS also have a characteristic adrenal dysfunction. This usually coexists with FOH but in 5% occurs independently as the adrenal form of PCOS.[34] This primary FAH is characterized by moderately excessive responses of DHEA and 17OH-preg to ACTH without evidence of a block in steroidogenesis. Elevated DHEAS is found in 20% to 60% of these cases. This has been postulated to represent the adrenal manifestation of a generalized steroidogenic dysregulation in PCOS.[35]

Excessive LH secretion relative to FSH was the first laboratory abnormality identified in classic PCOS.[34] Hypersecretion of LH occurs in about 90% of PCOS subjects as evidenced by elevated mean LH levels, an exaggerated LH response to GnRH, increased LH pulse amplitude, and increased LH pulse frequency. However, obesity suppresses LH levels, and most obese women have normal baseline and stimulated LH levels.[36] In addition, because of the pulsatile nature of LH secretion, a random LH level may be well within the normal range in a woman with PCOS.

Metabolic Abnormalities. About two-thirds of women with PCOS are insulin resistant, and the degree of insulin resistance in PCOS exceeds that of women without PCOS who are matched by body mass index (BMI) or degree of adiposity.[37] Women with PCOS are at increased risk for developing type 2 diabetes. Impaired glucose tolerance (IGT) or frank diabetes is evident in approximately 45% of women with PCOS by their fourth decade. Long-term follow-up of women with PCOS substantiates an increased prevalence of type 2 diabetes compared with that of appropriate control groups. The conversion rates from normal glucose tolerance to either IGT or type 2 diabetes are also high in women with PCOS.[38,39]

The development of elevated fasting or glucose challenge glucose levels is evidence of compromised ability of the pancreatic beta cells to compensate for insulin. Alterations in insulin secretion are demonstrable in PCOS women, which may have a genetic basis, since they are present more often in women with PCOS who have a first-degree relative with type 2 diabetes.[38]

Women with PCOS are also at increased risk for metabolic syndrome. Up to 43% of nondiabetic women with PCOS meet diagnostic criteria for metabolic syndrome well before the end of their fourth decade, and most of these meet the criteria before the end of their third decade of life.[28] Indeed, the prevalence of metabolic syndrome in young PCOS women is similar to that in women aged 50–60 years.[28] The metabolic syndrome and its individual components are particularly common among those PCOS women with the highest insulin levels and BMI.[28]

Women with PCOS are also at increased risk of cardiometabolic disease.[40] Dyslipidemia is reported in up to 70% of PCOS patients.[41] Various lipid patterns have been described, the most common being increased levels of low-density lipoprotein (LDL) cholesterol, very-low-density lipoprotein (VLDL) cholesterol, and triglycerides, and reduced levels of high-density lipoprotein (HDL) cholesterol (particularly decreased HDL2, the most anti-atherogenic HDL subtype) compared with control women. Qualitative disorders of LDL cholesterol have also been described and are characterized by an increased amount of small, dense LDL cholesterol, which is an independent predictor of cardiovascular morbidity and mortality. The latest systematic review and meta-analysis including 23 cohort studies found that women with PCOS had increased risks of hypertension (risk ratio: 1.75) and nonfatal cerebrovascular disease events (risk ratio: 1.41). Over 10 years of follow-up, the frequency of hypertension of women with PCOS has increased from 16.1% (95% CI: 11.0%–21.2%) to 34.7% (95% CI: 28.1%–41.3%). However, no significant differences were found for coronary disease events (risk ratio: 1.78, 95% CI: 0.99–3.23). Due to the paucity of mortality data, the meta-analyses could not be performed for fatal CVD events.[40] Consequently, prognosticating events from these findings should be done with caution. During 24 years of follow-up, the Nurses' Health Study II found that irregular and long menstrual cycles in adolescence and adulthood are associated with a greater risk of premature mortality (age < 70 years) from cancer and CVD. This relation is slightly stronger among women who smoke.[42] Future clinical trials are needed to assess the ability of cardiometabolic screening and management in women with PCOS.

Women with PCOS have an increased rate of nonalcoholic fatty liver disease (NAFLD) (hazard ratio: 2.23). In addition to increased BMI and dysglycemia, androgen excess contributes to the development of NAFLD in women with PCOS.[43] NAFLD is also associated with insulin resistance. Ultrasound evidence of fatty liver occurs significantly more frequently in obese PCOS subjects than in obese controls and is associated with hyperinsulinemia and insulin resistance. NAFLD was present in 41% of obese PCOS subjects in one series, and half of those had elevations of ALT, suggesting the possibility of the more severe nonalcoholic steatohepatitis.

Endometrial Carcinoma. Women with PCOS have about a 2.7-fold increased risk for endometrial cancer. Most endometrial cancers in this population are well-differentiated adenocarcinomas and have a good prognosis.[44] Although 5% or fewer endometrial cancers occur in women younger than 40 years of age, the majority have PCOS. PCOs are present in the pathologic specimens of 62% of women younger than 50 years of age with endometrial carcinoma.

Pathogenesis

Ovarian Dysfunction. FOH accounts for the vast majority of PCOS. Early *in vitro* studies showed that the ovary was the primary androgen source in PCOS.[34] Women with classic PCOS have a characteristic pituitary-ovarian response to testing with an acute GnRH agonist challenge. Their gonadotropin responses resemble those of males in that they have significantly greater early LH and lesser FSH responses than normal females. They have greater 17OH-prog and androstenedione, without evidence of a block in the subsequent steroidogenic steps or consistent abnormalities in earlier steps in the steroidogenic pathway, suggesting increased ovarian 17-hydroxylase and 17,20-lyase activities as part of a generalized overactivity of steroidogenesis. This dysregulation of ovarian steroidogenesis can manifest in the absence of LH excess or sonographic abnormalities.

Dysregulation of ovarian steroidogenesis appears to account for most FOH. Dysregulation in turn appears to result from resetting of the LH steroidogenic dose-response curve, "escape from downregulation," rather than from excessive LH stimulation. Both *in vivo* and *in vitro* studies indicate that the steroid responses of PCOS women do not fall along the normal LH steroid dose-response curve, but rather seem displaced upward and to the left,[34,44] indicating hypersensitivity to LH stimulation.

The cause of dysregulation of theca cell function could be intrinsic or extrinsic to the ovary. IGFs and inhibins are FSH-inducible ovarian factors that are capable of interfering with downregulation of ovarian steroidogenesis. Insulin is a key endocrine factor because it amplifies the effect of gonadotropins on steroidogenesis. The abnormality of thecal function in PCOS resembles the escape from downregulation that occurs when normal theca cells are treated with insulin or IGFs.[34] Studies of theca cell cultures support an intrinsic thecal abnormality in PCOS.[45,46] In primary and long-term cultures, PCOS theca cells secrete excessive amounts of androgens and androgen precursors, basally and after c-AMP stimulation. These findings persist when insulin is absent from the culture medium. Thus, the persistent increased androgen production of the PCOS ovary is a result of a generalized upregulation of specific steroidogenic enzymes and is consistent with an intrinsic theca cell abnormality rather than an effect of chronically excessive LH stimulation. This concept is supported by the finding of persistent thecal hypersensitivity to gonadotropins after long-term gonadotropin suppression in functionally typical types of PCOS.

Disturbed granulosa cell function underlies PCOM and arrested ovulation. Granulosa cells from patients with PCOS are hyperresponsive to gonadotropins. They overexpress the LH receptor and secrete estradiol in response to LH at an inappropriately early stage, which indicates premature luteinization. These small antral follicles also manifest inhibin B hyperresponsiveness to FSH. Granulosa cells furthermore overproduce estradiol in response to high levels of FSH, likely contributing to the increased risk for developing ovarian hyperstimulation syndrome (OHSS) during fertility treatment in women with PCOS.

Excessive folliculogenesis results from an increased proportion of follicles leaving the resting (primordial) phase to begin growing and then having a prolonged life span. It is related to disturbed elaboration of AMH, which regulates ovarian follicle growth by a paracrine negative feedback effect on the recruitment of primordial follicles.[47] It is possible that these granulosa cell abnormalities reflect an intrinsic defect in intraovarian regulation of early folliculogenesis. Complex mesenchymal–epithelial interactions and endocrine, paracrine, and metabolic influences affect follicular development.[47] An independent folliculogenesis disturbance is supported by evidence of persistently abnormal granulosa cell function after long-term suppression of ovarian hyperandrogenism and by the presence of PCOM in the absence of ovarian hyperandrogenism.

Oocyte gene expression is also dysregulated and the possibility has been raised that this might be related to high pregnancy loss of some PCOS patients. Good morphological oocytes have abnormal gene expression profiles that are associated with defective meiosis or early embryonic development.[48] As upregulated differentially expressed genes at the germinal vesical stage of PCOS mainly related to mitochondrial function, it suggests that aberrant mitochondrial function at the germinal vesical stage may contribute to a decline in oocyte quality of PCOS patients.[49] These data are compatible with excessive androgen and epigenetic metabolic signals contributing to the reduced developmental competency of PCOS oocytes.

Neuroendocrine Dysfunction. Elevated LH was initially thought to cause PCOS by increasing ovarian androgen production. However, the typical ovarian dysfunction of PCOS is often found in the absence of gonadotropin abnormalities. Furthermore, the normal process of desensitization to LH would seem to preclude LH excess from being a primary cause of androgen excess. It now appears that elevated LH may be the result rather than the cause of androgen excess. A modest rise in androgen levels normally stimulates LH pulsatility rather than suppresses it, which requires a substantial elevation. Patients with PCOS are less sensitive to suppression of the LH pulse frequency by sex steroids, compared with controls. Furthermore, anti-androgen treatment normalizes the inhibitory effect of progesterone on elevated LH pulse frequency. These results suggest that androgen excess increases LH pulse frequency by interfering with the hypothalamic inhibitory feedback of progesterone and that LH hypersecretion in PCOS results from androgen excess interfering with the inhibitory feedback of estradiol and progesterone.[50]

Insulin Resistance and Hyperinsulinism. Insulin resistance and compensatory hyperinsulinemia also play an important role in the pathogenesis of PCOS, a state in which steroidogenic and adipose tissues are paradoxically sensitive to insulin in the setting of overall resistance to the glucose metabolic effects of insulin.[37] Distinct postreceptor-binding defects in insulin signaling have been described in fibroblasts, adipocytes, and skeletal muscle cells in PCOS. These defects are specifically associated with impaired glycogen synthesis and glucose uptake and do not involve mitogenic signaling. In contrast to skeletal muscle and skin fibroblasts, there is no evidence for intrinsic defects in insulin signaling in the PCOS adipose cell lineage, although *in vivo* environmental effects could not be excluded.[37]

The relationship between insulin resistance and hyperandrogenism appears to primarily result from the effect of compensatory hyperinsulinemia on steroidogenesis. In the ovary, insulin normally acts in conjunction with LH to upregulate LH binding and enhance the androgenic response to LH (see Fig. 124.3). Clinical evidence uniformly indicates that steroidogenesis in PCOS proceeds as if sensitive to insulin, although it has been difficult to directly demonstrate an effect of insulin on ovarian function. All insulin-resistant states are associated with PCOS, as discussed later (see "Other Ovarian Hyperandrogenic Disorders" below). In rare instances, severe insulin resistance can be the primary pathogenic event in PCOS. Furthermore, any treatment that lowers insulin levels reduces androgen levels in PCOS. Insulin may act via its own receptor in theca cells by a signaling pathway separate from that mediating its metabolic effects. Insulin-resistant states also suppress SHBG, which increases testosterone bioavailability.

Androgen excess has been reported to cause insulin resistance *in vitro* in a minority of studies.[51]

In one of these, high-dose androgen induced resistance to insulin as stimulation of glucose uptake in cultured adipocytes from normal women. Treatment with the anti-androgen flutamide for 12 months significantly reduces visceral fat mass and improves insulin sensitivity.[52] Consequently, the potential exists for a vicious cycle between insulin resistance/hyperinsulinism and hyperandrogenism. Androgens may contribute to insulin resistance indirectly.[53] Visceral fat, which is characterized by increased lipolytic activity, is thought to be important to the pathogenesis of insulin resistance and the increased free fatty acid levels in PCOS women. Free fatty acids cause insulin resistance in the skeletal muscle. Thus, hyperandrogenemia may affect adipocyte insulin sensitivity so as to favor visceral body fat distribution, which results in relative increases of free fatty acids, which, in turn, induce skeletal muscle insulin resistance.

Etiology. The cause of PCOS is unknown, but considerable evidence suggests that it is a complex, heritable trait that first manifests at the onset of puberty and interacts with other congenital or environmental factors resulting in the PCOS phenotype.[38] About 50% of sisters of PCOS probands have hyperandrogenemia, and about one half of those will also be anovulatory. Furthermore, about 70% of sisters have PCOM, and one quarter are anovulatory. Diabetes-related defects in insulin secretion and action are common in primary relatives of women with PCOS. In a Dutch twin-family study, the correlation between monozygotic twins for PCOS was 0.71, and for dizygotic twin or non-twin sister pairs, the correlation was 0.38.[54] These family studies demonstrate a significant genetic component in the pathogenesis of PCOS. While the candidate gene approach has yielded no consistent association, genome-wide association screening has identified at least 16 candidate genes closely related to insulin signaling, sexual hormone function, and other.[55,56] Among them is the DENND1A gene that upregulates steroidogenesis by unrecognized mechanisms.[57]

The intrauterine environment may play a role in the pathogenesis of PCOS. Congenital virilization is well-established to cause PCOS in humans and in animal models. CAH is the most common, but not the exclusive, virilizing disorder causing this outcome. Untreated women with nonclassic CAH also are insulin resistant. As in multiple species, congenitally virilized rhesus monkeys have ovarian and adrenal hyperandrogenism, oligomenorrhea, polyfollicular ovaries, and elevated LH levels; they also have abdominal obesity, insulin resistance, IGT, and dyslipidemia. The LH hypersecretion seen in congenitally virilized animal models appears to result from congenital androgen exposure interfering with the negative feedback effect of ovarian steroids on LH, as in PCOS.[58] Besides this, elevated prenatal AMH can also reprogram the fetus and induce PCOS in adulthood.[59]

Inconsistent associations with low or high birth weight have been reported to be associated with PCOS. In some populations, intrauterine growth restriction is associated with premature adrenarche and PCOS risk. A meta-analysis including 42 studies in 7041 women with PCOS and 63,722 women without PCOS found that PCOS was associated with higher gestational weight gain, higher risks of preterm birth and large for gestational age, and lower birth weight, while this association varied by geographic continent, PCOS phenotypes, and study quality. However, PCOS was associated with none of these outcomes on BMI-matched studies.[60]

Postnatal environmental risk factors for PCOS include obesity and other insulin-resistant states, which can be viewed as precipitating latent susceptibility traits to become manifest. Premature adrenarche appears to pose about a 2-fold increase in PCOS risk in some populations. It is likely that this represents the first manifestation of dysregulated steroidogenesis in these cases.

Ovarian Neoplasms

Androgen-secreting ovarian tumors are very rare causes of androgen excess. About 1% of ovarian tumors that comprise testicular cell types can cause hyperandrogenism followed by characteristic virilization.[61] Virilizing ovarian tumors may be malignant or benign and are frequently suspected by abrupt onset, usually distinct from menarche, of rapidly progressive virilization, testosterone concentrations > 200 ng/dL, and characteristic ultrasound or computed tomography (CT) findings. However, androgen elevations are sometimes modest, in which case the presentation will be indolent. The most common virilizing ovarian tumor is the Sertoli-Leydig cell tumor, which may be gonadotropin-responsive. Ovarian lipid cell tumors are also typically gonadotropin-responsive and also dependent, in part, on ACTH. Ovarian virilizing tumors typically secrete predominantly androstenedione and are thus characterized by a disproportionate elevation of serum androstenedione relative to testosterone. Mild elevation of urinary 17-ketosteroid excretion characteristically results. Ovarian androgen-secreting tumors represent a highly heterogenous group of rare endocrine tumors with possible genetic penetrance including a *FOXL2* mutation. Metabolic implications and long-term outcomes of these kind of tumors are unknown and require more detailed follow-up studies.[61]

Other Ovarian Hyperandrogenic Disorders

Symptoms consistent with PCOS are present in about half of women with classic CAH and about one fifth of women with nonclassic CAH.[62] It is associated with a higher degree of LH hyperresponsiveness to GnRH agonist testing than in PCOS. Adrenal rests of the ovaries, as are found in rare cases of CAH, may also mimic PCOS.

Ovarian steroidogenic blocks in the pathway to estradiol are rare causes of hyperandrogenism and multicystic ovaries. This can result from congenital defects in the activity of ovarian 3β-HSD, 17β-HSD, or aromatase (see Fig. 124.3). The severity of hypoestrogenism depends upon the degree of deficiency of enzyme activity. Aromatase gene mutations reported to date have resulted in congenital virilization with ambiguous genitalia.

Subjects with “true hermaphroditism” (ovotesticular disorder of sex development) are characterized by the presence of functional testicular and ovarian tissue (see Chapter 102). They occasionally present as menstruating, phenotypic females with signs of androgen excess such as clitoromegaly. The diagnosis can be made by the response to gonadotropin stimulation.

All extreme states of insulin-resistant hyperinsulinemia, such as congenital diabetes mellitus caused by insulin-receptor mutations (e.g., Donohue’s syndrome or leprechaunism) or lipodystrophy, are accompanied by PCOS.[34] Less extreme, but nevertheless severe, insulin resistance (pseudo-Cushing’s syndrome and pseudo-acromegalic gigantism) in childhood may precede PCOS. In addition, modest forms of insulin resistance also are associated with PCOS, including type 1 and type 2 diabetes mellitus. Like IGF-1, elevated insulin levels seem to cause PCOS by increasing the activity of steroidogenic enzymes in the ovaries and adrenal glands.

Acromegaly may also be associated with PCOS, possibly because of the steroidogenic effects of elevated IGF-1 on the ovaries and adrenal cortex.[63] Its presentation is usually insidious.

Epilepsy is significantly associated with PCOS independent of drug treatment, although valproic acid directly augments transcription of the steroidogenic gene CYP17 and can cause elevated serum testosterone.[64]

The PCOS phenotype can occur as a complication of portal hypertension or portosystemic shunting.[65,66] This has been attributed to impaired steroid metabolism. Virilization during pregnancy may be due to a luteoma or hyperreactio luteinalis.[67] These conditions represent benign hyperplastic thecal luteinization of the ovary, solid and cystic respectively, which spontaneously regress postpartum. Luteomas appear not to be associated with excessive levels of hCG; in contrast, hyperreactio luteinalis is almost always associated with hCG excess and may be due to defective regulation of its placental secretion. Maternal virilization occurs in 10% to 50% of women with luteomas and in 25% of those with hyperreactio luteinalis. Fetal virilization is rare owing to placental aromatization of androgen to estrogen.

Congenital Adrenal Hyperplasia

CAH is a term historically applied to disorders that arise from an autosomal recessive deficiency in the activity of an adrenocortical enzyme step necessary for corticosteroid biosynthesis (see Fig. 124.4).[2] Because of inefficient cortisol secretion, there is diminished negative feedback inhibition of ACTH secretion, which markedly increases its secretion and leads to compensatory adrenocortical hyperplasia. The result is accumulation of androgen precursors proximal to the enzyme defect. CAH is potentially life-threatening in its classic (severe) form and may be asymptomatic or cause female infertility in its nonclassic (mild) form.[68] It is now appreciated that CAH can occur as the result of enzyme deficiency in any step of corticosteroid biosynthesis: 21-hydroxylase, 3β-HSD type 2, 11β-hydroxylase, and P450 oxidoreductase. About 95% of CAH is due to 21-hydroxylase deficiency and other forms of CAH are very uncommon.[69] Each enzyme deficiency leads to characteristic clinical syndromes and biochemical abnormalities, as described below.

21-Hydroxylase Deficiency. Classic CAH due to 21-hydroxylase deficiency occurs in 1 in 10,000 to 1 in 20,000 live births based on data from millions of newborns screened worldwide. It is subclassified into salt-wasting and simple virilizing forms diagnosed during infancy, but affected individuals may develop signs and symptoms resembling PCOS during adolescence. Classic 21-hydroxylase deficiency typically presents with genital ambiguity due to congenital virilization. Screening for CAH due to 21-hydroxylase deficiency by 17OH-prog assays are recommended in all newborn screening programs.[70]

Nonclassic (“late-onset” or “attenuated”) 21-hydroxylase deficiency, a milder form of CAH with residual 21-hydroxylase enzyme activity, can present as premature pubarche or with peripubertal or postpubertal onset of hirsutism, acne, and/or amenorrhea. After PCOS, it is the next most common cause in women of androgen excess presenting in adolescence and early adulthood and accounts for about 2%–3% of hirsutism in the general population[32] and 4.2% of women with androgen excess.[62] Some ethnic groups, e.g., Ashkenazi Jews (prevalence 1:27), Hispanics (1:40), and Slavs (1:50), are at much higher risk than White Americans (1:200).[71] They can exhibit oligo-ovulation, polycystic-appearing ovaries, and elevated serum LH levels. Some cases are entirely cryptic with no clinical manifestations, discovered serendipitously in family studies. The degree of clinical severity is correlated with the degree of 21-hydroxylase deficiency elucidated by ACTH testing. ACTH response patterns and molecular genetic techniques have shown that the rapid 17OH-prog response to an intravenous bolus of ACTH distinguishes nonclassic cases and heterozygotes, from normals better than baseline steroid levels.[72]

Mutations in *CYP21A2* gene, located on the short arm of chromosome 6, result in lack of 21-hydroxylase. A continuum of disease phenotypes generally correlates with *CYP21A2* genotypes. Almost 300 *CYP21A2* mutations are known, most with defects of gene conversions and large deletions.[68,70]

3β-Hydroxysteroid Dehydrogenase Type 2 Deficiency. Deficiency of 3β-HSD type 2 due to *HSD3B2* gene mutations classically presents in infancy with genital ambiguity due to congenital virilization, accompanied by decreased cortisol, aldosterone, and androstenedione concentrations, but increases in renin, ACTH, and DHEA. Rarely, it presents later in its nonclassic form as hyperandrogenic anovulation. The phenotype varies according to different genetic defects with *HSD3B2* mutations.[73]

11β-Hydroxylase Deficiency. Deficiency of 11β-hydroxylase (CYP11B1) classically presents with genital ambiguity caused by congenital virilization, accompanied by hypertension and advanced bone age. Late-onset and the nonclassic form of hyperandrogenism is rare, and hypertension and hypokalemia are not necessarily present.[2] This disease is more common in Middle East and North America. The accumulated precursor substrate 11-deoxycortisol, although rarely measured routinely, may serve as a serum marker for 11β-hydroxylase deficiency.[74]

Cytochrome P450 Oxidoreductase Deficiency. Cytochrome P450 oxidoreductase deficiency (PORD), a rare, autosomal recessive form of CAH, is commonly diagnosed during infancy or childhood. Based on the severity of *POR* gene mutations and subsequent impairment of POR-dependent enzymes, PORD manifests with a broad spectrum of clinical phenotypes from menstrual cycle abnormalities, infertility, and polycystic-appearing ovaries, to ambiguous genitalia in both 46, XX and 46, XY women.[75] Some nonclassic PORD without genital and skeletal malformations in postpubertal females are very rare and remain poorly characterized.

Other Adrenal Hyperandrogenic Disorders

Adrenal Neoplasms. Adrenal tumors are a very rare cause of hyperandrogenism. Rapid progression of androgenic symptoms, signs of virilization, and elevated androgen levels usually make the tumor diagnosis straightforward. Very high testosterone levels (>200 ng/dL) suggest an androgen-secreting tumor, but some tumors present with lower levels, and only about half of patients with virilizing adrenal tumors have a marked elevation of DHEAS (>700 µg/dL). If an androgen-secreting tumor is suspected, pelvic ultrasound should be done. If negative, it should be followed by an adrenal CT scan.

Glucocorticoid-Suppressible Hyperandrogenism. Hyperprolactinemia may present as hyperandrogenic oligo-anovulation; galactorrhea is typical, although not necessarily present. Polycystic-appearing ovaries and LH hyperresponsiveness to GnRH may be associated with a prolactinoma and acromegaly. DHEA and DHEAS levels are elevated, as is the serum free testosterone, in part because of a direct effect of high levels of prolactin on adrenal cortical function. Mild to modest elevations in prolactin levels can also be found in otherwise classic PCOS. In these instances, it is important to establish that the prolactin elevation is not a consequence of primary hypothyroidism, prolactinoma, or medications.

Cortisone reductase deficiency is a rare autosomal recessive disorder that results from a defect in the peripheral metabolism of cortisol. Increased ACTH production is necessary to compensate for the excessively rapid cortisol turnover caused by failure to regenerate cortisol from cortisone in peripheral tissues. This disorder is caused either by deficiency of 11β-HSD type 1 (HSD11B1), which is functionally the major cortisone reductase, or more commonly by "apparent" cortisone reductase deficiency, inactivating mutation of hexose-6-phosphate dehydrogenase (H6PDH), which is a cofactor for cortisone reductase. Establishing this diagnosis requires urinary steroid profiling with increased urinary 17α-hydroxycorticoids, but low cortisol excretion.

Apparent DHEA sulfotransferase deficiency is due to a genetic defect in DHEA metabolism that does not affect corticosteroid secretion. Inactivating mutations of the sulfate donor to SULT2A1 (3′-phosphoadenosine-5′-phosphosulfate synthase 2, PAPSS2) prevent sulfation of DHEA, yielding high DHEA but undetectable DHEAS levels. Premature pubarche preceded hyperandrogenic anovulation in two reported girls, who also suffered skeletal growth defects.[77]

Glucocorticoid-Nonsuppressible Hyperandrogenism. Glucocorticoid resistance is a rare congenital form of ACTH-dependent adrenal hyperandrogenism. It results from defects in glucocorticoid receptor signaling, resulting in inadequate negative feedback by cortisol, with consequent excessive ACTH release and adrenal hyperplasia, elevated cortisol, and DHEAS secretion. Cushing's syndrome due to diverse forms of adrenal hyperplasia and neoplasm is associated with hyperandrogenic anovulation, although this is seldom the presenting feature. Moreover, polycystic-appearing ovaries can occur in Cushing's syndrome.

Idiopathic Hyperandrogenism

Approximately 8% of hyperandrogenic patients have no ascertainable glandular source of androgen despite thorough testing. Patients who have normal ovulatory cycles and normal ovaries, independently of having elevated androgen levels or with hirsutism, are traditionally diagnosed as having *idiopathic hyperandrogenism* (IHA). IHA is a diagnosis of exclusion in hyperandrogenic patients who do not fulfill the diagnosis of PCOS, nonclassic adrenal enzymatic deficiencies, or other uncommon hyperandrogenic disorders. The pathogenesis of IHA is largely unknown.

Obesity can modify the androgenic phenotype, accounting for most cases of IHA and can mimic PCOS by causing hyperandrogenic anovulation. In PCOS patients who meet NIH diagnostic criteria, the IHA subset without an identifiable ovarian and adrenal source for androgen excess were obese. These patients were characterized by mild hyperandrogenemia, and most had normal size ovaries and normal LH and AMH levels.[78] Adipose tissue is a major site for the formation of testosterone from the circulating precursor androstenedione. Thus, obesity is accompanied by both increased testosterone production and suppressed SHBG. Gonadotropins are suppressed in obesity, in part from increased clearance, and possibly partly related to abnormal estrogen metabolism. Estrone formation from androstenedione is increased, and estradiol metabolism is diverted to active rather than inactive metabolites.

Other contributors to IHA include increased peripheral metabolism of inactive steroid precursors to active androgens by hereditary defects and anabolic steroid use. The latter can cause virilization in women and present with features similar to those of virilizing tumors. Anabolic steroids should be suspected in athletes and women with sexual dysfunction (see Chapter 128). Importantly, many steroids used for these purposes are not detected by routine androgen assays.

KEY POINTS

- PCOS is the most common cause of hyperandrogenism in women.
- Funcional ovarian hyperandrogenism due to a unique type of steroidogenic dysfunction is the essential feature of most PCOS.
- PCOS is associated with obesity and insulin resistance, and the ovarian hyperandrogenism and metabolic abnormalities require distinct treatment considerations.

DIAGNOSIS OF HYPERANDROGENISM

Clinical Hyperandrogenism

Clinical hyperandrogenemism should be considered in women with hirsutism, moderately severe acne vulgaris, or other cutaneous manifestations including seborrhea and alopecia. Severe excess androgen can result in virilization manifesting as clitoromegaly, masculinization, and other features described above. Hirsutism is the most common feature of hyperandrogenism. Over 70% of hirsute women showed increased androgens and are often accompanied with other pathophysiological features.[31] Most women with focal hirsutism and regular menses who have no other evidence to suggest an underlying cause have a very low likelihood of excess androgen production and do not require an endocrine workup. Similarly, women with isolated mild hirsutism (score 8 to 15) are unlikely to have a medical disorder that would change management. However, in women with symptomatic hirsutism of any degree, or acne that is poorly responsive to topical treatment, androgen levels should be assessed. Rapid development or progression of hirsutism, progression despite therapy, or evidence of virilization (such as clitoromegaly, increasing muscularity, deepening of the voice, or balding) increase the likelihood of an androgen-secreting neoplasm or exogeneous androgen use. However, tumors producing only moderate amounts of androgen have indolent progression of signs and symptoms.[20] Evaluation of a woman for hirsutism includes assessment of the pattern of hair growth, so as to differentiate it from hypertrichosis (see earlier), and its quantity. The mFG is the most common visual assessment tool.

Biochemical Hyperandrogenism

Markers for Diagnosis. Although hirsutism constitutes clinical evidence of hyperandrogenism in the consensus diagnostic criteria for PCOS, it is not necessarily indicative of androgen overproduction, as discussed earlier. Guidelines suggest that testing for hyperandrogenemia center around measurement of serum testosterone. Unfortunately, no optimal marker or test method for diagnosis can be recommended based on current evidence.

Testosterone was suggested as the key androgen in past decades. High-quality assays, such as LC-MS/MS and extraction/chromatography immunoassays, are suggested to assess total or free testosterone. However, these reliable testosterone assays are not available to many physicians. The automated assays used in most laboratories are generally not suitable for clinical assessment. Systematic differences between assays and excessively broad normal ranges derived from populations of apparently normal women with unrecognized androgen excess further complicate interpretation of testosterone levels provided by many laboratories.

An elevation in serum bioavailable (includes loosely bound to albumin) testosterone is relatively the single most sensitive test to establish the presence of hyperandrogenemia compared with total testosterone, DHEAS, and androstenedione. The serum bioavailable testosterone concentration is about 50% more sensitive for the detection of hyperandrogenemia than the total testosterone concentration. This results from SHBG, which is the main determinant of the bioactive portion of serum testosterone, the fraction that is bioavailable, often being low in hyperandrogenic women. However, there are no reliable direct assays for bioavailable testosterone. Calculated bioavailable testosterone, calculated free testosterone, and the free androgen index (FAI = 100 × (total testosterone/SHBG) are recommended according to the guideline to assess biochemical hyperandrogenism in PCOS.[79] Considering the secretion of testosterone, serum bioavailable testosterone is best assessed in the early morning in amenorrheic women or in the early follicular phase of regularly cycling women. Patients with an initial normal testosterone level in whom clinical features consistent with hyperandrogenism are present or emerge should have repeat testing, preferably an early morning serum bioavailable testosterone level in a reliable specialty laboratory.

Routine testing for other androgens, such as DHEAS and androstenedione, can be considered when bioactive testosterone is not raised, but provides limited additional information in the diagnosis of PCOS. The level of DHEAS is increased in approximately 15% of women who have normal levels of total and bioavailable testosterone. These two markers are more useful in differential diagnosis of specific androgen excess disorders. DHEAS which is of adrenal origin can be elevated slightly in some PCOS patients. But if it increases significantly, sometimes along with virilization, an adrenal tumor should be suspected. Increased androstenedione is a feature of 21-hydroxylase–deficient nonclassic CAH.

Evaluation. It is because reliable assays are not available that there are no precise cutoff values of the above markers for diagnosis of hyperandrogenism. A mildly elevated level in a woman with a normal bioavailable testosterone level is unlikely to be clinically relevant aside from being associated with acne. Very high levels of total testosterone (>200 ng/dL [6.94 nmol/L]) or of DHEAS (> 700 µg/dL [19 µmol/L]) heighten the likelihood of an underlying ovarian or adrenal neoplasm. However, such high levels usually do not indicate an androgen-secreting neoplasm, and lesser elevations may occur with androgen-secreting tumors. If a neoplasm is suspected, a transvaginal ultrasound should be performed. If no ovarian tumor is identified, further imaging studies (e.g., abdominal CT for an adrenal neoplasm) may be warranted. Nearly one third of women with PCOS can be identified as having hyperandrogenemia by total testosterone measurement, while more than half can be identified by bioavailable testosterone. Once hyperandrogenemia is documented, the diagnosis of PCOS depends on exclusion of other hyperandrogenic disorders. The laboratory evaluation to determine the cause of hyperandrogenism varies among specialists, and the effect of various approaches on outcomes is uncertain.

Ultrasonography, performed initially, can exclude rare but serious ovarian (and sometimes adrenal[80]) tumors. In addition to identifying ovarian changes consistent with PCOS, other ovarian pathology such as hermaphroditism can be detected. Those whose ultrasound shows a tumor or other explanation for hyperandrogenism should be referred for treatment of the underlying disorder. Although the presence of polycystic-appearing ovaries on ultrasound is one of the diagnostic criteria for PCOS, ovaries from women with PCOS are sonographically normal in about 25% of cases. Conversely, PCOs may be found on ultrasound examination in up to 50% of women without PCOS. Therefore, the following endocrine studies can be considered in women with hyperandrogenism regardless of whether or not the ultrasound shows normal or polycystic ovaries: prolactin, thyroid function, 17OH-prog, and possibly a measure of cortisol production. All of these endocrine studies will be normal in patients with PCOS. An early morning non-luteal phase 17OH-prog value below 170 to 200 ng/dL excludes nonclassic CAH with ~95% specificity.[81] An abnormal result in urine cortisol, late night salivary cortisol, or 1 mg overnight dexamethasone suppression test would provide evidence for endogenous Cushing's syndrome,[82] although a more definitive workup is indicated if Cushingoid features are present (**see Chapter 97**). An abnormality of any of these tests suggests that the androgen excess has a cause other than PCOS, which should be pursued accordingly.

More thorough endocrine testing, as recommended by the American Association of Clinical Endocrinologists,[83] will detect the small fraction of patients who have rare disorders that mimic PCOS and are missed by the above approach. The cost-effectiveness of such an approach is unknown, however. Further workup to identify the origin of androgen excess may also include: (1) assessment of androstenedione, the immediate precursor for testosterone, or other steroid intermediates; (2) assessment of the response to cosyntropin of 17OH-prog, DHEA, and other steroid intermediates as appropriate, and/or genotyping to exclude forms of CAH; (3) assessment of urinary corticoid metabolites to exclude cortisone reductase deficiency; (4) dexamethasone suppression test to suppress androgens arising from a functional adrenal source; (5) acute GnRH agonist administration to distinguish the steroidogenic response of PCOS/hyperthecosis from an ovarian androgen-secreting tumor; (6) CT or more specialized imaging studies if there is reason to suspect an androgen-secreting tumor; and (7) assessment of the suppressive response to combined oral contraceptive (COC) or GnRH agonist treatment.

KEY POINTS

- Hyperandrogenism can be diagnosed clinically and/or biochemically.
- Clinical hyperandrogenism should be considered in women with hirsutism, moderately severe acne vulgaris, seborrhea, and alopecia.
- Biochemical hyperandrogenism is frequently determined by testing serum bioavailable testosterone, however, no optimal marker or test method for diagnosis can be recommended based on current evidence.

TREATMENT OF POLYCYSTIC OVARY SYNDROME AND OTHER ANDROGEN EXCESS DISORDERS

Androgen Suppression

Androgen suppression generally involves reduction of androgen levels or their end-organ effects. This is usually accomplished by (1) suppression of ovarian androgen production, (2) alteration of binding of androgens to their serum binding proteins, (3) impairment of the peripheral conversion of androgen precursors to active androgen, and (4) inhibition of androgen action at the target tissue level. With all medical treatments, there appears to be an inverse association between efficacy and BMI.

Combined Oral Contraceptives. COCs alone are recommended in PCOS adult patients for management of hyperandrogenism. Adolescents with a clear diagnosis of PCOS can be prescribed with COCs as well. The estrogenic component of most COCs currently in use is ethinyl estradiol. It is responsible for the suppression of LH and thus serum androgen levels and results in a dose-related increase in SHBG, thus lowering the free fraction of serum testosterone. COC therapy has also been demonstrated to decrease DHEAS levels, perhaps by reducing ACTH levels.

In theory, the choice of a specific COCs should be predicated on the progestational component, as each progestin has a variably suppressive effect on SHBG levels and variable androgenic effect on metabolic biomarkers. Progestins promiscuously signal through diverse steroid pathways. First-generation progestins such as norethindrone, norgestrel, and levonorgestrel are mildly androgenic, as judged from their attenuation of the estrogen-induced increase in SHBG. Norgestimate and desogesterel are virtually nonandrogenic; cyproterone is anti-androgenic. Despite these subtle differences in progestin, common symptoms in PCOS can be controlled with COCs that contain lower doses of ethinyl estradiol combined with most progestins.[84] Thus, there is no specific type of COC or dose of estrogen or progestin that is recommended.

Assessment of adequacy of ovarian suppression can be made as early as the end of the third week after starting treatment; by this time, ovarian androgen suppression is complete. The effect on acne can be expected to be maximal in 1 to 2 months. In contrast, the effect on hair growth may not be evident for 6 months, and the maximum effect requires 9 to 12 months.[85]

With absolute and relative contraindications as well as side effects of COCs, detailed assessments for PCOS patients can help to weigh the risks and benefits of using them for individuals. Elevated risks of venous thromboembolism, CVD, and metabolic morbidities of COCs should be taken into consideration, especially for PCOS patients with specific risk factors such as high BMI, hyperlipidemia (including hypertriglyceridemia), and hypertension. According to the World Health Organization (WHO), absolute contraindications for COCs include deep vein thrombosis (DVT)/pulmonary emboli (PE), known thrombogenic mutations, multiple risk factors for arterial CVD, history of ischemic heart disease or stroke, complicated valvular heart disease, breast cancer, and others.[86] COCs with 35 μg ethinyl-estradiol plus cyproterone acetate (not available in the United States) are not recommended as the first-line medication for PCOS and should only be used for moderate to severe hirsutism or acne, whereas levonorgestrel, norethindrone, and norgestimate are associated with relatively low risk of DVT. Anti-androgens can be considered for hirsutism and androgen-related alopecia when COCs are contraindicated or poorly tolerated, and no anti-androgen has been shown to be more efficacious than another. If 6 months or more of COCs and cosmetic therapy fail to improve hirsutism, anti-androgens can be added.

Anti-Androgens. Cyproterone acetate (not available in the United States) is the prototypic anti-androgen.[22] It acts mainly by competitive inhibition of the binding of testosterone and DHT to the AR. In addition, it may act to enhance the metabolic clearance of testosterone by inducing hepatic enzymes. By means of its progestogenic properties, cyproterone acetate can also suppress the secretion of gonadotropins and result in decreased ovarian androgen synthesis. And because of its potent progestational activity and its prolonged half-life, it is administered in a “reverse sequential” manner: cyproterone acetate 50 to 100 mg/day from day 5 to 15 of the cycle, with ethinyl estradiol in a dose of 35 to 50 mcg/day from day 5 to 26 of the cycle. The dose of cyproterone acetate may be reduced incrementally at 6-month intervals after maximum improvement has occurred. Side effects of cyproterone acetate include irregular uterine bleeding, nausea, headache, fatigue, weight gain, and decreased libido. To prevent potential feminization of a male fetus, effective forms of contraception should be used with anti-androgens.

Spironolactone in doses of 100 to 200 mg/day is as effective an anti-androgen as cyproterone acetate.[22] It is a potent antimineralocorticoid developed as a progestational analog that has diverse effects on steroid metabolism. Its side effects are remarkably few; however, patients must be monitored for hyperkalemia and hypotension. Its most frequent side effect is menstrual irregularity when used alone.

Flutamide is a potent nonsteroidal anti-androgen without progestational, estrogenic, corticoid, antigonadotropic, or androgenic activity that is efficacious in the treatment of hirsutism.[22] Because of the risk for significant hepatotoxicity, however, flutamide should not be used as initial therapy for hirsutism. If flutamide is needed to treat severe hirsutism unresponsive to other anti-androgens, it should be used at low doses (no more than 375 mg/day).[22] Liver function tests should be monitored periodically on therapy.

Other Agents for Treatment of Androgen Excess. Finasteride, a 4-aza-steroid, is a competitive inhibitor of type 2 5α-reductase. Although beneficial effects on hirsutism have been reported,[22] the prominence of type 1 5α-reductase in the PSU makes it unlikely to be an optimal form of treatment. Insulinsensitizing agents such as metformin and thiazolidinediones can modestly improve hyperandrogenism.[38] Metformin is not as effective as COCs in the management of hirsutism in adult PCOS patients with patients with BMI between 25 and 30 kg/m^2.[87] Additionally, regarding treatment for hirsutism, either metformin alone or COCs alone may be less effective than the two combined. PCOS patients with high metabolic risk, such as diabetes risk or IGT, may benefit most from the combination of COCs with metformin.

Chronic administration of GnRH agonist suppresses pituitary-ovarian function, thus inhibiting both ovarian androgen and estrogen secretion. Uncontrolled trials of GnRH agonists in ovarian hyperandrogenism have reported significant reduction in the mFG score. Because of the reduction of serum estrogen levels and the concomitant reduction in bone mineral density with GnRH agonist therapy, an agonist should always be combined with estrogen-progestin add-back for long-term use. This regimen is more effective for hirsutism than are COCs alone.[22] GnRH agonist therapy may be most useful in women with severe forms of ovarian hyperandrogenemia such as ovarian hyperthecosis, but the effect on hirsutism is modest.[22] In 2018, a selective oral GnRH antagonist, elagolix, has been approved alone or in combination with progestin add-back therapy to treat endometriosis and leiomyomas, respectively. These therapies may also potentially offer benefit to women with PCOS.

Ovulation Induction and Assisted Reproduction

Infertility is a major health complication of PCOS and mainly caused by oligo/anovulation. Approximately 40% of PCOS women present with infertility, requiring fertility treatment. Ovulation induction and assisted reproduction are crucial managements for infertile women with PCOS. Ovulation and ovulation induction are adversely affected by overweight and obesity status. Healthy lifestyle is recommended in all PCOS patients and weight loss is recommended for obese PCOS women, as first-line treatment for infertility. Modest weight loss of 5% to 10% may result in return to regular menses or unassisted pregnancy in many women with PCOS.

Ovulation Induction. Letrozole, the best characterized aromatase inhibitor for ovulation induction, is the first-line agent an/oligo-ovulatory infertile PCOS women, although they are not approved for this indication by the US Food and Drug Administration. Aromatase inhibitors prevent conversion of androgens to estrogens. The usual letrozole dose is 2.5 to 5 mg/day for 5 days. According to a Cochrane review, compared to clomiphene citrate (CC), the chance of live birth increased 40%–60% for letrozole.[88] Moreover, ovulation failure and risk of multiple gestation are favored in letrozole versus CC. A daily dose of 5 mg of letrozole resulted in a similar pregnancy rate to 75 IU FSH, despite a significantly lower rate of ovulation in a large study of women not ovulating on 100 mg of CC.[89] A randomized controlled trial including clomiphene-resistant PCOS patients demonstrated that letrozole was comparable with CC in combination with metformin with regard to ovulation rate, pregnancy rate, and miscarriage rate per patient.[90] When letrozole is not available or not approved, other medications for ovulation induction can be used, including CC.

CC, a selective estrogen receptor modulator, can be used alone for ovulation induction for infertile women with PCOS. The usual regimen is 50 mg/day for 5 days. The dose can be increased by 50 mg/day to a maximum dose of 150 mg/day in subsequent cycles if ovulation does not occur. Using a graduated regimen of 50 to 150 mg daily for 5 days, ovulation can be induced in about 80% of women. The probability of ovulation and live birth decreases with increasing androgen levels, BMI, and age. There is a 5%–7% incidence of twin pregnancy, a 0.3% incidence of triplet pregnancy, and a < 1% OHSS rate associated with the use of CC. According to a 2019 systematic review, CC plus metformin increased the ovulation rate and clinical pregnancy rate compared with CC used alone.[91] If PCOS patients are clomiphene-resistant, metformin can be added in ovulation induction instead of persisting with CC alone.

Metformin can also be used alone for anovulatory infertility in PCOS women; however, clinicians should inform patients of other medications that are superior in ovulation induction. A systematic review suggested that metformin achieved increased ovulation, pregnancy, and live birth rates versus placebo, and was associated with a high rate of gastrointestinal side effects.[91] Another Cochrane systematic review compared effects of CC and metformin on pregnancy outcomes and found no significant differences in ovulation rate, pregnancy, and live birth rates.[92]

For those who fail first-line oral agents, gonadotrophins can be used as second-line agent for ovulation induction. A systematic review demonstrated equivalence of urinary-derived gonadotrophins and recombinant FSH with clinical pregnancy, live birth, multiple pregnancy, and miscarriage rates.[93] In PCOS, stimulation is initiated with 37.5 to 75 IU/day, instead of the standard 150 IU, and patients are maintained on this dose for 1 to 2 weeks. This low-dose regimen decreases risk for OHSS and multiple gestation. Gonadotropin dose is stepped up at 37.5 IU increments every 7 days if no follicular growth occurs at the initial dose as determined by ultrasound. Alternatively, treatment can be initiated at higher doses, 100 IU, and "stepped down" when follicular growth is detected by ultrasound. The step-up protocol is more likely to result in monofollicular development and less likely to result in OHSS versus the step-up protocol. Low-dose regimens result in monofollicular development in about 70% of cycles, pregnancy rates of ~20%, multiple gestation rates of ~6%, and < 1% risk for OHSS. About 95% of patients will ovulate with a 55% cumulative pregnancy rate after six cycles. To bring down the multiple pregnancy rate, only when fewer than three mature follicles are developed can ovulation be triggered; otherwise canceling the cycle is recommended.

Gonadotrophins can be considered as first-line treatment for ovulation induction if a conservative stimulation protocol is used along with ultrasound monitoring and counselling on cost and the possibility of multiple pregnancy. Compared with CC plus metformin, use of gonadotrophins is preferable for clomiphene-resistant women with PCOS.[15] Gonadotropins can also be used with metformin since preliminary evidence indicated that adding metformin for PCOS patients undergoing ovulation induction with gonadotropins might improve the live birth rate.[94]

Assisted Reproductive Technology. For PCOS patients who fail to conceive with ovulation induction or have other concomitant causes of infertility (e.g., severe male factor), assisted reproductive technology including *in vitro* fertilization (IVF) and intracytoplasmic sperm injection (ICSI) and embryo transfer (ET) can be considered. Although IVF/ICSI is more inconvenient and costly, it provides PCOS patients with good chances for pregnancy and minimal multiple pregnancy risk with elective single ET. However, the elevated risk of OHSS during controlled ovarian hyperstimulation in IVF/ICSI still a major clinical concern. To mitigate this risk, GnRH antagonists have been included in the protocol for ovarian stimulation. Compared with the GnRH agonist long protocol, GnRH antagonist protocol reduces the total gonadotropin dose, the stimulation days, and the risk of OHSS. A systematic review and meta-analysis revealed a significantly decreased OHSS risk in the GnRH antagonist group (RR: 0.53, 95% CI: 0.30–0.95) compared with the long agonist protocol group, and no difference in the number of oocytes retrieved, ongoing pregnancy rates, and live birth rates.[95] As for triggering oocyte maturation, when hCG is used, it is recommended to use at the lowest dose in order to prevent OHSS. Patients undergoing GnRH antagonist protocol can administer a single bolus of GnRH agonist to induce the endogenous LH surge, leading to lower incidence of OHSS than hCG to trigger oocyte maturation and ovulation. However, a Cochrane review suggests that GnRH agonist trigger is associated with lower ongoing birth rate and live birth rate, as well as a higher miscarriage rate after fresh ET, which can be overcome in cycles of frozen ET. So, for women undergoing cycles with a GnRH antagonist protocol who plan to cancel fresh ET or who are at a high risk of OHSS, trigger with GnRH agonist can be implemented. Some clinicians also add low amounts of hCG to the agonist trigger to achieve a better mature oocyte yield. An elective "freeze-all" strategy can be an option for women with PCOS as well. A randomized controlled trial reported a higher live birth rate from frozen versus fresh ET (49.3% vs. 42.0%) (95% CI: 1.05–1.31; $P = .004$) and lower OHSS risk [RR 0.19 (95% CI: 0.10–0.37; $P < .001$)]; however, the risk of preeclampsia was also elevated in the frozen ET group (RR 3.12, 95% CI: 1.26–7.73; $P = .009$).[96] A 2017 Cochrane systematic review showed comparable cumulative live birth rates with fresh and frozen ET.[97] *In vitro* maturation of immature oocytes retrieved from antral follicles is a treatment option for PCOS patients, which eliminates the hCG trigger in a stimulated or unstimulated cycle. However, it is not widely used.

Prevention of Long-Term Complications

Since PCOS is a disease with endocrine and metabolic disorders affecting millions of women, long-term health of PCOS patients is an important issue that prompts public caution. Although the long-term CVD risk independent of BMI in women with PCOS is unclear,[39] risk of CVD requires screening, as the prevalence of CVD among PCOS patients is elevated. The risk for CVD should be evaluated for all women with PCOS, including obesity, smoking, dyslipidemia, hypertension, IGT, and lack of physical activity.[39] Regular monitoring of weight change and excess weight at least 6–12 monthly and blood pressure testing annually or more frequently should be offered to women with PCOS. Women with PCOS who are overweight or obese should get a fasting lipid profile tested.[39] Lifestyle interventions such as weight loss, exercise, and smoke cessation are suggested for PCOS patients who are overweight or obese. Studies across different countries and populations demonstrate enhanced risk of type 2 diabetes in the perimenopause and beyond for PCOS patients,[39] and women with PCOS have a higher risk of gestational diabetes.[97]

Assessment of glycemic status should be monitored every 1–3 years depending on the presence of risk factors for diabetes. As for endometrial cancer, women with PCOS have a 2- to 6-fold increased risk during the premenopausal period, and transvaginal ultrasound scan to investigate the endometrium should be conducted for women with PCOS; however, optimal prevention for endometrial cancer remains uncertain.

KEY POINTS

- The principles for treating androgen excess disorders include suppressing androgen production and activity, solving infertility, and preventing long-term complications.
- The common agent used for androgen suppression are combined oral contraceptives.
- Letrozole and clomiphene citrate are the most common agents for ovulation induction.
- The long-term health of PCOS patients is an important issue that prompts public caution.

SUMMARY AND FUTURE DIRECTIONS

Androgens are mainly produced by the ovary, adrenal gland, and via peripheral tissue conversion in women, regulated by tropic hormones and intraglandular paracrine and autocrine mechanisms. The common clinical manifestations of androgen excess comprise cutaneous abnormalities (hirsutism, acne, and patten balding), polycystic ovarian morphology on ultrasonography, and metabolic dysfunctions. Clinical hyperandrogenism is currently diagnosed by a hirsutism score determined by the mFG scale, while the diagnosis of biochemical hyperandrogenism is questionable, and measurement of free testosterone using high-quality radioimmunoassay or tandem mass spectrometry assay is recommended. PCOS is the most common cause of androgen excess disorders in reproductive age women. However, other rare causes of hyperandrogenism should always be considered in the differential diagnosis. There is still controversy regarding the etiology, pathophysiology, and targeted treatment of androgen excess disorders, especially PCOS. In the future, validated methods for the diagnosis of hyperandrogenism, well-designed studies for evaluating the best treatment for androgen excess and resultant disturbances, as well as further basic studies for underlying mechanisms of pathophysiology of hyperandrogenism are warranted.

Summary, 2089

Endometriosis is a common, chronic, estrogen-dependent, inflammatory disorder defined by the presence of endometrial glands and stroma in extrauterine ("ectopic") sites (Fig. 125.1A). It affects 6% to 10% of women of reproductive age and clinically can manifest with dysmenorrhea, dyspareunia, chronic pelvic pain, infertility, and poor pregnancy outcomes.[1] Endometriosis is most commonly found on the ovaries, pelvic peritoneum, and the bowel, and less commonly on the pleura of the lungs, the pericardium, and in previous abdominal and/or vaginal incisions. The prevalence of this condition in women experiencing pain, infertility, or both is as high as 50%.[1] Staging is based on extent of disease and associated adhesions[2] or on anatomic location (superficial peritoneal disease, ovarian endometriomas, deep infiltrating disease). No correlation exists between disease stage and symptomatology, although pain does correlate with site of disease and type of lesion, and staging does not predict chance of pregnancy or outcomes related to medical or surgical therapies.[2] The steroid hormone dependence of this disorder is striking: prolonged periods of unopposed estrogen predispose women, female primates, and men to the disorder, and natural or surgical menopause generally results in suppression.[3] Via upregulation of aromatase, endometriosis lesions can synthesize estradiol,[3] thereby bypassing the need for ovarian estradiol. Also, resistance to progesterone action, resulting in persistence of estrogen responsiveness, is now a well supported pathophysiologic feature of endometriosis.[4] An improved understanding of the molecular basis has led to new therapies and new therapeutic candidates (see later). This debilitating condition also poses quality-of-life issues for the individual patient and requires a multidisciplinary approach to achieve patient goals and well-being.[5,6] Diagnosis and treatment of endometriosis account for a significant portion of healthcare costs in the United States, estimated to approach $69 billion in 2009.[7] In this chapter, the epidemiology, pathogenesis, pathophysiology, and genetics of this disorder are reviewed, along with approaches to diagnosis and therapeutics to relieve pain and achieve fertility.

EPIDEMIOLOGY

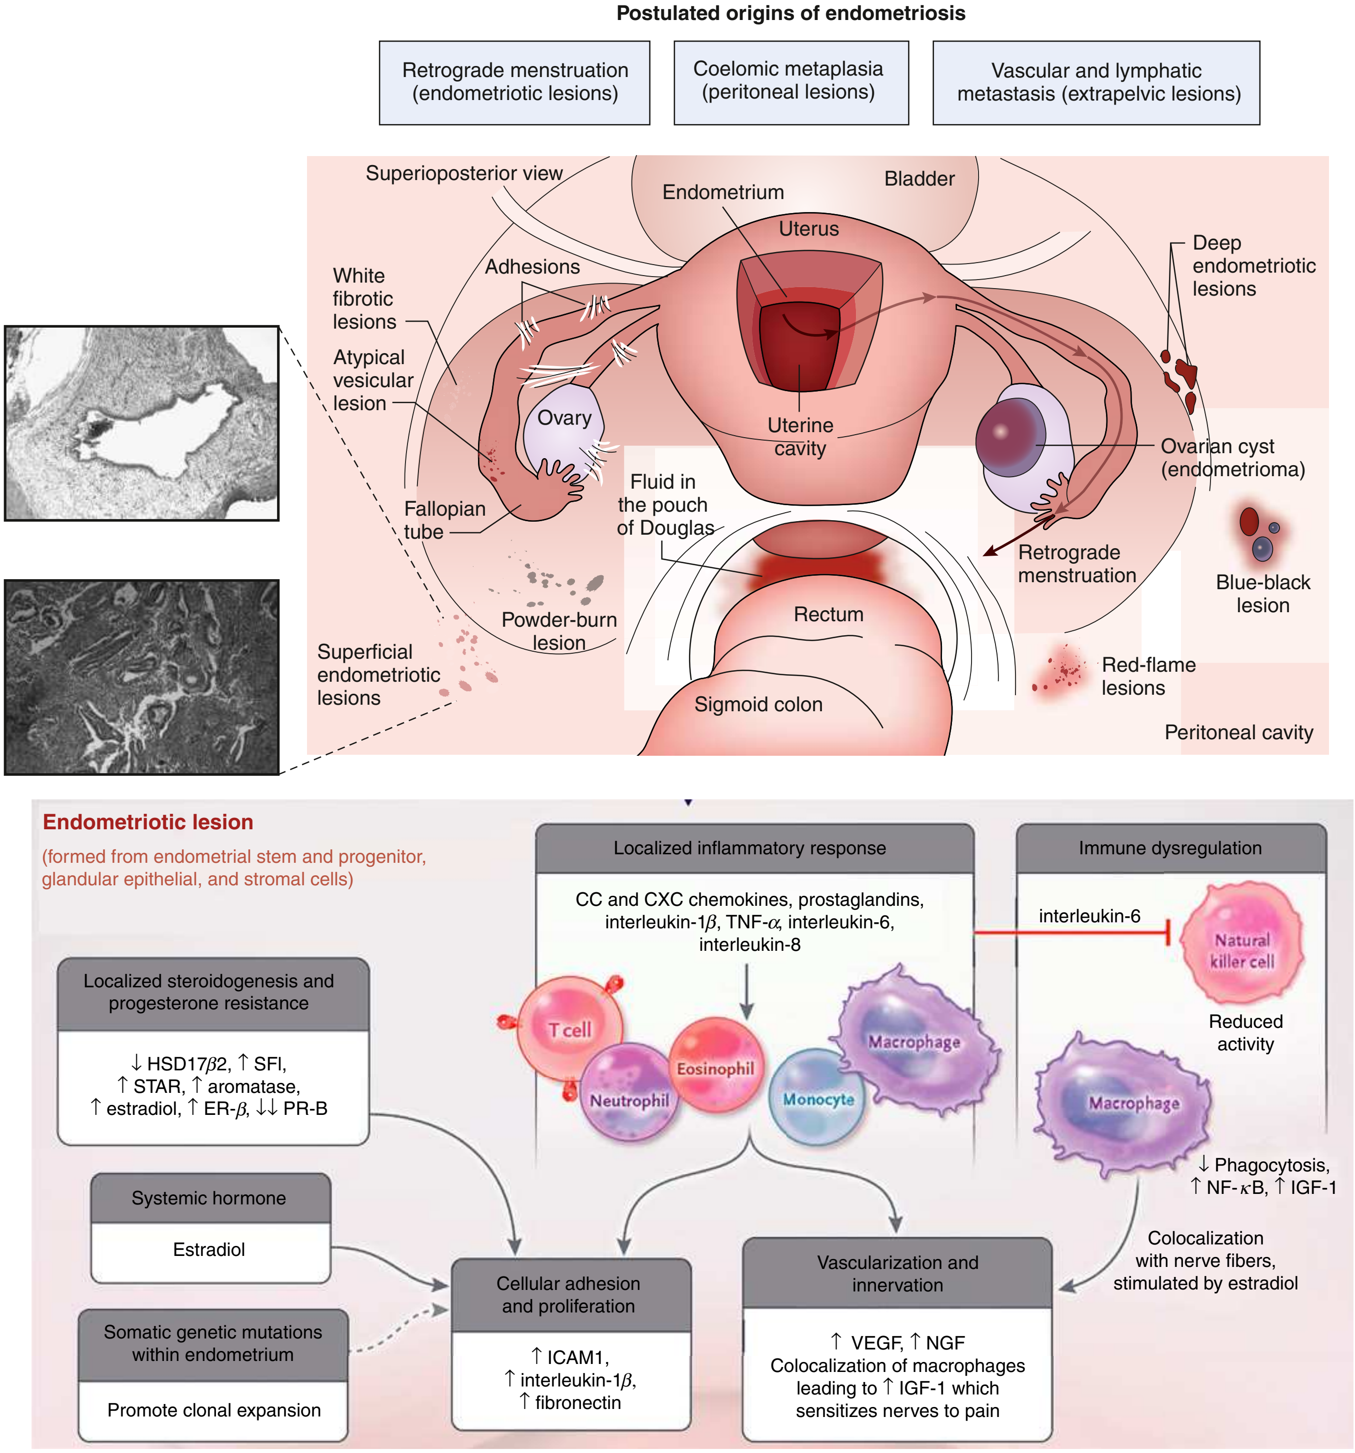
Although typically diagnosed during the reproductive years, endometriosis is the leading cause of secondary dysmenorrhea in adolescents,[8] with a reported prevalence of endometriosis as high as 64% in this population.[9] Supporting data from the Nurses' Health Study II demonstrate that increased risks to developing endometriosis include menarche at less than or equal to 10 years of age, low birth weight (<5.5 lbs), body mass index (BMI) less than or equal to 25, nulliparity, and a family history of endometriosis.[10,11] Rates of endometriosis are greater among White women, followed by Asian, then Black, and then Latina women[12], although access to care has brought these estimates into question. Rates are nearly 3-fold higher in women with waist-to-hip ratios of less than 0.60 compared with 0.70 to 0.79 (relative risk [RR] = 2.78, 95% confidence interval [CI]: 1.38–5.60).[13] Interestingly, the rate of endometriosis is significantly lower in women who experienced vaginal parturition than in women who delivered by cesarean section or did not deliver at all, and the rate of endometriosis is inversely related to the sonographically-measured diameter of the internal cervical os.[14] This finding highlights the potential contribution of vaginal delivery in mitigating retrograde menstruation, the predominant theory in the pathogenesis of endometriosis (see later). Endometriosis has been observed in postmenopausal women, with nearly all cases occurring in women taking some form of hormone replacement therapy, further highlighting the estrogen-dependence of this condition.[15]

KEY POINTS

- Endometriosis is a chronic, estrogen-dependent, progesterone-resistant, inflammatory disorder affecting up to 10% of women of reproductive age and up to 50% of women with pelvic pain and/or infertility.

PATHOGENESIS

Though originally described by Shroen in 1690, the precise pathogenesis of this enigmatic disorder remains unknown.[16] Theories proposing



Postulated origins of endometriosis
Retrograde menstruation (endometriotic lesions)
Coelomic metaplasia (peritoneal lesions)
Vascular and lymphatic metastasis (extrapelvic lesions)
Superioposterior view
Endometrium
Bladder
Uterus
Adhesions
White fibrotic lesions
Atypical vesicular lesion
Ovary
Deep endometriotic lesions
Uterine cavity
Ovarian cyst (endometrioma)
Fluid in the pouch of Douglas
Fallopian tube
Retrograde menstruation
Blue-black lesion
Powder-burn lesion
Rectum
Superficial endometriotic lesions
Red-flame lesions
Sigmoid colon
Peritoneal cavity
Endometriotic lesion
(formed from endometrial stem and progenitor, glandular epithelial, and stromal cells)
Localized inflammatory response
CC and CXC chemokines, prostaglandins, interleukin-1β, TNF-α, interleukin-6, interleukin-8
Immune dysregulation
interleukin-6
Natural killer cell
Reduced activity
Localized steroidogenesis and progesterone resistance
↓ HSD17β2, ↑ SFI, ↑ STAR, ↑ aromatase, ↑ estradiol, ↑ ER-β, ↓↓ PR-B
T cell
Eosinophil
Neutrophil
Monocyte
Macrophage
Macrophage
↓ Phagocytosis, ↑ NF-κB, ↑ IGF-1
Colocalization with nerve fibers, stimulated by estradiol
Systemic hormone
Estradiol
Cellular adhesion and proliferation
↑ ICAM1, ↑ interleukin-1β, ↑ fibronectin
Vascularization and innervation
↑ VEGF, ↑ NGF Colocalization of macrophages leading to ↑ IGF-1 which sensitizes nerves to pain
Somatic genetic mutations within endometrium
Promote clonal expansion

Figure 125.1 **Pathogenesis and pathophysiology of endometriosis.** Inset, 10% hematoxylin and eosin stain of a peritoneal lesion of endometriosis and late proliferative endometrium taken from the same patient at the time of surgery. Note the presence of glands and stroma surrounded by fibrosis. (Adapted from Zondervan KT, Becker CM, Missmer SA. Endometriosis. *N Engl J Med.* 2020;382:1244–1256, used with permission.)

a nonendometrial origin for lesions are supported by histologically-confirmed endometriosis in patients with Müllerian agenesis and in men with prostate cancer undergoing high-dose estrogen treatment.[17-19] On the other hand, the theory of benign metastasis holds that ectopic endometrial lesions result from lymphatic or hematogenous dissemination of endometrial cells.[20-22] Microvascular studies demonstrate lymph flow from the uterus into the ovary, supporting this hypothesis.[23] Endometriosis within lymph nodes has been documented in 6.5% of women at lymphadenectomy and 6.7% of women at autopsy.[24] The strongest evidence for the theory derives from reports of histologically proven endometriotic lesions occurring in sites distant from the uterus or pelvis, including bone, brain, and lung.[25]

The most widely accepted description of endometriosis pathogenesis is Sampson's theory of retrograde menstruation and transplantation (Fig. 125.1A), which postulates that sloughed endometrial tissue, displaced in a retrograde manner through the fallopian tubes during menses, contains viable, steroid-sensitive cells that are capable of implanting outside the uterus.[26] Although this hypothesis is attractive, it does not explain why retrograde menstruation, a physiologic event,[27] does not result in endometriosis in all women. The volume of displaced menstrual debris has been considered to be relevant to establishment of the disorder, as women with endometriosis have a higher volume of refluxed menstrual blood than those without the disorder.[27] In addition, the occurrence during the menstrual phase of subendometrial myometrial contractile waves exhibiting a retrograde pattern in women with endometriosis as opposed to an antegrade pattern in women without disease further supports Sampson's theory and suggests that endometriosis may have some of its origin in myometrial dysfunction.[28] Endometriosis can be induced in baboons by cervical occlusion[29] and is uniformly observed in adolescent girls with primary amenorrhea caused by cervical hypoplasia or aplasia, vaginal agenesis, or other Müllerian anomalies associated with outflow tract obstruction.[30] Even subtle compromise of antegrade menstruation may predispose to endometriosis, as evidenced by a higher prevalence of disease in women with a uterine septum.[31]

The inability of any single theory to account for the variety of clinical presentations and pathological features of endometriosis may derive from its clinical heterogeneity, with peritoneal endometriosis, ovarian endometriosis, and deep infiltrating endometriosis (DIE) possibly developing via different mechanisms.[32] Indeed, epithelial cells isolated by laser capture microscopy from eutopic endometrium and ectopic endometrium (peritoneal and ovarian lesions) and subsequent analysis using cDNA microarrays with 9600 genes revealed that samples cluster by site (ovarian endometrioma vs. nonovarian disease), underscoring that ovarian and peritoneal endometriosis have different complements of gene expression and may represent different disorders.[33] Whereas peritoneal and ovarian endometriosis are plausibly accounted for by retrograde menstruation, DIE is less so, as it is typically located in deeper subperitoneal locations as the intestine muscularis or bladder. The endometrial stem cell theory of endometriosis[34] aligns with the widely accepted retrograde menstruation model, while also providing an explanation for the pathogenesis of the DIE lesional subtype. Next-generation sequencing studies of passenger mutations within the epithelial and stromal cells of DIE lesions support clonality of the epithelial compartment, likely reflecting an epithelial stem cell origin.[35] Though it is possible that these stem cells derive from the bone marrow, somatic mutations in endometriosis-associated genes have been observed in the epithelial compartment of normal endometrium but not the bone marrow, consistent with an endometrial origin for these progenitors.[36]

Genetic Basis

A genetic predisposition to the development of endometriosis is well supported. Monozygotic twin studies observed high concordance rates for histologically confirmed endometriosis and disease stage.[37] An increased risk of endometriosis is seen among first-degree relatives of affected women.[38] Abundant genetic evidence supports endometriosis as a multifactorial, polygenic disease, with the proportion of disease variance due to genetic factors estimated at 26%.[39] Additional support for polygenic inheritance is earlier age of onset for familial versus nonfamilial cases and similar age of onset among affected relatives.[40] In addition, a strong familial tendency prevails in nonhuman primates.[41]

Genome-wide association studies (GWAS) provide high-resolution haplotypes of single nucleotide polymorphism (SNPs) in cohorts of women with and without endometriosis toward the identification of genes associated with endometriosis risk. A metaanalysis of ten GWAS datasets involving 17,045 cases and 191,596 controls identified directional association of SNPs in 14 genetic risk loci across populations of European and Japanese ancestry.[42] Though positional evidence of genes near risk loci implicates involvement of hormonal pathways, WNT signaling, cell adhesion, and inflammation-related pathways, functional involvement of these variants in mediating disease pathogenesis awaits multiomic integration. Recently, a large-sale GWAS metaanalysis revealed 27 genetic loci associated with endometriosis ($P < 5\times10^{-8}$), of which 78% had greater effect sizes in stage III/VI versus stage I/II disease.[43] Additional clinical disorders significantly positively correlated with endometriosis included uterine fibroids, excessive and irregular menstrual bleeding, osteoarthritis, diabetes, menstrual cycle length and age at menarche.

Environment

Developmental Origins of Endometriosis Risk. The pre- and perinatal periods are susceptible windows during which exposure to xenoestrogens and other endocrine-disrupting chemicals (EDCs)[44] can induce developmental programming and increase risk for female reproductive tract disorders, including endometriosis.[45] As endometriosis is an estrogen-dependent disorder, it is biologically plausible that EDCs mimicking estrogen actions may reprogram uterine endometrium for endometriosis development later in life and that EDCs that can alter immune function can predispose to subsequent disease. Uterine morphogenesis is a genetically controlled process, conserved across species, and involves ERα and *Wnt* and *Hox* gene family members.[46] Animal studies show *in utero* exposures to some estrogen-like EDCs (e.g., diethystilbestrol [DES] and bisphenol A [BPA]) result in abnormal female reproductive tract development[47] and endometriosis-like tissue in adult female offspring.[48] *In utero* exposure of female mice to tetrahydrochlorodibenzo-p-dioxin (TCDD) augments growth of surgically-induced endometriosis in response to later TCDD exposure.[49] Moreover, adult female mice directly exposed *in utero* (F1, F2 generation) or indirectly exposed (F3 generation, transgenerational inheritance) to TCDD display uterine progesterone receptor (PR) promoter hypermethylation, decreased fecundity, and preterm birth versus unexposed controls,[50] similar to the uterine phenotype and clinical outcomes of women with endometriosis.

In women, the most compelling evidence of development in adulthood after *in utero* exposure to DES derives from the Nurses' Health Study II.[11] This prospective study of 116,678 female nurses 25 to 42 years old revealed 5% endometriosis prevalence at baseline and an incidence of 2941 laparoscopically confirmed cases, with pain symptoms prompting diagnosis in 77% of subjects and an infertility work-up prompting diagnosis in the remaining 33%. A history of *in utero* exposure to DES increased by 80% a woman's chance of having laparoscopically proven endometriosis as an adult. Other risk factors were low birth weight and preterm birth, suggesting developmental effects, which are supported by other studies demonstrating Müllerianosis and endometriosis tissue in human female fetuses.[51] The relationship of these with adult disease has not (yet) been established.

Exposures in Adulthood and Endometriosis Risk. Exposures to EDCs during adulthood, with or without prior exposure, may also predispose to developing or promoting endometriosis and result in abnormal PR signaling, characteristic of endometrium and lesions of women with endometriosis (see later).[45] There is abundant evidence in adult nonhuman primates and rodents that organochlorines, including TCDD, pesticides such as methoxychlor and DDT, and polychlorinated biphenyls promote endometriosis.[51] For example, adult rhesus monkeys exposed to TCDD at 5 to 25 ppt daily for 4 years developed symptomatic endometriosis with dose-dependent severity.[52] In mouse models of surgically induced disease (autologous uterine tissue transplantation to peritoneal structures), TCDD and other polyhalogenated hydrocarbons increased lesion sizes in a dose-dependent manner relative to vehicle controls.[53] Furthermore, in a model wherein endometriosis-like lesions in adult female nude mice were induced by seeding human endometrial tissue fragments onto the peritoneum, TCDD resulted in loss of uterine PR and prevented progesterone-mediated suppression of disease establishment seen in controls.[54] TCDD blocked progesterone inhibition of matrix metalloproteinase (MMP) expression in endometrial stromal cells *in vitro*, similar to the human endometrial and lesion phenotype[55] (see later). Interestingly, the EDC BPA promoted cell proliferation of surgical endometriosis in a mouse model,[56] and di(2-ethylhexyl)phthalate (DEHP) increased surgically-induced endometriosis invasion and growth in adult female mice, accompanied by upregulation of MMP-2, MMP-9, Ki67, and Pax4 and decreased cleaved capsase.[57] Overall, the data strongly support EDCs increasing disease burden and severity in animal models.

With regard to women, four recent systematic reviews and meta-analyses of epidemiologic studies demonstrated associations of persistent and nonpersistent EDCs and endometriosis risk. Cano-Sancho et al.[58] analyzed 17 studies that provided effect sizes and metrics sufficient for pooling estimates through metaanalysis and reported: for dioxins: odds ratio (OR) 1.65 (95% CI: 1.14–2.39); polychlorinated biphenyls (PCBs): OR 1.70 (95% CI: 1.20–2.39); and organochlorine pesticides (OCPs): OR 1.23 (95% CI: 1.13–1.36). Wen et al.[59] analyzed 30 epidemiologic studies and reported: for PCBs: OR 1.58 (95% CI: 1.18–2.21); OCPs: OR 1.40 (95% CI: 1.02–1.92); and DEHP: OR 1.42 (95% CI: 1.19–1.70). Overall OR across all exposures (including phthalate esters as a class) was 1.41 (95% CI: 1.23–1.60). They found no significant associations with BPA, consistent with data from Smarr et al.,[51] and they did not report on dioxins. Sirohi et al.[60] reported on 29 studies and found that phthalate esters were positively associated with endometriosis prevalence, and the majority of studies (71%) revealed significant association between BPA, organochlorinated EDCs (dioxins, dioxin-like compounds, OCPs, PCBs) and endometriosis prevalence. Notably, they found one study with positive association of two heavy metals (copper and chromium), but not cadmium, lead, or mercury, with endometriosis prevalence. Overall, despite statistical significance, the data should be interpreted with caution because of heterogeneity of disease phenotypes (stage, disease type), small effect sizes, differences in study designs, varied definitions of endometriosis, confounders of age, BMI, parity, lactation history, exposure to mixtures versus one chemical at a time, varied analytical methodologies, and definition of controls.[51] That said, epidemiologic data support associations of EDCs with endometriosis, and experimental data from animal studies support such associations and underlying mechanisms. Currently, the precautionary principle is to advise minimizing EDC exposures in all women with and without endometriosis and during pregnancy.

Somatic Mutations

Increased somatic mutations, particularly cancer driver mutations, are commonly seen in DIE and ovarian endometriosis.[61,62] Somatically mutated genes in endometriotic lesions include *KRAS* (oncogene), *ARID1A* (tumor suppressor gene), *PIK3CA* (oncogene), and *PPP2R1A* (tumor suppressor gene). These genes are also frequently mutated in uterine endometrioid carcinoma, ovarian endometrioid carcinoma, and ovarian clear cell carncioma.[63] Not only are these somatic mutations a potential factor in the multistep process of malignant transformation, but they may also contribute to disease pathogenesis. Interestingly, the observed somatic mutations appear to be confined to glandular epithelial cells of endometriotic lesions.[61] In a classic series of experiments involving a murine model of endometriosis, *KRAS* activation in peritoneally transferred endometrial cells resulted in endometriotic lesions of the peritoneal lining and ovaries.[64]

KEY POINTS

- Genetics (including somatic mutations), retrograde menstruation, immune dysfunction in pelvic debris clearance, and epigenetically driven endocrine dysregulation are likely components of endometriosis pathogenesis.

PATHOPHYSIOLOGY

For tissue to implant and thrive in an ectopic location, cell(s) must survive after release from their originating niche, attach and invade into a new microenvironment, proliferate, and establish a new blood supply. Escape from immune clearance, attachment to peritoneal epithelium, invasion of the epithelium, establishment of local neurovascularity, and continued growth and survival are necessary if endometriosis is to develop from retrograde displacement of endometrium. As with normal endometrium, endometriosis tissue responds to cyclic changes in steroid hormones by proliferation and glandular secretion and by production of autocrine and paracrine factors that affect these processes[65] (Fig. 125.1A and B).

Cell Survival and Adhesion

Menstrual blood is found in peritoneal fluid (PF) of up to 90% of healthy women with patent fallopian tube(s) undergoing laparoscopy during menses.[27] The discrepancy between the nearly 90% rate of retrograde menstruation and the 6% to 10% prevalence of endometriosis remains an area of active study. Hereditary or acquired properties of the endometrium and/or the peritoneal epithelium, and/or defective immune clearance have all been proposed as factors influencing survival and implantation of ectopic endometrium. In the formation of peritoneal lesions, retrograde menstrual tissue must execute a molecular strategy to adhere to serosal surfaces. Confocal microscopy studies using an *in vitro* model of endometriosis observed the adherence and invasion of endometrial cells through peritoneal mesothelium.[66] Eutopic and ectopic endometrium from women with endometriosis evidence upregulation of the antiapoptotic gene *BCL-2*.[67] In addition to decreased apoptosis, enhanced proliferation may confer a selective survival advantage to the endometrium of women predisposed to endometriosis.[68] Importantly, peritoneal lesions demonstrate increased expression of estrogen receptor beta (ERβ),[3] shown in a mouse model to promote lesion development by inhibiting tumor necrosis factor alpha (TNF-α)-mediated apoptosis and increasing cellular adhesion and proliferation,[69] exemplifying a key molecular hallmark in endometriosis: estrogen dependence (Fig. 125.1B). Altered expression of integrins by endometrial stromal cells from women with endometriosis contribute to their increased capacity to adhere.[70] It is possible that proteases, growth factors, altered cytokine profiles, or a localized inflammatory microenvironment in women with endometriosis set conditions for the selective adhesion of endometrial cells to serosal surfaces.[71]

Matrix Degradation And Invasion

Endometriosis, a noncancerous disorder, can invade tissues and surfaces in a manner similar to that exhibited by malignancies. The balance between MMPs and their inhibitors (tissue inhibitors of metalloproteinases) is critical in maintaining the appropriate level of MMP activity, and failure to maintain this balance may contribute to matrix breakdown and cellular invasion, as observed in endometriosis. In menstrual phase eutopic endometrium, mRNAs for all the MMPs have been detected, with matrilysin (MMP-7) localized to the epithelium, and all other MMPs expressed in the stroma.[72] Epithelial-specific MMP-7 is expressed in endometriotic lesions during the secretory phase, but not in eutopic endometrium, which suggests that progesterone suppression of MMP-7 is dysregulated in endometriosis, and that this MMP may play a role in growth or progression of the disorder. Foci of MMP-1 expression closely correlate with matrix breakdown and with the absence of PR in adjacent epithelial cells.[73] Indeed, suppression of PR-B in eutopic and ectopic endometrium, possibly due to differential methylation of PR-B, HOX, and GATA transcription factors, may contribute to altered progesterone responsiveness.[74] *In vitro* treatment of eutopic endometrium acquired from affected women with progesterone failed to fully suppress pro–MMP-7 secretion and prevent the implantation of transplanted endometrium to establish experimental disease in mice.[75] Collectively, these results illustrate another molecular hallmark—progesterone resistance—in the pathophysiology of endometriosis (Fig. 125.B).

Cell Growth and Neoangiogenesis

Peritoneal fluid from women with endometriosis reflects a unique microenvironment characterized by increased mitogenic, angiogenic, morphogenic, and chemoattractant activities that are collectively conducive to lesional growth and survival. Growth factors and cytokines are released from a variety of cellular sources, including monocytes/macrophages, as well as endometrial, ovarian, and mesothelial cells within the peritoneal cavity.[76] Growth factors likely play a fundamental role in the pathophysiology of endometriosis by independently stimulating cell survival, growth, or differentiation. Macrophage-conditioned medium contains mitogenic activity, some of which is attributable to TGF-β,[77] platelet-derived growth factor (PDGF),[78] and basic fibroblast growth factor.[79] Epidermal growth factor,[79] insulin-like growth factors,[80] and PDGF[78] are potent mitogens for endometrial stromal cells, and hepatocyte growth factor (HGF) is a mitogen and morphogen for endometrial epithelial cells when cocultured with stromal cells.[81] HGF is also an angiogenic factor. Establishment of vascular supply is a necessary step in the growth and survival of endometriotic lesions, particularly in the peritoneal microenvironment, which is relatively avascular compared with the intrauterine environment. In fact, increased vascularity in the vicinity of peritoneal lesions is leveraged in the surgical identification of lesions at laparoscopy.[82] Angiogenic activity is increased in PF from women with endometriosis. Vascular endothelial growth factor (VEGF), a potent angiogenic factor, has been consistently detected in high concentrations in PF from women with endometriosis, and VEGF levels in the PF correlate directly with the stage of disease[83] (Fig. 125.1B). The consistent detection of VEGF expression across the spectrum of lesions provides compelling evidence for VEGF as the prominent angiogenic factor in endometriosis pathophysiology and a potential target for therapeutic strategies.[84]

Altered Endocrine Activity

The survival and growth of ectopically displaced endometrium is estrogen-dependent and regulated by estradiol released systemically from the ovary and locally from lesions themselves. Lesional production of estradiol is favored by the imbalance resulting from the increased expression of aromatase[85] and steroidogenic acute regulatory protein and decreased expression of 17β-hydroxysteroid dehydrogenase 2[86] in ectopic endometrial stromal cells (ESCs) (Fig. 125.2). Interestingly, increased expression of the transcription factors GATA6 and SF1 in ectopic ESCs results in in an endometriotic phenotype characterized by estradiol synthesis and impaired decidualization.[87] The observed increase in GATA6 and SF1 in these cells is in part a function of promoter hypomethylation.[74] ESCs from endometriotic lesions evidence increased levels of ERβ.[88] By increasing IL-1β, ERβ is a key mediator in the link between the molecular hallmarks of estrogen dependence and inflammation in the pathophysiology of endometriosis. The ERβ pathway inhibits TNF-α–induced cellular apoptosis, enhances cellular invasion, and downregulates PR expression, and suppression of ERβ activity via administration of a selective antagonist inhibited the growth of endometriosis in a mouse model.[69] This has important consequences with regard to therapies (see section on treatment) that are aimed primarily at decreasing circulating estradiol as a treatment strategy.

Support for progesterone resistance as a molecular hallmark in endometriosis is derived from results of global transcriptome analysis of eutopic endometrium in the late proliferative and early and mid-secretory phases in women with moderate to severe endometriosis compared with women without disease.[4] Of note was the marked persistence of estrogen regulated genes in early secretory endometrium (ESE) from women with disease at a time when progesterone action should inhibit their expression. In the proliferative-secretory transition, the fingerprint of persistence of cellular mitosis and minimal responsiveness of classically progesterone-regulated genes in ESE was also apparent in midsecretory endometrium. ESE specimens from women with disease clustered closer to proliferative endometrium specimens than ESE from women without disease, confirming the

observed resistance to progesterone action. These data underscore progesterone resistance in the endometrium of women with endometriosis and are consistent with inadequate clinical response to progestins in women with this disorder.[4]

MicroRNAs (miRNAs) are key regulators of gene expression through mRNA degradation or repression. Numerous miRNAs are expressed in the endometrium and serum of women with versus without endometriosis that predict target genes, including *TGF-βR2*, *ERα*, *ERβ*, and *PR*.[89] Steroid hormone treatment of human endometrial cells *in vitro* revealed differentially regulated expression of hsa-miR20a, hsa-miR21, and hsa-miR26a, which were partly reversed following cotreatment with ICI-182780 and RU486.[90] Differential expression of a number of miRNAs in eutopic and ectopic endometrium and isolated endometrial cells suggests that aberrant or altered expression of some miRNAs regulated by ovarian steroids may influence the expression of specific target genes with key roles in endometrial cellular activities and in the pathophysiology of endometriosis. Circulating miRNAs have recently been reported to diagnose endometriosis with high accuracy and specificity.[91]

Immunity and Inflammation

Abundant evidence indicates that endometriosis is a chronic inflammatory condition with associated immune dysfunction, and central to endometriosis pathophysiology are enhanced estrogen signaling, disrupted progesterone signaling, and inflammation in the disease tissue and eutopic endometrium[3,92-94] (Fig. 125.3). These processes are interrelated and largely contribute to the pain and infertility in affected women. Recent mass cytometry analysis of PF demonstrated a heterogeneous and complex inflammatory microenvironment with specific endometriosis-associated immune signatures within the innate and adaptive immune lineages, distinct phenotypes marked by CD69 versus controls without disease, and different signatures across disease stages.[95] There are increased numbers of PF activated macrophages involving c-Jun signaling,[96] proinflammatory reactive oxygen species

(ROS) generated from the breakdown of blood, and increased cytokines and chemokines, including IL-1β, IL-6, IL-8, TNF-α, monocyte chemotactic protein, and regulated on activation normal T expressed and secreted.[92] Interestingly, higher plasma IL-1β levels are observed years before the diagnosis of endometriosis.[97] IL-1β activation of cyclo-oxygenase-2 increases production of prostaglandin-E2, which in turn activates steroidogenic acute regulatory protein and aromatase to increase local estradiol production.[3] This pathway highlights the interplay of estrogen dependence and inflammation in endometriosis. The NF-κB pathway plays a central role in endometriosis-associated inflammation[92] and is activated in stromal fibroblasts by ROS resulting from iron overload, possibly due to impaired clearance of retrograde menstruation, lesion-associated bleeding,[98] or endometrioma cyst fluid accumulation. In a rat model of endometriosis, a candidate NF-κB inhibitor (disulfiram) prevented the growth of endometriosis lesions.[99]

In addition to inflammation, a growing body of evidence supports relative immune dysfunction in women with endometriosis. For instance, natural killer cell activity is impaired in women with endometriosis, which may set conditions for immune evasion of retrogradely menstruated endometrial cells.[100] A recent systematic review and metaanalysis revealed an association between endometriosis and autoimmune disorders, including thyroid disease.[101] Whether it is an autoimmune disorder with accompanying increased generalized B-cell activity and association with autoantibodies to phospholipids and endometrium is yet to be determined. Increased antibody production may be the consequence of a general inflammatory response initiated by activated macrophages and other antigen-presenting cells in response to the ectopic endometrial tissue, rather than a cause of the disease. Alterations in immune function have been described in endometriosis,[92] but the changes are complex, and none independently or satisfactorily explains the pathogenesis of this disorder. In addition, it is not clear whether the alteration is the cause of endometriosis or secondary to the inflammatory reaction that endometriosis induces.

Mechanisms Underlying Pain and Infertility

Pelvic pain associated with endometriosis may be manifest as dysmenorrhea, dyspareunia, dyschezia, and/or chronic, noncyclic pelvic pain.[102] Pain symptoms vary with the location of the disease, stage, type of lesion, and depth of invasion. The pathophysiology of endometriosis-associated pain is believed consequent to inflammation, adhesions, lesional innervation, and increased prostaglandin production by ectopic implants.[103] Red vesicular lesions, for example, produce higher amounts of prostaglandins.[104] Adhesions may cause pain by damage to tissues and subsequent scarring or damage to nerves and/or blood supply resulting in ischemia or tissue hypoxia. Understanding the etiology of endometriosis-associated pain is prerequisite to the design of novel therapies (see treatment section later). Important contributions include a murine model of innervation of endometriosis lesions[105] and the demonstration of nerve fibers in ectopic and eutopic endometrium (functionalis and basalis) from women with endometriosis (Fig. 125.4).[106,107] Although transcriptomic analysis of eutopic endometrium had revealed neurotransmitter receptors and ligands using a variety of approaches,[108] demonstration of unmyelinated nerves (nociceptors) in eutopic and ectopic endometrium suggests mechanisms involved in the pathogenesis of pain. Finally, ascending nociceptive signals in the central nervous system may result in central sensitization and alterations in pain processing, brain chemistry, and function that are unique in women with endometriosis and may explain pain that is refractory to medical and surgical treatments.[105,109]

Endometriosis is strongly associated with infertility. A metaanalysis of 22 studies revealed a significant reduction in *in vitro* fertilization (IVF) pregnancy rates in women with endometriosis relative to women with tubal factor infertility.[110] A recent metaanalysis of 27 studies comparing IVF outcomes in women with and without endometriosis confirmed a decrease in clinical pregnancy rates, but only in women with advanced (stage III–IV) disease (RR 0.79, 95% CI: 0.69–0.91).[111] Endometriosis-associated infertility may be due to mechanical factors affecting gamete/embryo transit, sperm/oocyte/embryo toxicity, endocrine disturbances, immunologic abnormalities, and/or implantation defects. Notably, the proinflammatory PF from women with endometriosis adversely affects sperm motility, sperm velocity,[112] and sperm binding to the zona pellucida in a hemizona assay[113] and significantly reduces mouse embryo blastocyst development rates, suggesting a direct embryotoxic effect.[114] There is an abundance of data demonstrating eutopic endometrial abnormalities (progesterone resistance, inflammatory phenotype) leading to an inhospitable environment for embryo implantation (attachment and stromal decidualization).[115] Dysregulated genes in women with disease include $\alpha_v\beta_3$ integrin, *HOXA10*, *MUC1*, glycodelin, and *BCL6*. Recently, Lessey and colleagues demonstrated that inflammatory cytokines promote *BCL6* expression, which correlates with progesterone resistance, and high *BCL6* expression in the implantation window is associated with endometriosis, unexplained infertility, and implantation failure.[116] These observations and others are opening the field to novel diagnostic and therapeutic development.

DIAGNOSIS

Endometriosis may be suspected but cannot be reliably diagnosed on the basis of presenting symptoms or physical exam, although recently, clinical algorithms to predict disease based on these parameters and family history have been developed.[102] Rather, the gold standard for diagnosing endometriosis is histologic confirmation of endometrial glands and stroma in laparoscopically directed biopsies of suspected lesions.[117] Peritoneal endometriosis is heterogeneous in appearance, with a variety of lesional subtypes including red vesicular, powder burn, or white fibrotic lesions. Recognition of endometriosis varies among surgeons, and inaccuracy has been documented in visual diagnosis.[118] Confounding presentations with other disorders and the requirement for a surgical diagnosis result in an average latency of 8 to 11 years from symptom onset to definitive diagnosis.[119] Unfortunately, disease may progress during this interval, as longitudinal placebo-controlled trials with second-look laparoscopy demonstrate that 71% to 83% of untreated lesions will progress or remain stable over a 12-month period.[120,121]

Though unreliable for the diagnosis of peritoneal endometriosis and associated adhesions, imaging techniques such as ultrasonography and magnetic resonance imaging (MRI) perform well in the detection of ovarian endometriomas, with 80% to 90% sensitivity and 60% to 98% specificity.[122] Also known as a “chocolate cyst,” an endometrioma is sonographically characterized by a hazy appearance on ultrasound and histologically by the presence of endometrial glands and stroma in the cyst wall. MRI is increasingly being used to evaluate deep infiltrating disease, with high accuracy (74% sensitivity and 95% specificity), and to plan the surgical approach.[123]

Noninvasive biomarker discovery for diagnosing endometriosis is an active area of study. Two recent systematic reviews of all proposed endometriosis-related biomarkers (proteins, cytokines, angiogenic and growth factors, miRNAs) over the previous 25 years in serum, plasma, urine, and endometrium were unable to identify unequivocally clinically useful biomarkers, due to low numbers of subjects, small populations for

validations, cycle- and stage-dependence, poorly defined controls, and low sensitivity and specificity.[124,125] Recently, however, two commercial tests have been developed towards endometriosis diagnosis based on circulating miRNAs[91] and endometrial *BCL6* expression.[116] Though promising with regards to developing a noninvasive approach, surgical diagnosis for peritoneal disease remains the gold standard.

KEY POINTS

- Diagnosis of peritoneal disease is currently surgical, while deep infiltrating endometriosis and ovarian endometrioma can be detected radiologically.

THERAPIES

Therapy for endometriosis is individualized to the patient's presenting symptoms and treatment goals. The majority of medical treatments for endometriosis-associated pain are incompatible with concomitant fertility interests, and therefore it is important to establish the patient's treatment priorities. The management approach includes treatment of existing disease and adhesions and prevention of disease recurrence. The latter consideration is underscored by the high rate of pain recurrence within 6 to 12 months of treatment completion.[126] Treatment strategies include surgical removal or ablation of existing

endometriotic disease, suppression of lesional activity, or empiric pain and fertility approaches (Table 125.1). For prevention of endometriosis recurrence, current strategies are based on reduction or elimination of menstruation. Generally, the therapeutic approaches to endometriosis can be categorized as medical or surgical.

Medical

Pain. Medical approaches are thought to reduce endometriosis-associated pelvic pain through a variety of mechanisms, including suppressing cyclic ovarian and/or lesional production of estradiol, inhibiting the action of estradiol, minimizing inflammation, and reducing or eliminating menses.[127,128] Combined oral contraceptives, oral progestins, long-acting progestins (implants, intrauterine device), gonadotropin-releasing hormone (GnRH) analogs, danazol, and aromatase inhibitors are among the most commonly used medical treatments for endometriosis pain management. These medications reduce estradiol bioavailability via inhibition of ovulation. Many may also prevent disease recurrence by minimizing menstrual blood volume and flow. Nonsteroidal antiinflammatory drugs (NSAIDs) can be a useful adjunct in pain management because of their inhibition of prostaglandin synthesis.[127,128]

Use of a combined oral contraceptive pill with an NSAID represents the first-line approach to cyclic pelvic pain and is often attempted prior to surgery.[117] A randomized controlled trial demonstrated significant reduction in dysmenorrhea pain scores in women using oral contraceptive pill relative to placebo.[129] In patients with dysmenorrhea refractory to a cyclic oral contraceptive regimen, continuous oral contraceptive pill use is more effective in relieving pelvic pain.[130]

Long-term hypoestrogenism is beneficial for relief of pain symptoms and can be achieved with GnRH agonists, such as leuprolide acetate. A systematic review of 15 randomized trials involving 1821 patients observed a 60% to 100% improvement in dysmenorrhea pain scores with use of GnRH agonists.[131] As this treatment can result in a mostly reversible 13% decrease in bone density over a 6-month interval, "add-back" therapy with low-dose estrogens and progestins has been advocated to reduce the side effects of hypoestrogenism and decreased bone density. Although most women continue to experience significant relief of pain, approximately 30% have recurrence of symptoms within 6 months after therapy is discontinued.[132]

By inducing significant endometrial atrophy and subsequent amenorrhea, the levonorgestrel intrauterine system (LNG-IUS) is a promising approach to the prevention of disease recurrence. Indeed, randomized studies have demonstrated that LNG-IUS is more effective than no treatment in the reduction of endometriosis-associated pain after conservative surgery.[133]

Danazol, a synthetic androgen, is approved by the US Food and Drug Administration for the treatment of endometriosis-associated pain. The immunosuppressive effects of danazol render it unusual among the hormonal treatments, and this feature may add to its efficacy in the treatment of endometriosis. Though relatively effective with respect to pain control, oral danazol was associated with androgenic side effects (weight gain, acne, changes in serum lipoprotein cholesterol profile) that limited patient acceptance, leading to a search for alternative routes of administration. Several nonrandomized prospective studies investigating vaginal danazol have demonstrated treatment efficacy without significant androgenic side effects.[134]

Aromatase inhibitors such as letrozole have proven effective in the control of pain associated with endometriosis. The application of these agents is based on the discovery of high levels of aromatase expression in endometriotic lesions relative to eutopic endometrium from women without endometriosis.[3] This enzyme catalyzes the conversion of androgens to estrogens, thereby increasing local estradiol bioavailability. They are best coupled with a progestin to suppress ovulation, because an aromatase inhibitor administered alone in a premenopausal woman can induce ovulation.[135]

Newer medical treatments for endometriosis-associated pain that have demonstrated promise in preclinical and/or small clinical studies include PR modulators, GnRH antagonists, kinase signaling pathway inhibitors, TNF-α inhibitors, angiogenesis inhibitors (e.g., anti-VEGF, dopamine agonists), antioxidants, niclosamide, antiinflammatory agents, and dual suppression of estrogenic and inflammatory activities.[84,136-138]

Fertility. In contrast to their beneficial role in pain management, hormonal therapies are not beneficial in the treatment of endometriosis-associated infertility.[127,128] A Cochrane analysis revealed that ovulation suppression with GnRH analogs, oral contraceptives, medroxyprogesterone acetate, or danazol, compared with placebo in women with endometriosis, has no advantage regarding clinical pregnancy rates.[139] Surgical reduction of endometriotic lesional burden avoids delay associated with ovarian suppression and may improve the pregnancy rate, particularly in patients with stage I to II endometriosis (see later). Historically, endometriosis-associated infertility has been treated with controlled ovarian hyperstimulation coupled with intrauterine insemination, or IVF. The finding of a nearly 50% reduction in IVF pregnancy rates in women with advanced (stage III–IV) endometriosis[110] suggests that IVF, as traditionally conducted, incompletely addresses the pathophysiology of endometriosis-associated infertility and led to the search for adjuncts to optimize fertility in this cohort. GnRH agonist (i.e., leuprolide acetate) treatment for 3 to 6 months preceding IVF improved pregnancy rates in women with endometriosis, and this initial finding was confirmed in a subsequent metaanalysis of three randomized trials involving a total of 165 women.[140] Minimizing chronic niche inflammation has been proposed to improve fertility.[141] Notably, a recent cohort study of 85 women with unexplained infertility and elevated *BCL6* expression in the implantation window were treated with no additional therapy before an IVF cycle or with endometriosis therapies (2 months of GnRH agonist + norethindrone acetate or laparoscopic ablation of disease). Those undergoing medical suppression or laparoscopic treatment for endometriosis had a significantly higher live birth rate, at 50% (95% CI: 23.7–76.3) and 52.4% (95% CI: 32.4–71.7), respectively, compared with controls, at 7.4% (95% CI: 2.9–17.6).[142] While these data are impressive, a randomized controlled trial is needed to determine the efficacy of this screening method and medical (and surgical) treatment in women with elevation of the endometrial inflammatory biomarker *BCL6* in the implantation window for pregnancy success.

Surgical

Pain. Laparoscopy affords unique advantages in detecting and treating endometriosis-associated pain, and laparoscopic-assisted ablation or excision of endometriotic lesions is the most prevalent surgical approach. Laparoscopic surgery improves pelvic pain after 6 months (OR 4.97; 95% CI: 1.85–13.9).[126] A Cochrane review[143] demonstrated that laparoscopic excision was superior to drainage/ablation of endometriomas larger than 3 cm, with significant reductions in the rates of endometrioma recurrence (OR 0.41 [0.18–0.93]), requirement for further surgery (OR 0.21 [0.05–0.79]), dysmenorrhea recurrence (OR 0.15 [0.06–0.38]), dyspareunia recurrence (OR 0.08 [0.01–0.51]), and baseline pain recurrence (OR 0.10 [0.02–0.56]).

Interruption of nerve pathways represents an alternative approach to controlling pelvic pain. A review of randomized clinical trials[144] reported that laparoscopic uterine nerve ablation (LUNA)—interruption of nerves along the uterosacral ligaments—versus no LUNA showed no difference in secondary dysmenorrhea pain scores. In contrast, laparoscopic presacral neurectomy (LPSN)—in which the nerve bundle is removed within the boundaries of the interiliac triangle—plus treatment of endometriosis versus treatment of endometriosis alone showed improvement in secondary dysmenorrhea pain scores at the 6-month (OR 4.52 [1.84–11.09]) and 12-month (OR 3.14 [1.59–6.21]) postoperative timepoints.[145] However, there are increased risks of adverse effects with presacral neurectomy, including urinary urgency and constipation. Definitive surgery for recalcitrant pelvic pain is total hysterectomy and bilateral salpingo-oophorectomy, performed by laparotomy or laparoscopy or as a laparoscopically-assisted vaginal procedure. In women who have successful pain relief, however, symptoms recur in 12% to 54% within a year of therapy.[146] This observation suggests that adjunctive medical therapy may be helpful, and indeed, both preoperative and postoperative medical therapies have been efficacious.[147]

Fertility. Laparoscopic assessment and treatment of endometriosis-associated infertility is a viable option, particularly for patients with coexisting pelvic pain symptoms. Laparoscopy offers the opportunity to stage endometriosis toward triaging further infertility treatment, as patients with more advanced (stage III–IV) disease may need to consider IVF, particularly if concomitant ovarian reserve concerns are present. A controlled trial involving 341 women with infertility undergoing laparoscopy showed a significantly higher cumulative pregnancy rate in women with stage I to II endometriosis randomized to ablation of lesions as compared with untreated patients (30.7% vs. 17.7%).[148] A second smaller study did not confirm these results, although a subsequent metaanalysis of the two trials favored surgical treatment (OR for pregnancy = 1.7; 95% CI: 1.1–2.5).[149] The management of infertile patients with endometrioma(s) is less clear, as surgical removal with respect to reduction of inflammation must be weighed against the deleterious impact on ovarian reserve owing to collateral damage to adjacent healthy ovarian tissue.[150] Surgical removal of endometriomas is recommended if they are large (>3 cm), or if concern exists regarding the exact nature of the ovarian lesion. In general, by reducing endometriotic disease, the inflammatory response within the pelvis is reduced. Based on known actions of the mitogens, morphogens, chemoattractants, and angiogenic factors within the PF, it is likely that a reduction in these factors will result in an environment that is more favorable for fertility.

KEY POINTS

- Treatments for endometriosis-related pelvic pain focus on surgery, anti-inflammatory drugs, and hormonal therapies minimizing or inhibiting menstrual flow and blocking estrogen synthesis and action, with newly identified signaling pathways holding promise for future therapeutic targets.

Integrated Approach to the Patient With Endometriosis

Management of patients with endometriosis requires a multidisciplinary team that includes expertise in gynecology, general surgery, reproductive endocrinology and infertility, urology, immunology, genetics, oncology, psychology, nursing, nutrition, pain management, and complementary medicine, as well as patient support groups.[5] A unilateral approach to achieving patient goals is unwise, as most patients with endometriosis have multiple issues that warrant careful, integrated, and sensitive attention.

Endometriosis-Associated Cancer Risk

The first report on the morphologic relationship between endometriosis and ovarian cancer was presented by Sampson in 1925.[151] Two case-controlled studies by Ness and colleagues on ovarian cancer revealed endometriosis as a risk factor,[152,153] and the coexistence of endometriosis and ovarian cancer has been reported to range between 0.7% and 5% of all cases with ovarian endometriosis.[154] Berqvist and colleagues, using the National Swedish Inpatient Register, identified 64,492 women discharged from hospital with a diagnosis of endometriosis over a 31-year period (between 1969 and 2000) and linked the data to the National Swedish Cancer Register to evaluate standardized incidence ratios (SIR) of cancer.[155] Elevated risks were found for ovarian cancer (SIR 1.43; 95% CI: 1.19–1.71), and women with early diagnosed and longstanding endometriosis had a higher risk of ovarian cancer (SIR of 2.01 and 2.23, respectively). A large pooled analysis of case control studies established a history of endometriosis to be associated with a nearly 50% increase in ovarian cancer risk (OR 1.46; 95% CI: 1.31–1.63).[156]

Important clinical and molecular differences exist among the histologic subtypes of ovarian cancer. In the general population, the serous subtype is most common, representing approximately 70% of cases, whereas endometrioid (20%) and clear cell (5%) carcinomas are less prevalent. Compared with serous carcinoma, endometrioid and clear cell tumors are associated with younger age of onset, presentation at an earlier stage, and reduced sensitivity to common ovarian cancer chemotherapeutic regimens.[218] A link between the endometrioid and clear cell histologic subtypes of ovarian cancer and endometriosis is well supported. In women undergoing surgery for ovarian cancer, the rate of endometriosis is significantly higher with clear cell (26.3%) and endometrioid (21.1%) subtypes than with mucinous (5.6%) or serous (3.6%) subtypes.[157] Synchronous incidence of endometriosis with clear cell (41%) and endometrioid (38%) ovarian cancer suggests malignant transformation,[158] and conceptualization of endometriosis as a precursor lesion for these histologic subtypes is supported by molecular evidence. A mouse model of *K-RAS* protooncogene activation in the ovarian epithelium coupled with targeted deletion of the *PTEN* tumor suppressor gene resulted in development of endometriosis and endometrioid ovarian cancer,[64] highlighting the potential for malignant transformation of endometriosis to ovarian cancer. *ARID1A* has been strongly implicated in the malignant transformation of endometriosis, with somatic mutations observed in 46% of clear cell carcinomas and 30% of endometrioid carcinomas.[63] In several patients, *ARID1A* somatic mutations were evident in tumor and contiguous atypical endometriosis, but not in distant lesions, suggesting malignant transformation from local ovarian endometriotic tissue. The iron-rich microenvironment within ovarian endometriomas is associated with an increase in ROS, which may predispose to cancer-inducing somatic mutations in these lesions.[159]

A study of Swedish women with endometriosis cross-referenced against the National Swedish Cancer registry demonstrated a protective effect against ovarian cancer for both one-sided oophorectomy (OR 0.19; 95% CI: 0.08–0.46) and excision of all visible endometriosis (OR 0.30; 95% CI: 0.12–0.74).[160] Oral contraceptive pills represent a more conservative chemoprophylactic approach, as use for greater than 10 years was associated with an 80% reduction in epithelial ovarian cancer risk among women with endometriosis.[161] Further study is needed to accurately identify women with endometriosis at risk for tumorigenesis and to validate appropriate preventative measures.

SUMMARY

Endometriosis may be a result of modern advances in the twentieth and twenty-first centuries, including contraception (decreased frequency of pregnancy, and thus greater numbers of menses during a woman's reproductive lifetime), hormonal replacement therapy, and modern industrial development with its attendant immunotoxicants and estrogen-like compounds. Advances in basic and clinical research regarding the pathophysiology of endometriosis have begun to identify therapies to minimize pain or maximize fertility. The ultimate therapy for this disorder, however, is prevention. Hysterectomy for endometriosis increased dramatically between 1965 and 1984,[226] probably because of an increased awareness of the presence of endometriosis and perhaps because of an increasing incidence of the disorder. A major global effort to minimize environmental toxins, coupled with pharmacologic suppression of menses, would ideally reduce the incidence of this disease. Although this result may be long in coming, patient advocacy, education, and support, coupled with basic and clinical research in endometriosis, should also be high priorities in a national women's health agenda.

  Pathogenesis, 2099
  Diagnosis, 2099
  Treatment, 2099
  Summary, 2100

KEY POINTS

- Uterine fibroids are the leading indication for hysterectomy and a cause of significant morbidity and healthcare expenditures for reproductive age women.
- Fibroids are more common and more severe in women of African descent, and the cause of this disparity is not clear.
- A salient feature of fibroids is their responsiveness to steroid hormones, and most current treatments target steroid action.
- The discovery of stem cells in leiomyoma may lead to better understanding of their pathophysiology and the development of new treatments.
- Adenomyosis is a disease that often coexists with uterine fibroids and endometriosis and causes heavy menstrual bleeding, pain, and subfertility, but has been less well understood because until recently it required hysterectomy for pathologic identification.

UTERINE FIBROIDS

Introduction

Uterine fibroids are common noncancerous neoplasms that arise from the myometrium, but their impact on women is not benign. They are the leading indication for hysterectomy and disproportionately impact women of African descent. While new medical, surgical, and procedural therapies are providing many women with alternatives to hysterectomy, a limited understanding of their pathophysiology limits new approaches. The understanding of this disease is broadening beyond the gonadal steroids estrogen and progesterone to include the role that stem cells, growth factors, and the active extracellular matrix (ECM) play in this disease.

Epidemiology and Classification

The prevalence of uterine fibroids, often referred to as uterine leiomyomas or myomas, ranges from 4.5% to 68.6%, with the incidence of ultrasound-confirmed fibroids in a US population being lower in White women than Black women, at 70% and 80%, respectively.[1,2] Uterine fibroids are symptomatic in women of reproductive age, and symptoms often wane when women reach menopause, both due to the lack of menstruation and the lower levels of the gonadal steroids estrogen and progesterone.[3]

Women with uterine fibroids experience a range of symptoms depending on the number, size, and location of their fibroid(s). Fibroid size ranges from a few millimeters to over 30 centimeters.[4] The most common symptom is abnormal uterine bleeding (AUB), designated as AUB-L when due to fibroids (leiomyomas), which is primarily heavy or prolonged menstrual bleeding and can often result in iron-deficiency anemia. Other fibroid symptoms include bulk symptoms such as bowel dysfunction, protruded abdomen, frequent urination, and painful intercourse. The presence of uterine fibroids may contribute to infertility, miscarriage, and pregnancy complications.[3]

Symptomatic uterine fibroids also impact a women's emotional and psychosocial well-being. Women have reported feelings of helplessness, fear, and anxiety surrounding their uterine fibroid diagnosis, and many report decreased quality of life. Women also reported missing work and social activities due to uterine fibroid symptoms.[5] Expense to the US healthcare system for uterine fibroid diagnosis and treatment has been estimated at approximately $34 billion dollars annually.[3]

Risk Factors. There are a few nonmodifiable risk factors that contribute to the development of uterine fibroids. Race is a risk factor seen in all studies. Black women have a higher prevalence of uterine fibroids and have a higher disease burden (larger fibroid volumes, increased number of fibroids) and more severe symptoms at time of diagnosis compared with White women. Black women also have a lower age at diagnosis compared with their White counterparts.[1,2] Furthermore, they are three times as likely to be hospitalized and seven times more likely to undergo uterine-sparing surgical myomectomies than women of other races.[6] Newer research suggests that Latina women may also have more severe symptoms compared with Black and White women in the United States.[7] Other nonmodifiable risk factors linked to fibroids include early menarche and polycystic ovarian syndrome. Nulliparous women are also at higher risk for uterine fibroids.[8] Family history of fibroids and diabetes may also be linked to the disease.[1,8]

Some modifiable factors such as diet are linked to uterine fibroid development. Women with a higher intake of fruits and vegetables are less likely to develop uterine fibroids, while women who consume a diet rich in red meats are at higher risk. High intake of long-chain omega-3 fatty acids is positively correlated with uterine fibroids.[8] A diet deficient in vitamin D and dairy is also positively correlated with uterine fibroids.[8,9] Alcohol and caffeine consumption are also a moderate risk factor.[8]

Protective Factors. Parity appears protective for fibroids and may be due to the uterine remodeling that occurs after delivery. Smoking cigarettes has an inverse relationship with the development of fibroids.[8] There is contradictory information about hormonal contraceptives. Most studies suggest that oral contraceptives (OCs) and depot forms of progestins may decrease the risk for uterine fibroids, but data from the Nurses' Health Study suggest that OCs started before age 16 may be associated with increased risk.[1]

Classification. All classification systems for uterine fibroids are based on anatomical location, and specifically the relationship between the fibroid and the serosal (outer) and mucosal (inner) surfaces of the uterus (Fig. 126.1). There are three general types of fibroids, with the most common being intramural (within the myometrium) and not reaching either uterine surface. Submucosal fibroids are inside the uterus, in contact with the endometrium. Subserosal fibroids are at the outer uterine surface. An updated classification system is provided by the International Federation of Gynecology and Obstetrics (FIGO).[10] The FIGO classification system uses numerical values to expand on the classic system to clarify extent of protrusion from the mucosal or serosa surfaces and describes fibroids that span the uterus. However, there are still clinical limitations in using the FIGO classification for diagnosis.[11]

Typically, the type of fibroid impacts the patient's symptoms. Both submucosal and intramural fibroids are linked to abnormal uterine bleeding. Subserosal fibroids show no effect on fertility, while submucosal fibroids may affect fertility, and their removal may improve fertility outcomes. Intramural fibroid position impacts fertility; however, their removal is associated with conflicting fertility outcomes.[12] Subserosal fibroids are also associated with bulk symptoms.

KEY POINTS

- Uterine fibroids are benign tumors arising from the myometrium. They are the leading indication for hysterectomy and a cause of significant morbidity and healthcare expenditures for reproductive age women. They are more prevalent and have greater disease burden in Black women, but the cause of this disparity is unclear.

Pathogenesis

Despite the public health impact of these tumors, their specific etiology remains unclear. Early genetic studies suggest that fibroids are monoclonal tumors, derived from a single myocyte. Neoplastic transformation of a myocyte to a leiomyoma cell is likely due to a single mutation, with mutations in the mediator complex subunit 12 (*MED12)* gene reported in approximately 70% of uterine fibroids.[13,14] Mutations affecting the expression of the high mobility AT-hook 2 (*HMGA2*) gene have also been reported in a large number of fibroids, and appear to be mutually exclusive with *MED12* mutations.[15] Regardless of the nature of the genetic hit, a common salient feature of fibroids is their responsiveness to steroid hormones, thus providing an opportunity for intervention. Estrogen and progesterone lead to tumor expansion by stimulating a modest rate of cellular proliferation and the production of copious amounts of ECM, predominantly collagen.[16,17]

Role of Progenitor Cells. A small population of stem-progenitor cells has been discovered in fibroids and appears to be important in fibroid pathophysiology.[18,19] Somatic stem cells, or tissue-specific stem cells, are a small group of cells present throughout the body that asymmetrically divide, resulting in self-renewal and daughter cells that differentiate into tissue-specific cell types. These cells, which are key for tissue regeneration and repair, are critical in maintaining normal organ function.[20,21] Similarly, tumor-initiating cells, or tumor progenitor cells, are a small group of cells within a tumor that can undergo

asymmetric division and thereby have the capacity for self-renewal and tumor maintenance and growth.[22,23] A subset of cells characteristic of somatic stem cells exist in human and mouse myometrial tissues, and these cells self-renew and produce daughter cells in a hormone-dependent manner (Fig. 126.2).[24-26] Additionally, a small population of cells consistent with undifferentiated somatic stem cells or tumor progenitor cells has been isolated from fibroid tissue.[18,19] It is possible that, during myometrial stem cell regeneration, a mutation may transform this population to tumor stem cells (Fig. 126.2). Subsequently, the tumor stem cells, via clonal expansion, would give rise to a fibroid (Fig. 126.2). Stem cells derived from fibroid tissue, but not myometrium, carry *MED12* mutations, suggesting that *MED12* may be one of the genes in which a mutation transforms a myometrial stem cell into a fibroid progenitor cell, which then interacts with the surrounding myometrial tissue to give rise to a fibroid tumor.[18] Uterine hypoxia and aberrant estrogen signaling have also been implicated in the transformation of a myometrial stem cell into a fibroid progenitor cell.[27,28]

When cell suspensions containing fibroid progenitor cells and mixed myometrial cells are injected under the kidney capsules of immunodeficient mice treated with estrogen and progesterone, they grow into significantly larger tumors than those containing differentiated fibroid cells and mixed myometrial cells. The tumors derived from fibroid progenitor cells also have a higher proliferation index than tumors without these cells.[18] Intriguingly, fibroid progenitor cells are relatively deficient of estrogen receptors (ERs) and progesterone receptors (PRs) but have tumorigenic capabilities when stimulated by estrogen and progesterone. Moreover, fibroid progenitor cells require the presence of either mature fibroid or myometrial cells for proliferation and growth. It is possible that these cells rely on strikingly higher levels of steroid hormone receptors in surrounding differentiated myometrial and fibroid cells to mediate estrogen and progesterone action via paracrine signaling (Fig. 126.2).[18] Moreover, multiple studies have suggested a role for paracrine pathways in the communication between fibroid stem-progenitor cells and the surrounding differentiated cells, involving the wingless-type (WNT)/β-catenin, insulin-like growth factor (IGF) 2/insulin receptor-A, and receptor activator of nuclear factor κB ligand (RANKL)/RANK pathways.[29-31] These promising results may indicate future therapeutic targets, although much remains to be explored in fibroid progenitor cells and the role they play in fibroid pathogenesis.

Steroid Hormone Action—Estrogen. Estrogen acts primarily via two nuclear receptors, ERα and ERβ, which are expressed in both the myometrium and in fibroids,[32-34] and estrogen binding upregulates expression of several genes thought to play a role in fibroid pathogenesis, including multiple growth factors, collagen, and ER and PR (Fig. 126.3).[35-37] Conflicting results have been reported regarding levels of ER expression in fibroids compared with the surrounding myometrium.[38-40] Although the exact roles of ERs in fibroid development have not been fully elucidated, it is thought that ERβ regulates the transcriptional activity of ERα, which is the stronger transcriptional activator of the two.[40] Additionally, several studies have shown that ERα

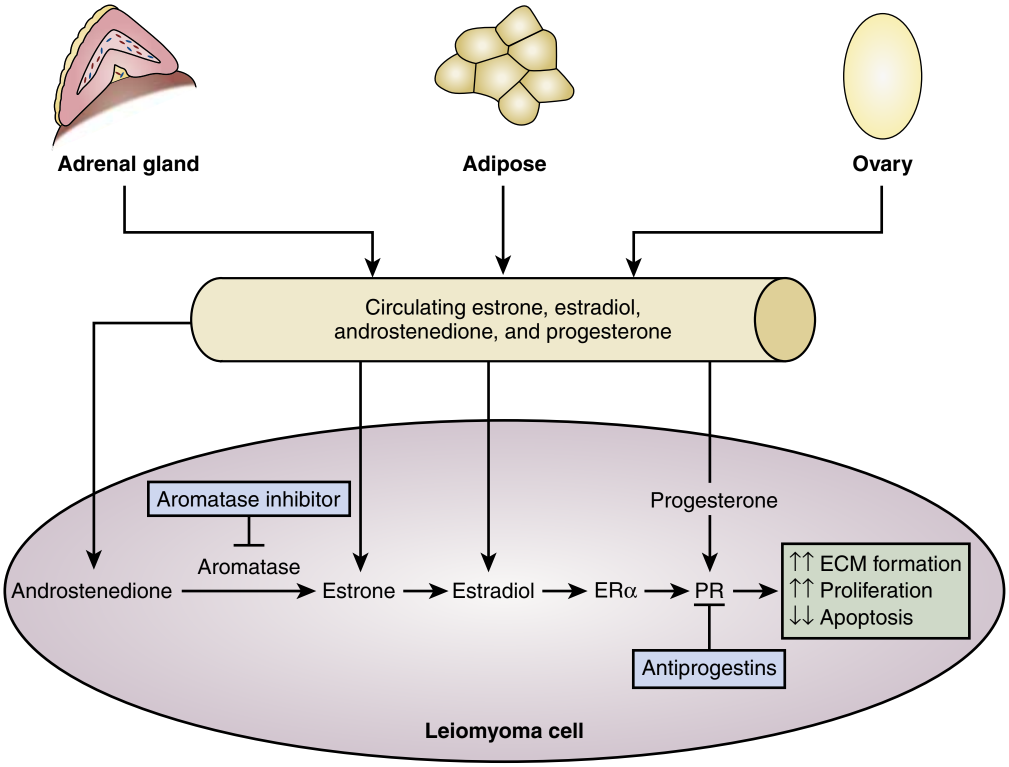

Figure 126.2 **A,** Normal myometrial tissue goes through cyclic growth under the influence of ovarian progesterone secreted in a cyclic fashion. Normal myometrial stem cells undergoing self-renewal and proliferation possibly play a central role in this process. Because stem cells are deficient in estrogen receptor α (ERα) or progesterone receptor (PR), surrounding mature myometrial cells with high steroid receptor expression mediate steroid action via paracrine mechanisms. **B,** If one of the myometrial stem cells is affected by a mutation, this cell is transformed. It may then continue clonal expansion at a rate higher than that of a normal myometrial stem cell. **C,** The mutated myometrial cell gives rise to a leiomyoma via increased self-renewal and proliferation. It eventually differentiates into mature leiomyoma cells with high ERα and PR expression, which, via paracrine signaling, stimulates further stem cell proliferation. Mature leiomyoma cells also lay down extracellular matrix (ECM) under the influence of estrogen and progesterone. This eventually gives rise to a clinically recognizable uterine fibroid.

Figure 126.3 **Role of sex steroids in leiomyoma pathology.** The ovary, adrenal gland, and adipose tissue produce the precursors, androstenedione and estrone, of the biologically active estrogen, i.e., estradiol. Ovary also secretes progesterone. These steroids reach leiomyoma tissue in circulating blood. Aromatase converts androstenedione to estrone that is further reduced to form estradiol in leiomyoma. Estradiol via estrogen receptor α (ERα) induces the expression of progesterone receptor (PR) in leiomyoma tissue. Progesterone of ovarian origin acts via PR to increases the formation of extracellular matrix (ECM) and cell proliferation and decreases apoptosis.

polymorphisms increase susceptibility to fibroids.[41,42] ERα is also activated via phosphorylation (without estrogen binding) by the mitogen-activated protein kinase (MAPK) pathway, leading to the hypothesis that estrogen-bound ERα induces growth factor expression, which can then stimulate the MAPK pathway and further activate ERα via phosphorylation in an autocrine fashion.[43]

While estrogen has traditionally been thought of as the primary hormone responsible for fibroid growth, *in vivo* and *in vitro* studies have shown that progesterone is required for estrogen-driven fibroid growth, suggesting that estrogen is necessary, but not sufficient, for proliferation.[44-46] Moreover, estrogen/ERα regulates expression of PR, and disruption of the estrogen-signaling pathway by transfection significantly decreases both *ER* and *PR* gene expression.[44,47] Finally, in an *in vivo* human fibroid xenograft model, treatment with estrogen and progesterone stimulated not only fibroid cell proliferation, but also ECM formation, and these effects were abolished by cotreatment with the PR antagonist mifepristone (RU486).[44] These findings suggest a more permissive role for estrogen, acting via induction of PR expression, and thereby allowing fibroid responsiveness to progesterone.[44,48]

Fibroids are exposed to estrogen not only through ovarian steroidogenesis, but also through local conversion of androgens by aromatase within the tumors themselves.[49] In cultured fibroid cells, the addition of androstenedione leads to production of estrone, which is then converted to the more potent estradiol by 17β-hydroxysteroid dehydrogenase (17β-HSD).[50] Furthermore, incubation of cultured fibroid cells with androstenedione leads to similar rates of cellular proliferation as estradiol, suggesting that fibroids are capable of producing enough estrogen to sustain their own growth.[50] The addition of aromatase inhibitors then decreases proliferation in cultured cells and decreases fibroid size clinically, further supporting that aromatase is the key enzyme mediating in situ estrogen production.[48,50] Fibroid tissue has remarkably higher levels of aromatase and 17β-HSD type 1 compared with adjacent normal myometrium, which, accordingly, leads to higher tissue levels of estrogens in fibroids as well.[49-52] Moreover, aromatase is not found in the myometrium of uteri without fibroids.[49] Finally, there is increased aromatase expression in fibroids of Black American women, who are disproportionately affected by fibroids.[48] Although the molecular mechanisms underlying regulation of aromatase are not completely understood, the transcription factor CCAAT/enhancer binding protein β is a key inducer of aromatase expression via regulating its proximal promoter I.3/II region, the predominant promoter utilized by fibroid cells.[45,53]

Steroid Hormone Action—Progesterone. Clinical and experimental studies confirm that progesterone plays a key role in uterine fibroid growth and development (Fig. 126.3).[54] Progesterone acts via PR, a member of the nuclear hormone superfamily of ligand-activated transcription factors.[55,56] The two predominant PR isoforms, PR-A and PR-B, are transcribed from the same gene by two distinct promoters, resulting in differently sized proteins and different transcriptional activities.[57-61] Selective ablation of PR isoforms in mice revealed that PR-A is necessary for ovulation and modulates the antiproliferative effects of progesterone in the uterus, and that PR-B is required for normal mammary gland development and function.[62,63] Several studies have reported increased expression of both PR-A and PR-B in fibroid tissue compared with adjacent normal myometrial tissue, but the specific role of each PR isoform in uterine fibroids has yet to be fully elucidated.[64-66]

Clinical studies in postmenopausal women have shown that fibroid proliferation increases significantly with hormone replacement therapy with combined estrogen and progestin, but not with estrogen replacement alone, supporting a key role for progesterone signaling in fibroid growth.[46] Additionally, proliferation markers and mitotic counts are highest in fibroid tissue during the luteal/secretory phase, when circulating progesterone is highest.[46,67] Despite the belief that progesterone is the primary hormone driving the growth of uterine fibroids, its specific role in the pathogenesis of fibroids is not completely understood. In cultured fibroid cells, treatment with antiprogestins decreases proliferation by downregulating several growth factors and their receptors, including IGF-I, epidermal growth factor (EGF), transforming growth factor (TGF) B3, vascular endothelial growth factor (VEGF)-A, and VEGF-B.[68-72] These treatments also induce apoptosis through activation of multiple differential apoptotic pathways, including the tumor necrosis factor–related apoptosis-inducing ligand-mediated signaling pathway and the endoplasmic reticulum stress-induced pathway,[73,74] and by reducing expression of the antiapoptotic protein BCL2 and stimulating expression of cleaved caspase-3 and cleaved PARP.[75] Furthermore, antiprogestins decrease ECM formation by increasing ECM metalloproteinase inducer, MMP-1, MMP-8, and membrane type 1-MMP protein contents and decreasing TIMP-1, TIMP-2, and type I and type III collagen protein levels.[72,76] Most recently, in an *in vivo* human fibroid xenograft model, Qiang et al.[77] demonstrated that estrogen plus progesterone, but not estrogen alone, induces ECM production via downregulation of miR-29b. Although grafts containing control vector-transduced cells gave rise to typical solid fibroid tumors, fibroid grafts with ectopic mir-29b expression failed to form solid tumors in the presence of estrogen plus progesterone,[77] supporting the hypothesis that dysregulation of mir-29b plays an important role in tissue fibrosis and tumor formation.[78-81]

Genomic studies have also shed some light on progesterone's role in fibroid pathogenesis. Expression of the tumor suppressor gene Kruppel-like transcription factor 11 (*KLF11*) is significantly lower in fibroid tissues compared with adjacent myometrial tissues, and the CpG island in the *KLF11* promoter is hypermethylated in fibroid tissue.[82] Therefore, dysregulation of *KLF11* may be a key factor involved in uterine fibroids. Using a genome-wide approach, a PR-binding site was found 20.5 kb upstream of the *KLF11* promoter, and *KLF11* knockdown markedly increased fibroid cell proliferation.[82] In primary cultures of uterine fibroid cells, treatment with the antiprogestin mifepristone (RU486) robustly regulates the protein and mRNA levels of KLF11 by enhancing recruitment of Sp1, RNA polymerase II, PR, and its coactivator SRC-2 to both the distal enhancer and basal promoter region of the *KLF11* gene. It is unclear whether these activities can alter *KLF11* methylation status. Additionally, using a chromatin immunoprecipitation-sequencing assay, another novel PR target gene, perilipin 2 (*PLIN2*), was recently discovered in fibroid cells.[83] *PLIN2* normally plays an important role in lipid droplet formation and stabilization, but its loss is linked to the expression of fibrogenic genes in hepatic fibrosis.[84-86] Moreover, in clear cell renal carcinoma, higher *PLIN2* expression is associated with better cancer-specific survival and cancer-free survival.[87] These findings strongly suggest that progesterone-mediated expression of *KLF11* and *PLIN2* may regulate both fibroid cell proliferation and ECM formation.

Fibrosis. Another hallmark of uterine fibroid pathogenesis is dysregulation of the ECM, resulting in excessive ECM deposition. Fibroids exhibit overexpression of multiple ECM glycoprotein components, including collagens, fibronectin, fibulin-3, laminins, and proteoglycans.[88,89] In particular, the ECM in uterine fibroids has been shown to have increased collagen types I, III, and V compared with the surrounding myometrium.[89] Overexpression of several growth factors in uterine fibroids, most notably activin-A, TGF-B, and platelet-derived growth factor, likely contribute to overproduction of ECM components.[88,89] Moreover, it has been hypothesized that the ECM itself may protect these growth factors from degradation, thus compounding the dysregulated growth.[88]

KEY POINTS

- A salient feature of fibroids is their responsiveness to steroid hormones, but genetic mutations, progenitor cells, and fibrosis from dysregulation of the extracellular matrix also play a role.

Diagnosis

Despite the high incidence, only 25% to 50% of women report fibroid-related symptoms.[1] Some fibroids are truly asymptomatic, and other symptoms are likely attributed to either normal function or other processes such as aging or musculoskeletal pain. Uterine fibroids are often first suspected when a mass is felt during a pelvic exam due to subserosal fibroids.[3] Fibroids are sometimes an incidental finding on an ultrasound ordered for another clinical indication.[8] The presence of uterine fibroids is often confirmed by ultrasonography, either transabdominally or transvaginally, based on the size of the uterus. Transvaginal ultrasonography provides more resolution and detail on size, number, and location of fibroids.[90] Serial ultrasounds may be useful for monitoring the size of uterine fibroids over time.[4] Instilling saline into the endometrial cavity while using ultrasound imaging for a sonohysterogram aids in defining submucosal fibroids and differentiates them from endometrial polyps and clot.[90]

Magnetic resonance imaging (MRI) is a more expensive imaging modality that is reserved for special uses for fibroid imaging. This technique is usually warranted when ultrasonography is inconclusive, uterine sarcoma is suspected, or the precise location or vascularity of a fibroid is important to determine use of specific treatment options.[4]

KEY POINTS

- Despite the high incidence, only 25%-50% of women report fibroid-related symptoms. Fibroids are often first suspected when a mass is felt during a pelvic exam due to subserosal fibroids but can be confirmed by ultrasonography.

Therapies

Treatment for uterine fibroids (Table 126.1) depends on symptoms, anatomy (including size, number, and location), and the reproductive goals of the patient. There are several medical and surgical procedures that should be individualized to the patient. Expectant management for asymptomatic patients and for symptomatic patients for 6 months is another option.

Expectant Management. Women with asymptomatic fibroids usually undergo a "watch and wait" approach. While data suggest that fibroids can decrease in size, there is no known way to naturally trigger fibroid regression. However, symptomatic women may wish to be more engaged with their providers regarding treatment. Patient decision aids (PDAs) can help facilitate a discussion between women and their health care providers to decide on the best course of treatment. PDAs can provide all the information of different treatment options to women. A study is currently underway providing PDA for uterine fibroid diagnosis.[91]

Medical Therapies. Most medical treatments focus on improving heavy menstrual bleeding. Contraceptive steroids are widely used for this noncontraceptive indication. The most widely used off-label medical treatment is OCs, in one study accounting for almost 80% of medical therapy for fibroids.[92] The progestin-releasing intrauterine device (IUD) is another effective off-label contraceptive steroid to decrease menstrual bleeding, but risk of expulsion is increased in a fibroid

TABLE 126.1 Surgical and Medical Treatments of Uterine Fibroids and Adenomyosis

Treatments	Uterine Fibroids	Adenomyosis
Medical		
Oral contraceptives	**X** [92]	**X** [120]
Progestin-releasing intrauterine device (IUD)	**X** [93]	**X** [120]
Nonsteroidal antiinflammatory drugs (NSAIDS)	**X** [93]	**X** [120]
Gonadotropin-releasing hormone (GnRH) agonists	**X** [93]	**X** [120]
Selective progesterone receptor modulators (SPRMs)	**X** [93]	
Tranexamic acid	**X** [93]	
Surgical

Myomectomy	**X** [93]	
Adenomyomectomy		**X** [115]
Radiofrequency ablation (RFA)	**X** [93]	

uterus. Nonsteroidal antiinflammatory drugs (NSAIDs) are used to decrease blood loss and treat menstrual pain as a result of fibroids, but high-quality evidence is lacking.[93]

There is moderate consistent evidence that gonadotropin-releasing hormone (GnRH) agonists decrease AUB-L, improve quality of life, and shrink fibroids.[93] GnRH agonist is thus used as primary treatment *and* as an adjuvant preoperative medical therapy, where either the absence of menses or volume reduction will greatly aid surgical treatment. The agonist depot leuprolide acetate is approved for preoperative therapy. GnRH agonists first lead to release of stored pituitary gonadotropins, producing a clinical flare, and then to castrate levels of gonadal steroids, thus placing women at risk for hypoestrogenic symptoms, including bone loss. It is these side effects that typically limit therapy to 6 months of use. A new generation of oral GnRH antagonists, in combination with steroidal add-back to limit hypoestrogenic side effects, is showing both safety and efficacy for fibroid treatment. Elagolix with add-back is now US Food and Drug Administration–approved,[94] and relugolix combination therapy is likely to be approved soon.[95]

Aromatase inhibitors act by competitively binding the aromatase enzyme and blocking its access to androgens and are used for off-label treatment.[96,97] The aromatase inhibitors currently on the market, such as anastrozole and letrozole, have been shown to result in greater than 98% inhibition of the enzyme.[97,98] The efficacy of letrozole and anastrozole has been established in multiple clinical trials, resulting in up to 52.5% reduction in fibroid volume and improved symptomatic control.[99-102] Importantly, letrozole has been shown to have similar efficacy as GnRH agonist in reducing fibroid size, but with the advantage of avoiding the profound hypoestrogenism caused by GnRH agonists and resultant side effects, although this is controversial.[100] Some studies suggest a more systemic effect of aromatase inhibitors, and others more localized effects.[100,103] Bone loss and increased cardiovascular risk, particularly in younger patients, are the most concerning potential consequences of prolonged hypoestrogenism from prolonged treatment with aromatase inhibitors.[98] As with all medical treatments for fibroids, once aromatase inhibitors are discontinued, fibroid growth rebounds.[100]

Selective PR modulators are also effective treatment options for uterine fibroids without the hypoestrogenic side effects of GnRH agonists.[93] Four of these agents—mifepristone (RU486), asoprisnil (J867), ulipristal acetate (CDB2914), and telapristone acetate (CDB4124)—reduce fibroid size and improve quality of life in women with uterine fibroids.[69,73,74,76,104-106] Unfortunately, severe liver toxicity led ulipristal to be significantly limited in the market internationally, and the others never received approval for treatment in the United States.[107]

Finally, tranexamic acid is an antifibrinolytic treatment that is used to decrease bleeding during surgery and during menses in women with hereditary bleeding disorders. In women with AUB-L undergoing surgical myomectomy, tranexamic acid as an off-label treatment reduced blood loss compared with placebo.[93] Likewise, it lessened AUB-L during menses, with mild adverse effects such as menstrual cramps, back pain, and sinus headaches. An advantage of tranexamic acid for AUB-L is that it only needs to be taken during the days of heavy menstrual bleeding, although increased risk of deep vein thrombosis can occur when combined with estrogen-containing contraceptive steroids.[108]

Surgical and Interventional Therapies. In contrast to medical therapies, most surgical and interventional therapies are reserved for women who have symptoms related to the size of the fibroids, or so-called bulk symptoms, those with a combination of AUB-L and bulk symptoms, or those who have failed medical therapies. However, new fibroids commonly form following conservative treatment, often incorrectly labeled as fibroid recurrence. Candidates for surgical and interventional therapy should be counseled about this risk and the risk of adhesion formation following surgery, which can impact fertility and pain.

The one surgical therapy that is often performed in women with isolated AUB-L or in asymptomatic women seeking fertility is hysteroscopic myomectomy, which only treats submucosal fibroids. It is performed on an outpatient basis with an intrauterine endoscope, and patients can typically return to work in less than a week.[3] Recent findings suggest that women have relief of some of their bulk symptoms and improvement of fertility with this approach.[109]

The most common procedure for treating uterine fibroids is hysterectomy, accounting for approximately 79.2% of fibroid procedural therapies.[8] In the United States, over 90% of hysterectomies are performed for noncancerous indications, and fibroids account for one half to three quarters of all hysterectomies.[3] The advantage of hysterectomy is that it prevents new fibroid formation and improves the decreased quality of life many women with fibroids experience. Women undergoing hysterectomy for uterine fibroids typically can retain their ovaries.

However, there is a growing literature that details long-term effects associated with hysterectomy even with bilateral ovarian conservation, including significantly increased rates of hyperlipidemia, hypertension, obesity, cardiac arrhythmias, congestive heart failure, and coronary artery disease.[110] Furthermore, many women who have a hysterectomy report increased *de novo* mental health concerns like depression and anxiety.[111]

Myomectomy is a uterine-preserving technique used to surgically remove uterine fibroids. There is low quality of evidence on myomectomy improving quality of life, and insufficient evidence on resolving AUB-L.[93] Depending on fibroid size and location, as well as surgical skill, myomectomy can be performed laparoscopically or robotically, with a shorter recovery time.[112] Abdominal myomectomy is more invasive but treats more extensive disease such as fibroids larger than 9 cm or if there are more than three to four. This method does have a longer recovery time compared to the laparoscopic technique,[113] and there is a risk that uterine fibroids may reoccur.

Radiofrequency ablation uses radiofrequency energy to shrink uterine fibroids via a laparoscopic or hysteroscopic approach. Small comparative trials have shown advantages compared with the excisional approaches, although data are limited.[93]

Uterine artery embolization (UAE) is a uterine-preserving procedure with strong and consistent evidence for improving quality of life for women with fibroids and reducing fibroid volume.[93] UAE blocks blood flow from uterine arteries, causing fibroid shrinkage, and is performed under sedation and local anesthesia, with short recovery.[4] It has the same success and quality-of-life improvement as myomectomy and hysterectomy, but has a higher reintervention rate than hysterectomy. Based on limited evidence, it is not considered first-line therapy for women who wish future pregnancy.

MRI-guided focused ultrasound surgery (MRgFUS) is a noninvasive procedure available in the United States that directs ultrasound ablation of uterine fibroids with the guidance of MRI, with low-level evidence for decreasing fibroid size.[93] A study on MRgFUS efficacy reported that women who underwent the procedure experienced decreased bleeding ($P = 0.001$) and pelvic symptoms ($P = 0.004$). There were no serious adverse effects, and two pregnancies were reported during follow-up.[114] There are also devices for ultrasound-guided focused ultrasound that are available primarily in China.[93]

KEY POINTS

- Treatment for fibroids depends on symptoms, anatomy including size, number, and location, and the reproductive goals of the patient. Many medical treatments focus on improving AUB-L, but there are a few that have shown evidence in decreasing fibroid size. Most surgical therapies are reserved for women who have bulk symptoms, the combination of AUB-L and bulk symptoms, or those who have failed medical therapies. The most common procedure being hysterectomy, accounting for approximately 79.2% of fibroid procedural therapies.

ADENOMYOSIS

Overview

Adenomyosis is a disease that commonly coexists with uterine fibroids and endometriosis and is a cause of heavy menstrual bleeding, pelvic pain, and reproductive dysfunction. Until the past decade, adenomyosis was typically only identified in women who were undergoing hysterectomy. The recognition that this disease is able to be identified by both ultrasound and MRI is changing the epidemiology of the disease and raising the question of whether symptoms previously attributed to endometriosis and fibroids are actually due to coexisting adenomyosis.

Epidemiology and Classification

Adenomyosis is a disorder where endometrial glands and stroma grow within the myometrium. There is resulting hyperplasia of the normal myometrial tissue, which thickens, causing an enlarged, boggy, globular uterus. It has a prevalence of 20% of women.[115] Symptoms include painful menses, heavy menstrual bleeding, pelvic pain, and possible infertility. These symptoms are similar to other gynecological conditions and make understanding adenomyosis difficult, because many women have endometriosis and/or uterine fibroids with adenomyosis.

Adenomyosis comes in several forms. Diffuse adenomyosis has endometrial implants scattered throughout the myometrium. Focal adenomyosis or an adenomyoma is a spherical collection that resembles a fibroid. Thickening or irregularity of the junctional zone is also a type of adenomyosis. Stated risk factors for adenomyosis include multiparity, older reproductive age, more miscarriages, abortions, and more uterine surgery. However, because adenomyosis is only diagnosed by hysterectomy, these risk factors may instead reflect the epidemiology of hysterectomy.[116]

KEY POINTS

- Adenomyosis is a disorder where endometrial glands and stroma grow into the myometrium, causing subfertility, pelvic pain, dysmenorrhea and heavy menstrual bleeding. It affects ~20% women, and can be diffuse or focal.

Pathogenesis

The specific pathogenesis of adenomyosis is unknown, but two prevailing theories exist (Fig. 126.4). The first is that adenomyosis is caused by invagination of the endometrial basalis into the myometrium, potentially due to a disrupted junctional zone.[117,118] The migration of the endometrium is thought to be supported by local hyperestrogenism, disordered uterine peristalsis leading to microtrauma, and activation of tissue injury and repair mechanism with proliferation and inflammation. The second commonly held theory is that displaced embryonic remnants or adult stem cells undergo metaplasia within the myometrium. A related theory, referred to as "outside-to-inside invasion," hypothesizes that retrograde menstruation enables ectopic endometrial cells to invade the myometrium.[117-119] Given the diversity in adenomyosis phenotypes observed, it is quite possible that a single theory cannot explain all subtypes.[119] Regardless of the inciting event, progression of adenomyosis has been hypothesized to be related to sex steroid hormone levels, genetic alterations, inflammatory cells, changes in the ECM, growth factors, and/or gain in migration of adenomyotic cells.[117,118]

KEY POINTS

- The pathogenesis of adenomyosis is unknown, but there are two prevailing theories: 1) A disrupted junctional zone leads to invagination of the endometrial basalis into the myometrium, or 2) displaced embryonic remnants or adult stem cells undergo metaplasia withing the myometrium.

Diagnosis

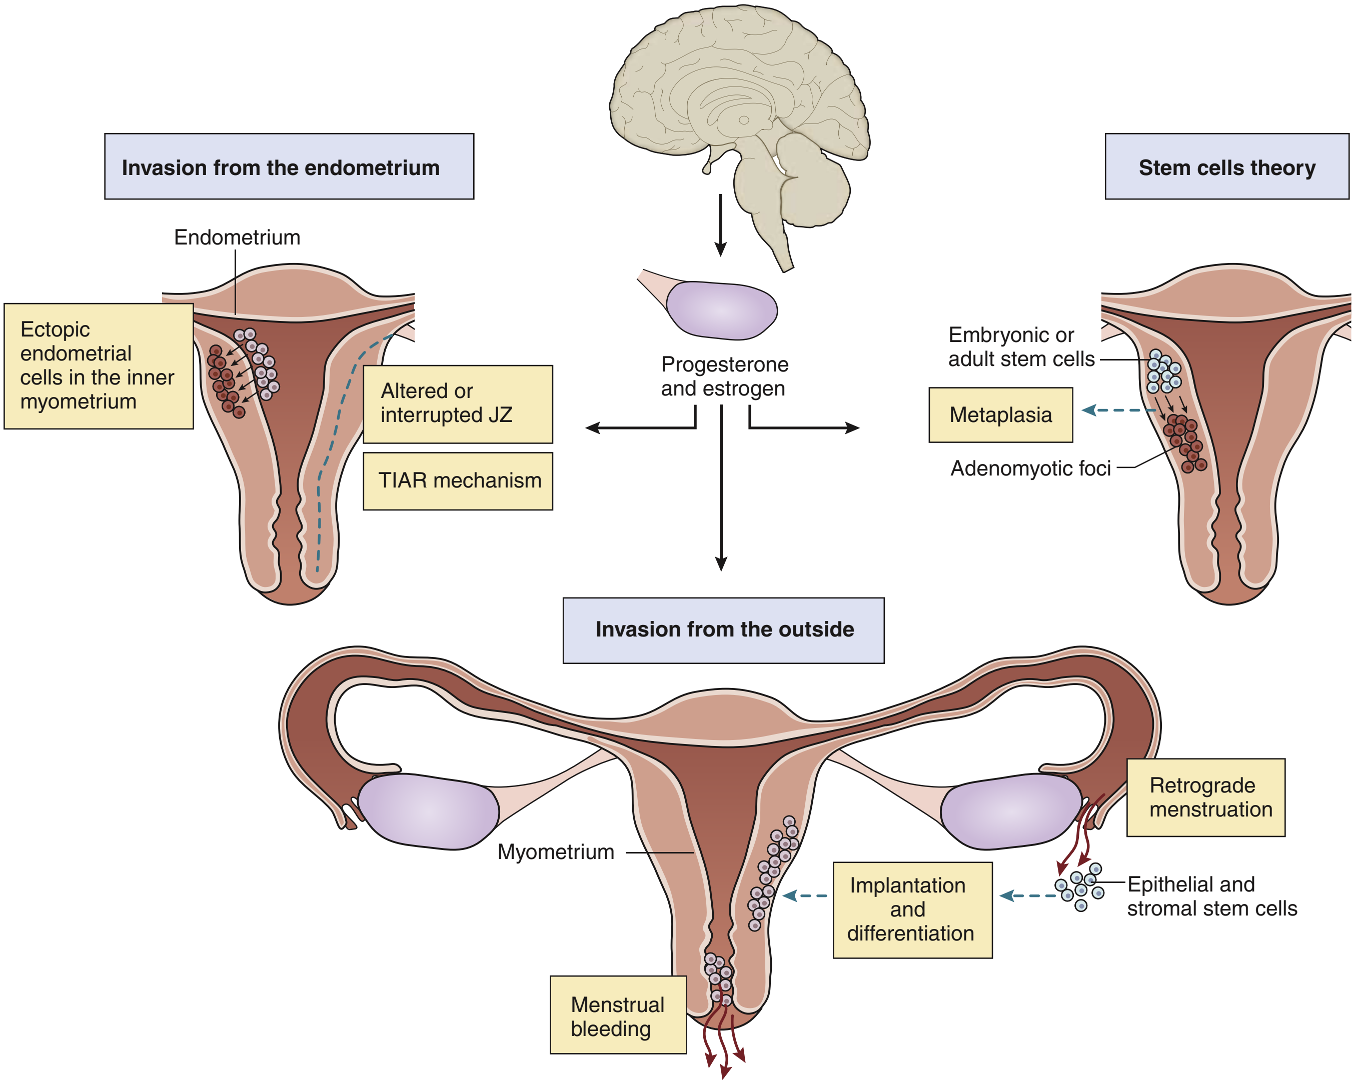
Transvaginal ultrasound can be used to diagnose adenomyosis, but is more user-dependent. Key signs include asymmetry of uterine walls, heterogeneity or cystic spaces within the myometrium, thickening or discontinuity of endometrial/myometrial border, and linear striation radiating out from the endometrium. Color-flow doppler can differentiate adenomyosis from symptomatic uterine fibroids by looking at vascular flow. MRI is used to confirm the diagnosis if the ultrasound was not clear. However, the only definitive diagnosis is by histological verification of endometrial islets within the myometrium. There is still an ambiguous classification for the different subtypes of adenomyosis.[116]

KEY POINTS

- Until the past decade, adenomyosis was typically only identified in women who were undergoing hysterectomy. The recognition that this disease is able to be identified by both ultrasound and MR imaging is changing the epidemiology of the disease, and raising the question of whether symptoms previously attributed to endometriosis and fibroids are actually due to coexisting adenomyosis.

Treatment

There is no medical therapy specifically for the treatment of adenomyosis[120]; thus, medical treatments used to treat uterine fibroids and endometriosis are often appropriated for adenomyosis (Table 126.1).



Invasion from the endometrium
Endometrium
Ectopic endometrial cells in the inner myometrium
Altered or interrupted JZ
TIAR mechanism
Progesterone and estrogen
Stem cells theory
Embryonic or adult stem cells
Metaplasia
Adenomyotic foci
Invasion from the outside
Myometrium
Retrograde menstruation
Epithelial and stromal stem cells
Implantation and differentiation
Menstrual bleeding

Figure 126.4 **Pathophysiology of adenomyosis.** Adenomyosis pathogenesis appears to be influenced both directly by the brain through peptides such as prolactin and oxytocin and indirectly through the gonadal steroids estrogen and progesterone. There are several theories of adenomyosis pathogenesis. **A,** The invasion hypothesis, where endometrium traverses an altered or interrupted junctional zone (JZ) leading to tissue injury and repair (TIAR). **B,** Metaplasia of resident stem cells from within the myometrium. **C,** Migration and differentiation of adult stem cells from the endometrium following retrograde menstruation. NSAIDs, OCs, and especially progestin-releasing IUDs can be used as a therapy for pain relief and abnormal uterine bleeding (AUB-A). Progestins are known to decrease the expression of the PR in the adenomyotic lesions in the myometrium. GnRH analogs are used to stop proliferation within the myometrium, and may induce apoptosis and reduce inflammation.

Surgical treatment varies. Hysterectomy is currently the only surgical procedure that permanently resolves symptoms of adenomyosis, but it is clearly not acceptable to many women. However, there is an increasing variety of other conservative procedures that can be done to improve some symptoms. Adenomyomectomy is a cytoreductive surgery that removes adenomyotic nodules, but has been associated with early uterine rupture during pregnancy, even with expert surgeons.[115] UAE and MRgFUS have been shown to improve symptoms of adenomyosis in some studies.[121] However, there is no comparative effectiveness research for uterine-sparing treatments for adenomyosis.[122]

KEY POINTS

- There is no medical therapy specifically for adenomyosis, but treatments for fibroids and endometriosis are often employed with mixed results. Less invasive surgical procedures, such as adenomyomectomy, can be attempted but the only definitive treatment remains hysterectomy.

Summary

Uterine fibroids are extremely common and are the leading indication for hysterectomy and a cause of significant morbidity and health care expenditures for reproductive-age women. For reasons that remain to be fully elucidated, fibroids are more common and more severe in women of African descent. The discovery of stem cells and genetic mutations in leiomyoma may lead to a better understanding of their pathophysiology and the development of new, potentially individualized treatments. A salient feature of fibroids is their responsiveness to steroid hormones, and most medical treatments, both established and experimental, target steroid action. There are also surgical and radiological treatment options for fibroids. Adenomyosis is a disease that often coexists with uterine fibroids and endometriosis and can cause heavy menstrual bleeding, pelvic pain, and subfertility. The exact pathophysiology of adenomyosis is unknown, but several theories exist. As such, there is currently no medical therapy specifically for adenomyosis, but many of the treatments for fibroids and/or endometriosis have been employed with varying success. The only definitive treatment for adenomyosis remains hysterectomy.

HYPOTHALAMIC-PITUITARY INFLUENCES, OVARIAN FUNCTION, AND BREAST DEVELOPMENT

KEY POINTS

- Breast development begins in the fetus with the mammary ridge and a rudimentary milk-duct system by birth.
- Main changes in mammary gland development are initiated at puberty and are dynamic across the life course and differ from woman to woman.
- Peri-pubertal changes in mammary duct elongation and branching are largely programmed by estradiol, progesterone, growth hormone (and prolactin) and growth factors.
- Age of clinical appearance of breast buds (thelarche) varies with race/ethnicity and BMI, with earlier thelarche onset in African American > Hispanic > White non-Hispanic > Asian girls) and with higher BMI.

In the nonpregnant female, development of the mammary gland is rigorously controlled by the ovary. Although puberty is often considered to be the point of initiation of ovarian function, the development of the ovary, in fact, is a gradual process (see Chapters 102, 117, and 120).[1] The complex regulatory mechanisms that control ovarian function involve gonadotropin-releasing hormone; luteinizing hormone (LH); follicle-stimulating hormone (FSH); the ovarian peptides inhibin, activin, and follistatin; growth hormone (GH); and prolactin (see Chapters 102 and 105).[2] The ovary is active during late fetal development and for a short time after birth but becomes relatively quiescent until the onset of puberty, when mammary ductal elongation and branching begin under the influence of estradiol (E2) and GH.[3] Although its exact mechanism is unclear, GH directly stimulates ductal growth in hypophysectomized-ovariectomized rats and may also act through its local mediator, insulin-like growth factor-1 (IGF-1). Normal duct development, however, requires the presence of E2 and progesterone acting, respectively, through the estrogen receptor (ER) and the progesterone receptor (PR), both of which are present in the mammary gland. E2 acts locally to stimulate DNA synthesis and promote bud formation, likely ER-mediated. Prolactin plays an additional role, but its specific actions are not fully understood. The response of the mammary gland to these complex hormonal and metabolic interactions results in developmental changes that permanently modify the architecture and biological characteristics of the gland.[3] The mammary gland, in turn, responds selectively to given hormonal stimuli, depending on specific topographic differences in gland development that modulate the expression of cell proliferation or differentiation. Hormone receptor knockout studies and tissue recombination and proteomic approaches have revealed sequential activation of hormone signaling in the breast epithelium, acting through coregulators, that govern morphogenesis and cell proliferation, depending on developmental stage (see Chapter 102).[5]

Adolescence

Although the main changes in the mammary gland are initiated at puberty, development continues during adulthood, and the final histomorphometry of the gland varies greatly from woman to woman.[3] Mammary gland development can be defined by the external appearance of the breast or by determination of mammary gland area, volume, degree of branching, or level of differentiation of the gland, such as lobule-type formation.[5]

The adolescent period begins with the first signs of sexual change at puberty and terminates with sexual maturity. Age at thelarche (initial clinical appearance of a breast bud) varies by race/ethnicity and BMI.[6,7] Median age at onset is 8.8, 9.3, 9.7, and 9.7 years for African American, Hispanic, White non-Hispanic, and Asian participants, respectively.[6] Girls with greater BMI reached breast stage 2 at younger ages, especially among girls with BMI >85th percentile.[7] With the approach of puberty, the rudimentary mammae begin to show growth activity in the glandular tissue and the surrounding stroma.[3-5] This glandular increase is as a result of the growth and division of small bundles of primary and secondary ducts (Fig. 127.1). These grow and divide in two ways. One

*This chapter is in memory of my long-time collaborator and companion, Dr. Irma H Russo, who passed away on June 25, 2013.

[†]deceased

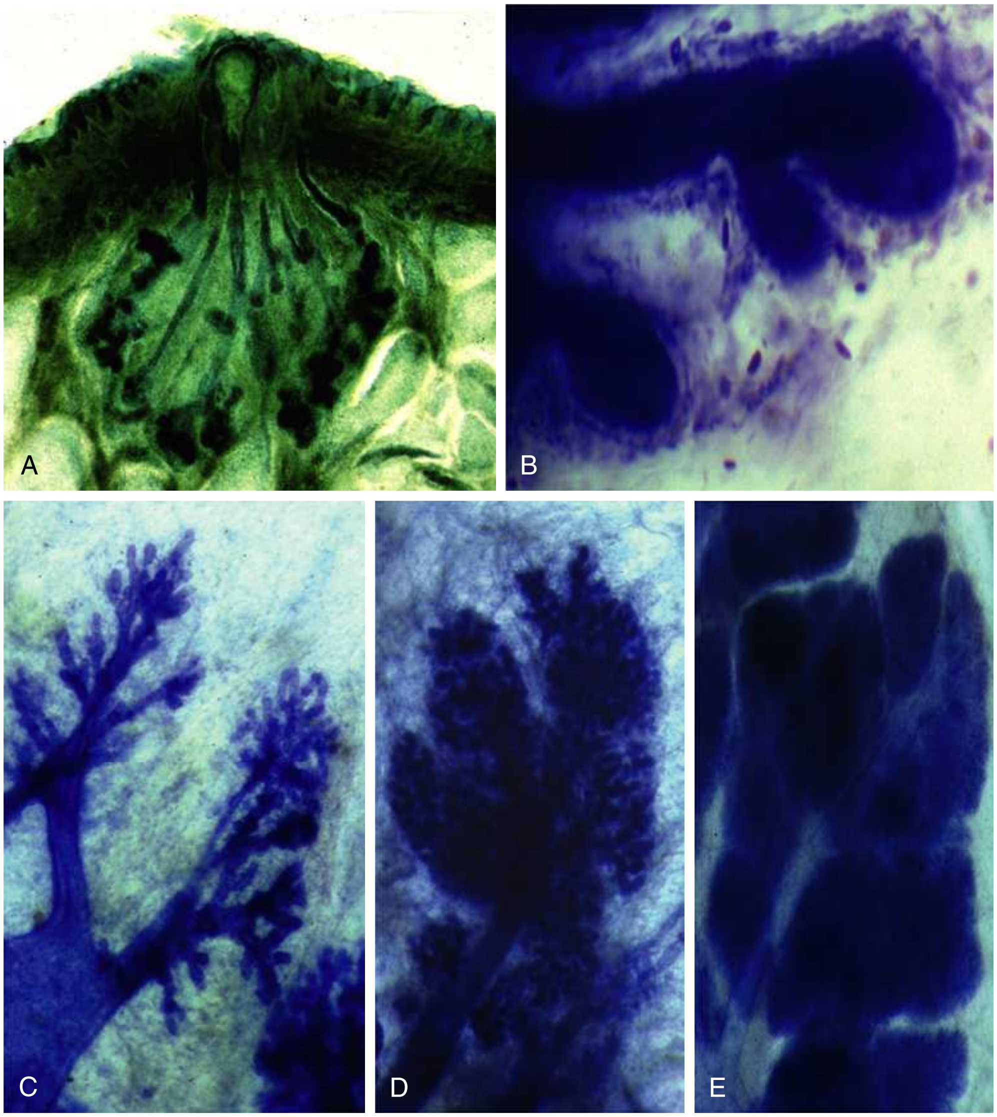

Fig. 127.1 Mammary gland development. **A,** Mammary gland of human female at birth formed by several excretory ducts, ending in terminal ducts. Detail of the inset showing the club-shaped terminal end bud from which lengthening and further divisions of the virginal ducts originate. Toluidine blue ×25. **B,** Before the onset of puberty in human females, the ducts grow and divide on a dichotomous and sympodial basis, a ball-shaped end bud sprouts from the duct, and new branches and twigs develop from the terminal and lateral end buds. Toluidine blue ×25. **C,** Whole mount preparation of breast tissue from an 18-year-old nulliparous woman showing type 1 lobules. Toluidine blue ×25. **D,** Whole mount preparation of human breast tissue from a 24-year-old nulliparous woman showing type 2 lobules. Toluidine blue ×25. **E,** Whole mount preparation of human breast tissue from a 35-year-old parous woman containing type 3 lobules. Toluidine blue ×25.

involves repeated dichotomous (Greek *dichomotos*, "divide into two parts") bifurcation of existing ducts, and the other involves localized buds on an expanding ductular base, a process called "sympodial" from the Greek *syn* + *podion* base. The ducts grow, divide, and form club-shaped terminal end buds (TEBs), giving rise to new branches, twigs, and small ductules or *alveolar buds* (Fig. 127.2). The "alveolar bud" identifies structures that are morphologically more developed than the TEB but are more primitive than the terminal structure of the mature structure (an acinus). Alveolar buds cluster around a terminal duct, forming the type 1 lobule or virginal lobule (Figs. 127.1 and 127.2). Each cluster comprises approximately 11 alveolar buds. Lobule formation in the female breast occurs within 1 to 2 years after onset of the first menstrual period. Full differentiation of the mammary gland is a gradual process that takes many years; in some cases, if pregnancy does not supervene, it is never attained.

THE MATURE BREAST

KEY POINTS

- Growth and differentiation of the breast continue beyond puberty and throughout the life course, and are programmed by a woman's pregnancy history.
- The morphologic and structural changes that occur in the breast in nulliparous versus parous women underscore profound alterations that reflect the function of the gland, as well as potential susceptibilities to breast cancer later in life.

Study of normal breast tissue in adult women identifies two additional and more mature types of lobule, designated types 2 and 3 (see Figs. 127.1 and 127.2). The transition from type 1 to the more mature types 2 and 3

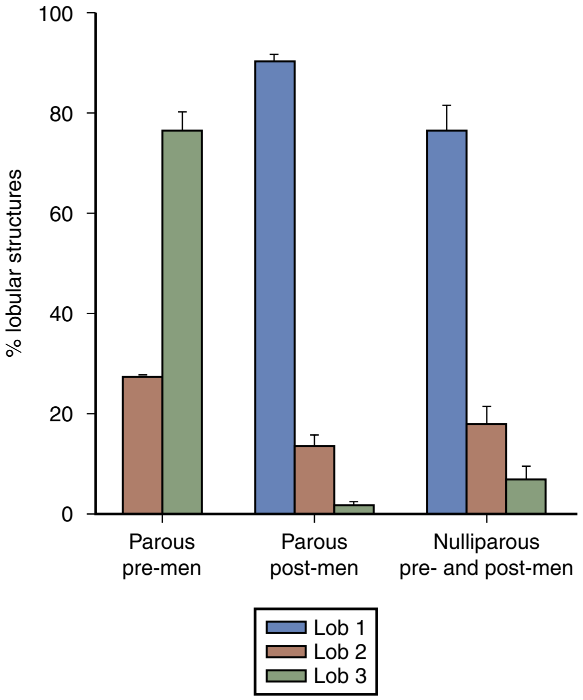

Fig. 127.2 Percentage of lobule-type structures in the breast of premenopausal (pre-men) and postmenopausal (post-men) parous women, and premenopausal and postmenopausal (pre-men and post-men) nulliparous women. Lobules type 1 (lob 1), lobules type 2 (lob 2), and lobules type 3 (lob 3).

TABLE 127.1 Characteristics of the Lobular Structures of the Human Breast

Structure	Lobular Area,[a] μm^2	No. of Ductules/ Lobules[b]	No. of Cells/ Cross Section[c]
Lob 1	48 ± 44	11.2 ± 6.3	32.4 ± 14.1
Lob 2	60 ± 26	47.0 ± 11.7	13.1 ± 4.8
Lob 3	129 ± 49	81.0 ± 16.6	11.0 ± 2.0

[a] Student's t-tests were done for all possible comparisons. Lobular areas showed significant differences between lob 1 vs. lob 3 and for lob 2 vs. lob 3 ($P < .005$).

[b] The number of ductules per lobule was different ($P < .01$) in all comparisons.

[c] The number of cells per cross-section was significantly different in ductules of lob 1 vs. lob 2 and lob 3 ($P < .01$).

From Russo J, Rivera R, Russo IH. Influence of age and parity on the development of the human breast. *Breast Cancer Res Treat.* 1992;23:211–218.

represents a gradual process, with sprouting of an increased number of new alveolar buds. In type 2 and 3 lobules, these are now called ductules; they increase in number from approximately 11 in the type 1 lobule to 47 in the type 2 lobule and 80 in type 3, respectively (see Fig. 127.1; Table 127.1). The increase in number results in a concomitant increase in the size of the lobules and a reduction in the size of each individual structure.[3,8]

Nulliparous Women

In these women, breast tissue contains more undifferentiated structures, such as terminal ducts and type 1 lobules, although occasional type 2 and 3 lobules are seen (Fig. 127.3). This pattern remains constant throughout the reproductive years unless pregnancy ensues. Type 2 lobules are present in moderate numbers during the early reproductive years but sharply decrease after age 23 years, whereas the number of type 1 lobules remains significantly higher. This observation suggests that some type 1 lobules may progress to type 2 lobules, but the number of type 2 lobules that progress to type 3 is significantly lower than in parous (P) women.[9]

Parous Women

In this group, the predominant structure is the most differentiated (type 3) lobule. The number of type 3 structures peaks during the early reproductive years and decreases after the fourth decade of life. Parity between the ages of 14 and 20 years correlates with a significant increase in the number of type 3 lobules that remain as the predominant structure until the age of 40 years, when the number of type 3 lobules decreases owing to their involution to predominantly type 1 lobules[9] (Fig. 127.3).

DISTRIBUTION PATTERN OF ESTROGEN RECEPTOR– AND PROGESTERONE RECEPTOR–POSITIVE AND PROLIFERATING CELLS IN THE MAMMARY GLAND

Even though the breast is influenced by numerous hormones and growth factors,[10-17] estrogens play a major role in promoting proliferation of normal (and neoplastic) breast epithelium.[18-24] They stimulate the proliferative activity of mammary epithelial cells by one of at least three different mechanisms: direct receptor-mediated stimulation,[19,25-32] indirect autocrine/paracrine loops,[22-23] or interruption of negative feedback factors.[21,33]

ERa, encoded by *ESR1*, and ERb, encoded by *ESR2*, with similar affinity for E2, are key mediators of E2 actions on the breast.[34-36] The essential roles of ER and PR on cell proliferation, essential for normal growth and development of the breast, derive from mouse knockout studies. ERa knockout mice display grossly impaired ductal epithelial proliferation and branching, and PR knockout mice display significant ductal development but decreased arborization and absence of alveolar differentiation.[37,38]

Our studies[10-13,18,39-41] and others[42] of mammary epithelial proliferation in rodents and humans have demonstrated that cell division varies with degree of differentiation of mammary parenchyma. In women, the highest level of cell proliferation is observed in the undifferentiated type 1 lobules (lob 1) of young nulliparous (NP) women.[10-13,18] The progressive differentiation of type 1 lobules into type 2 and 3 results in a concomitant reduction of mammary epithelial proliferative activity.[9-13] Further differentiation into type 4 lobules, characteristic of breast tissue during the end of pregnancy and during lactation, further lowers the rate of proliferation.

Our studies have also provided an understanding of the relationship between lobular differentiation, cell proliferation, and hormone responsiveness of the mammary epithelium. The ERa and PR content of the lobular structures is directly proportional to the rate of cell proliferation, both being maximal in the undifferentiated type 1 lobule and decreasing progressively in types 2, 3, and 4. The highest percentage of Ki67-positive cells occurs in type 1 lobules (Fig. 127.4 and Table 127.2), with a 3-fold lower percentage in type 2 lobules and a 10-fold decrement in type 3 lobules. Proliferating cells are found almost exclusively in epithelium-lining ducts and lobules, and occasional positive cells are found in the myoepithelium and the intra- and interlobular stroma. ER- and PR-positive cells are found exclusively in the epithelium, with type 1 lobules containing the highest number, decreasing progressively in type 2 and 3 lobules (see Fig. 127.4 and Table 127.2).

A double immunostaining technique for Ki67 and ER or PR has allowed quantitation in the same tissue sections of the spatial relationship between proliferating and receptor-positive cells. The percentages of ER- and PR-positive cells in type 1 lobules do not differ significantly

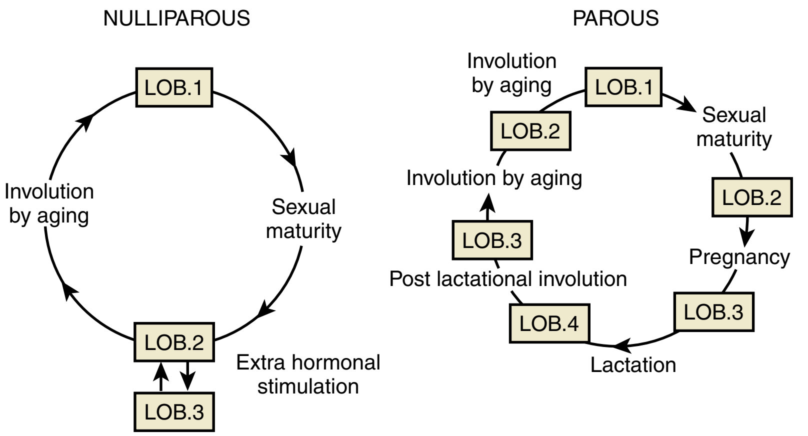

Fig. 127.3 Schematic representation of breast development based upon the relative percentage of lobules present. Nulliparous women's breasts contain primarily lobules type 1 (lob 1), with some progression to type 2 (lob 2) and only minimal formation of lobules type 3 (lob 3). Parous women undergo a complete cycle of development through the formation of lobules type 4 (lob 4), which later regress. (From Russo J, Rivera R, Russo IH. Influence of age and parity on the development of the human breast. *Breast Cancer Res Treat.* 1992;23:211–218.)

(7.5% and 5.7%, respectively, see Table 127.2). In type 2 lobules, they are reduced to 3.8% and 0.7%, respectively, and in type 3, they are negligible (see Table 127.2). Similar relative percentages of Ki67-, ER-, and PR-positive cells and the progressive decrease of positive cells have been observed as lobular differentiation progresses. However, cells positive for Ki67 are not the same as those that express ER or PR (see Fig. 127.4 and Table 127.2). Few cells (<0.5%) in type 1 lobules, and even fewer in type 2 and 3 lobules, are positive for both Ki67 and ER (Ki67+ER) (see Table 127.2). The percentage of cells exhibiting double labeling with Ki67 and PR antibodies (Ki67+PR) in type 1 lobules is lower than the percentage of double-labeled ER-positive cells (see Table 127.2).

KEY POINTS

- ER alpha and PR are key players in lobular differentiation, cell proliferation, and hormone responsiveness of the mammary epithelium.
- Evidence supports 3 types of mammary epithelial cells: ER+/Ki67+ that proliferate and are most abundant in type I lobules; ER+ that do not proliferate, and a few ER-/ Ki67+ cells.
- Growth factors likely produced by estrogen signaling through ERa can stimulate neighboring ER- cells to proliferate.
- ER- cells may convert to ER+ cells during neoplastic transformation.

That proliferating cells differ from those that are ER- and PR-positive supports an indirect mechanism for estrogen regulation of proliferation. A likely explanation is that estrogen acts on ER-positive cells, which respond to the increase in growth factors by acting in a paracrine fashion on neighboring ER-negative cells. This was confirmed by the finding that supernatants from estrogen-treated ER-positive cells stimulate the growth of ER-negative cell lines in culture and *in vivo* in nude mice bearing ER-negative breast tumor xenografts.[43,44] A paracrine mechanism can also explain inhibition of cellular proliferation. ER-positive cells treated with antiestrogens secrete transforming growth factor alpha, which inhibits proliferation of ER-negative cells.[29]

The findings that proliferative activity and the percent of ER- and PR-positive cells are highest in type 1 lobules compared with types 2 through 4 provide a mechanistic explanation for higher susceptibility of these structures to transformation by chemical carcinogens *in vitro*[45,46] and support the observations that type 1 lobules are the site of origin of ductal carcinomas.[47] However, the relationship between ER-positive and ER-negative breast cancers is not clear.[48-50] It has been suggested that ER-negative breast cancers may result from loss of the ability of cells to synthesize ER during clinical evolution of ER-positive cancers, or that ER-positive and ER-negative cancers may be different entities.[48,50] It is postulated that type 1 lobules contain at least three cell types: ER-positive cells that do not proliferate, ER-negative cells that are capable of proliferating, and a small proportion of ER-positive cells that can proliferate as well (Fig. 127.5). Therefore, estrogen may stimulate ER-positive cells to produce a growth factor that in turn stimulates neighboring ER-negative cells capable of proliferating (see Fig. 127.5). In the same fashion, the small proportion of ER-positive cells that can proliferate could be the source of ER-positive tumors. Also, conversion of ER-negative to ER-positive cells has been reported.[51,52] The presence of ERb opens the possibility that cells traditionally considered to be ERa-negative may be ERb-positive.[34,35] It has been found that ER is expressed during immortalization and transformation of ER-negative human breast epithelial cells, supporting the hypothesis of conversion from a negative to a positive receptor cell.[53]

Findings that proliferating cells in the human breast differ from those that contain steroid hormone receptors explain some *in vitro* data.[54-57] Notably, estrogen stimulates ER-positive MCF-7 cell proliferation, and enhanced expression of the receptor by transfection also increases the proliferative response.[54,58] However, when ER-negative cells such as MDA-MB 468 cells are transfected with ER, estrogen inhibits cell growth.[55-59] Although the negative effect of estrogen on ER-negative cells transfected with the receptor has been interpreted as an interference of the transcription factor used to maintain estrogen-independent growth,[58] no definitive explanation has been put forth for their lack of survival, although it can be explained by proliferating and ER-positive cells being two separate populations. Further support is provided by the finding that, when type 1 lobules of normal breast tissue are placed in culture, they lose their ER-positive cells, indicating that only proliferating cells that are also ER-negative can survive. It has been suggested that these constitute the stem cells.[59,60]

Although estrogens act through nuclear ERs that transcriptionally activate specific target genes, a membrane receptor coupled to alternative second messenger signaling mechanisms[61,62] is also operational and may stimulate a cascade of events leading to proliferation. This suggests that ERa-negative cells in the human breast may respond to estrogens through this or other pathways. It is clear that paracrine mechanisms are important in mediating cell proliferation. In the

Cells were quantitated in lobules type 1 (lob 1), type 2 (lob 2), and type 3 (lob 3) of the breast *(abscissa)*. Lob 1 ductules of the human breast. **A,** The single-layered epithelium lining the ductule contains Ki67-positive cells *(brown nuclei)* and ER-positive cells *(red-purple nuclei)* (×40). **B,** The single-layered epithelium lining the ductule contains brown Ki67-positive cells and red-purple PgR-positive cells. Sections were stained with 3,3′-diaminoben-zidine (DAB)/alkaline phosphatase-vector red, with light hematoxylin counterstain, and were photographed at ×40.

normal breast, proliferating and steroid hormone receptor–positive cells are different. This finding opens new possibilities to clarify the mechanisms through which estrogens may act on proliferating cells to initiate the cascade of events leading to cancer.

STEM CELLS IN THE NORMAL HUMAN BREAST AND THEIR IMPLICATIONS IN BREAST CANCER

Stem cells in adult structures are defined by their ability to self-renew *and* generate differentiated progeny. In the mammary gland, DeOme et al.[63] demonstrated that fragments of different parenchymal portions were able to generate fully functional mammary outgrowths in mice, forming ductal and lobuloalveolar structures composed of epithelial and myoepithelial cells. This concept was further developed by Kordon and Smith,[64] who demonstrated that the progeny from a single cell could comprise the epithelial population of a fully developed lactating mammary outgrowth in mice. Thus, development of the complete mammary tree from a small portion of a duct or from single cells attests to their multifaceted potential. However, it was not known whether these progenitor/stem cells would be capable of initiating cancer when

TABLE 127.2 Distribution of Ki67-, Estrogen Receptor (ER)–, and Progesterone Receptor (PR)–Positive Cells in the Lobular Structures of the Human Breast

Lobule Type	No. of Cells	Ki67	ER	PR	Ki67+ER	Ki67+PR
Lob l	19,339[a]	4.72 ± 1.00[de]	7.46 ± 2.88[h]	5.70 ± 1.36[k]	0.48 ± –0.28[n]	0.09 ± 0.01[o]
Lob 2	8490[b]	1.58 ± –0.45[f]	3.83 ± 2.44[i]	0.73 ± –0.57[l]	0.31 ± –0.21	0.28 ± –0.27
Lob 3	l7,750[c]	0.40 ± 0.18[g]	0.76 ± –0.04	0.09 ± 0.04[m]	0.01 ± 0.01	0.01 ± 0.01

[a] Total number of cells counted in lobules type 1 (lob l) in breast tissue samples from 12 donors.
[b] Total number of cells counted in lobules type 2 (lob 2) in breast tissue samples from five donors.
[c] Total number of cells counted in lobules type 3 (lob 3) in breast tissue samples of from three donors.
[d] Proliferative activity determined by the percentage of Ki67-positive cells, expressed as the mean ± standard deviation. Differences were significant in [e]lob 1 vs. [f]lob 2 (t = 1.98; $P < .05$), [f]lob 2 vs. [g]lob3 (t = 2.27; $P < .04$), and [e]lob 1 vs. [g]lob 3 (t = 2.56; $P < .01$).
ER-positive cells were significantly different in [h]lob 1 vs. [i]lob 2 (t = 2.04; $P < .05$) and [i]lob 3 (t = 4.03; $P < .001$).
PR-positive cells were significantly different in [k]lob 1 vs. [l]lob 2 (t = 2.27; $P < .05$) and [k]lob 1 vs. [m]lob 3 (t = 2.60; $P < .031$).
[n] Percentage of cells positive for both Ki67 and ER, expressed as the mean ± standard deviation.
[o] Percentage of cells positive for both Ki67 and PR, expressed as the mean ± standard deviation.

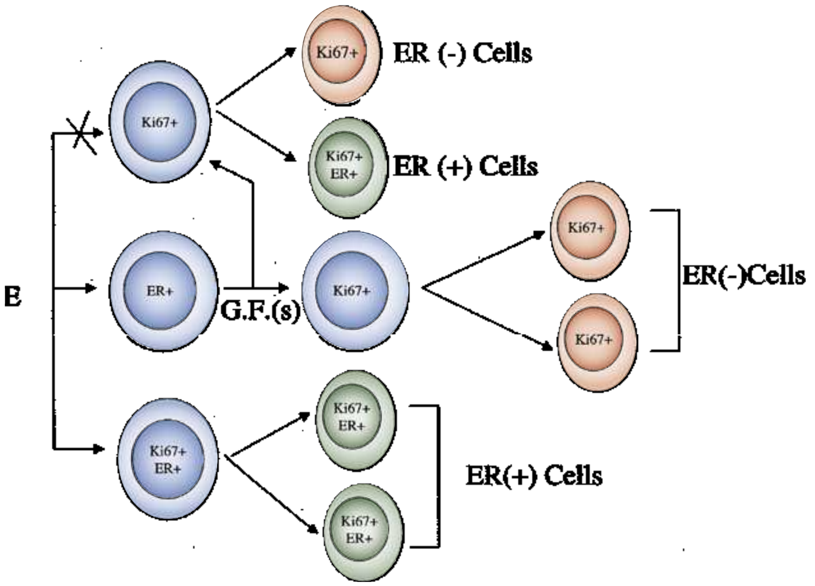

Fig. 127.5 Schematic representation of the postulated pathways of estrogen actions on breast epithelial cells. Cells expressing three different phenotypes might be present in the epithelium: estrogen receptor (*ER*)-negative Ki67-positive cells that are capable of proliferating, ER-positive cells that do not proliferate, and a small proportion of ER- and Ki67-positive cells. Estrogen may stimulate ER-positive cells to produce a growth factor that in turn stimulates neighboring ER-negative cells capable of proliferating. ER+Ki67–positive cells can proliferate and could be stimulated by estrogen to originate ER-positive daughter cells and probably tumors. ER-negative cells may convert to ER-positive cells during neoplastic transformation.

exposed to a carcinogenic agent. This issue was addressed by Russo and coworkers,[65-67] who demonstrated that cancer started in TEBs present in the mammary gland of young virgin rats. Analysis of these structures by electron microscopy allowed characterization of their cellular composition based on cell and nuclear size, nuclear-cytoplasmic ratio, amount of chromatin condensation, electron density of the cytoplasm, organelle number and distribution, and presence or absence of magnesium- and sodium/potassium-dependent ATPases. Based upon these criteria, in addition to myoepithelial cells, three types of epithelial cells were identified: light, intermediate, and dark.[66,67] Dark cells were the predominant type in TEBs; intermediate and myoepithelial cells were present in significantly lower percentages; and light cells were only occasionally seen. Analysis of the DNA labeling index revealed that all cell types proliferated, although at different rates, depending on their location within the mammary gland tree. Cell proliferation was maximal in intermediate cells located in TEBs and was significantly lower in dark and myoepithelial cells in the same location. High proliferation was associated with greater incorporation of 7,12-dimethylbenz(alpha) anthracene (DMBA) and a progressive dominance of intermediate cells in DMBA-induced intraductal proliferations and in ductal carcinomas.[8,67] These results indicated that intermediate cells were not only the targets of the carcinogen but also the stem cells of mammary carcinomas. Further work by Bennett et al.[68] demonstrated that intermediate cells isolated from DMBA-induced mammary tumors resulted in two cell types in culture: the dark cell, representing a terminally differentiated cell or a class in transition to differentiation, and intermediate cells, which could represent an undifferentiated, or stem, cell, a progenitor of dark and myoepithelial cells. Rudland and coworkers[69] isolated and characterized, from the normal rat mammary gland and from DMBA-induced mammary adenocarcinomas, epithelial cells that were cuboidal and gave rise to a mixture of cuboidal and spindle-shaped cells resembling fibroblasts. In confluent cultures, cuboidal cells acquired the morphology of a third type of cell, which was dark, polygonal, and with many small vacuoles, resembling dark cells ultrastructurally described by Russo et al.[67] Chepko and Smith[70] differentiated division-competent cell populations in murine mammary epithelium, including a subset of "large light cells" that were structurally and functionally compatible with early stages of secretory differentiation and "small light cells" that were the least differentiated, suggesting that large light cells were a direct precursor to terminally differentiated secretory and myoepithelial cells. These results confirmed Russo's work.[67]

A shift from the pioneering studies characterizing progenitor/stem cells by morphology and *in vitro* behavior began with the search for immunocytochemical and genomic markers.[71] Expression of keratins 6 and 14 defined subsets of morphologically distinct luminal mammary epithelial cells with kinetic properties expected for latent mammogenic stem cells. Keratin 6 was confined to a few mammary epithelial cells, the growing end buds, and the luminal epithelium, whereas keratin 14 was expressed in basally located fusiform cells such as the myoepithelial cells.[71] The authors emphasized the usefulness of these markers in identifying mammary epithelium–specific primordial cells. Stingl et al.[72,73] used new molecular markers to select subpopulations of cells with distinct differentiation potential. They described bipotent human mammary epithelial progenitor cells based on the expression of epithelial-specific antigen (ESA), sialomucin 1 (MUC1), common acute lymphoblast antigen (CALLA/CD10,) and a-integrin, in combination with exclusion of rhodamine dye. Hebbard et al.[74] observed that CD44, a member of the family of cell surface proteins that is expressed in breast carcinomas, is also expressed in normal mammary gland. In rodents, CD44 expression is first detected at puberty, and thereafter is regulated by the estrous cycle, disappears during lactation, and reappears during involution, suggesting that it is a stem cell marker. Novel studies in mouse mammary gland[75] have identified stem cells in TEBs and ducts by pulse-labeling HC-11 primary mammary epithelial cells with fluorescent TRITC-cell linker membrane label and BrdU. The cells were then transplanted into cleared juvenile syngenic mammary fat pads, where they were identified as long-lived, label-retaining mammary epithelial cells (LRCs) in mammary ducts that were actively growing or static. This study demonstrated that LRCs are stem cells, that their progeny (transitional cells) are arranged as transitional units (TUs), and that both express Zonula Occludens-1 and a-catenin, suggesting that TUs retain stem cells.

The study of markers for other stem cells has been useful in identifying mammary stem/progenitor cells. Sca1 (stem cell antigen 1), a hematopoietic stem cell antigen,[76] is expressed in mouse breast luminal epithelium enriched for functional stem/progenitor cells. These cells are BrdU label–retaining, lack expression of differentiation markers, and are PR-negative. The Sca1-positive population also exhibits "side population" (SP) properties, and it has been proposed that breast cancer resistance protein 1 (BCRP1) is responsible for this phenotype and may serve as a marker for stem cells from various sources.[77,78] Mammary epithelial cells with SP properties were also identified in human mammary gland. Alvi et al.[79] showed that 0.2% to 0.45% of both human and mouse epithelia were formed by distinct SP cells. These cells generated ductal and lobuloalveolar structures when transplanted into murine cleared mammary fat pads. The SP cells highly expressed BCRP1, Sca1, telomerase catalytic subunit, and low levels of differentiated markers for luminal (epithelial membrane antigen and cytokeratin 19) and myoepithelial cell types (cytokeratin 14). These cells were detected in all human breast samples studied, but their presence was not correlated with age, parity, contraceptive use, or day of menstrual cycle.

Further studies identified new markers that may be specific for human stem/progenitor cells. Gudjonsson et al.[80] isolated a cell line derived from human mammary cells expressing ESA and lacking MUC1 expression that gave rise to luminal epithelial and myoepithelial cells in culture. One ESA+/MUC1– cell generated a terminal ductal-lobular unit-like structure in basement membrane gel, similar to that formed when the cell line was implanted in mice. In contrast, an ESA+/MUC1+ subpopulation was differentiated and luminal epithelial–restricted, without stem cell properties. Dontu and coworkers[81] enriched the population of human mammary progenitor/stem cells by culturing them in suspension where they formed "nonadherent mammospheres." These structures differentiated along all three mammary epithelial lineages and clonally generated complex functional structures in three-dimensional culture systems. Cytological and immunocytochemical analysis of secondary mammospheres revealed they contained cells positive for a6 integrin, cytokeratin 5, and CD10; ESA-positive and cytokeratin 14–positive cells were less frequent. Muc1, a-smooth muscle actin, and cytokeratin 18 were not detected. In addition to cells, mammospheres contained extracellular material (ECM). However, immunostains for fibronectin and collagen IV, classical components of adult gland ECM, were negative, although approximately 20% of the mammospheres stained positive for laminin. In contrast, abundant expression of the embryonic ECM components tenascin and decorin was detected in mammospheres.[81] Moreover, comparing genomic profiles of undifferentiated cells from mammospheres with differentiated cells cultured on collagen revealed genes candidates for stem/progenitor cell markers. Some of these were already described in stem/progenitor cell–specific functions or regulation of self renewal, and abnormal expression of some has been correlated with breast cancer development, including proliferation, cell survival, and invasion. Other studies showed that the null mutation of the peroxisome proliferator-activated receptor-binding protein (PBP) resulted in defective mammary gland development and inability of mammary epithelial cells to form mammospheres, suggesting a role of PBP in the survival of mammary stem cells or in mammosphere formation.[82]

Genomic Signatures of Breast Changes After the First Full-Term Pregnancy in Premenopausal Women

Recently, we reported parity-associated gene expression differences in the breast of premenopausal women.[83] Because the breast undergoes involution after full-term pregnancy (FTP) (see Fig. 127.3), we examined gene expression in P versus NP women as a function of time since last FTP. Women ($n = 109$ [$n = 30$ NP, $n = 79$P]), 29 to 47 years old, were recruited.[83] Forty-three genes were differentially expressed (40 up- and three downregulated) between P and NP women.[83] Analyses of gene expression according to the time since last pregnancy (TSLP) identified 286 genes differentially expressed between P and NP samples (Fig. 127.6). Three expression patterns as a function of TSLP were noted (Fig. 127.7). The first consisted of 83 genes upregulated following the last FTP, but whose expression progressively returned to the level of expression observed in NP women (see Fig. 127.7A); these were named "transient" genes. The second cluster consisted of genes for which P–NP differences were highest for women with less than 5 years since last FTP, decreased with increasing TSLP, and remained elevated versus NP women. The 95 genes in this cluster were called "long-term changing" (see Fig. 127.7B). The third cluster included 60 genes whose fold changes between P and NP were constant, regardless of the TSLP. These were called "long-term constant" genes (see Fig. 127.7C).

Gene Ontology (GO) enrichment analyses showed an abundance of terms associated with developmental processes or immune response (Fig. 127.8), with less enrichment related to proliferation, intracellular transport, and cell death. Among the genes whose expression was transiently affected by parity, 55% were related to immune response. Among "long-term changing" genes, 32% were related to immune response (e.g., CD2), and 24% were involved in developmental processes. Notably, of the "long-term constant" genes, 56% were related to developmental/differentiation processes. These data indicate that the proportion of genes involved in immune response decreases among the genes that are upregulated irrespective of TSLP, while the proportion of genes related to developmental processes increases (chi-squared $P < .001$). Evaluation of

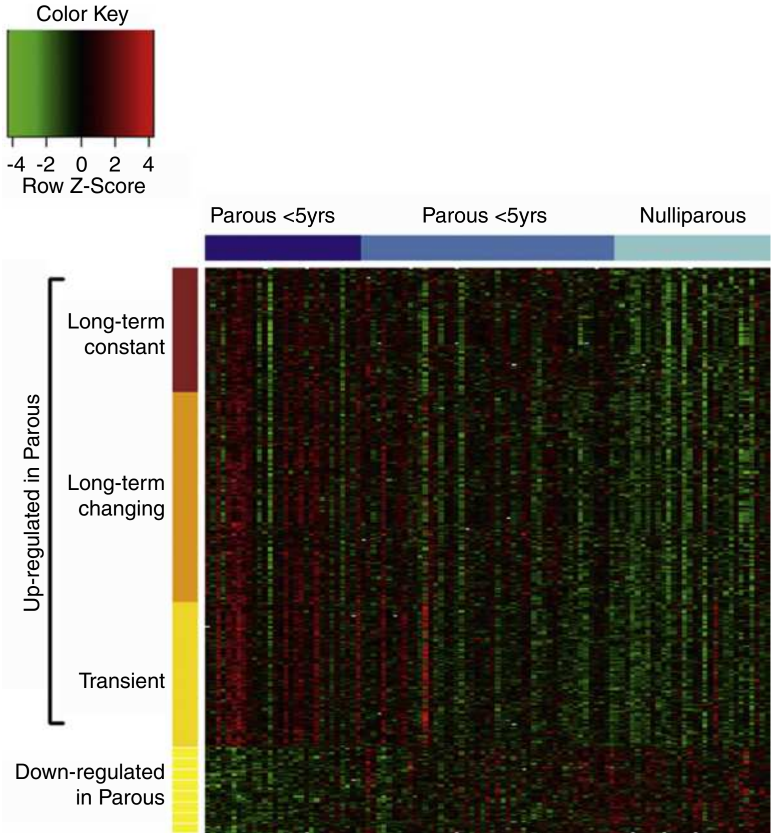

Fig. 127.6 Heatmap of all 416 probesets found differentially expressed between parous and nulliparous women. Each column represents a volunteer. Dark blue represents parous women within 5 years since last full-term pregnancy, blue represents parous women with more than 5 years since pregnancy, and cyan represents nulliparous women. Each line corresponds to a probeset, which, according to its pattern of expression within the parous breast samples compared with nulliparous, was classified as downregulated *(light yellow)*, transiently upregulated *(yellow)*, long-term changing *(orange)*, and long-term constant upregulated *(brown)*. (From Santucci-Pereira J, Zeleniuch-Jacquotte A, Afanasyeva Y, et al. Genomic signature of parity in the breast of premenopausal women. *Breast Cancer Res*. 2019;21:46.)

the canonical pathways represented by the differentially expressed genes also showed that pathways involved in signaling and activation of T-cells were enriched by both transient and long-term genes (Fig. 127.9.[83]

The 48 genes downregulated in the P breast fell into two patterns. Twenty-two genes, including *WIF1, EDN1, CXCL1*, and *FOXQ1*, were downregulated in the P breast and remained low compared with NP breast, irrespective of years since last FTP. The remaining 26 genes were downregulated in women with TSLP less than 5 years; however, expression increased, reaching similar or higher levels than in NP women, as TSLP increased. Limited numbers precluded conducting a GO enrichment analysis.[83]

We also analyzed 11 selected genes from our dataset in 5796 patients with breast cancer available in cBioPortal (www.cbioportal.org). One or more of these genes were altered in 770 (13%) breast cancer patients. *BHLHE22* was altered in the largest percentage of patients (6.9%); the GO alterations included amplification, deep deletion, and missense mutations. The other ten genes were altered in 1.5% or less of patients. An overall Kaplan–Meier survival curve generated to compare patients with versus without these 11 altered genes revealed shorter overall survival in the former group (median 143.13 vs. 168.3 months; logrank test $P = 9.09e{-}5$ (Fig. 127.10).

Gene expression was confirmed by reverse transcription polymerase chain reaction (RT-PCR) in a subset of 37 samples (20 P and 17 NP) of the NP versus P study.[83] Also, immunohistochemical (IHC) analyses validated protein expression of some genes in the microarray and RT-PCR analyses. Markers for dendritic cells, important in antigen presentation for T-cell activation and T-cell activation markers *per se*, were studied. CD123 and LAMP3 were detected in a few cells, with no differences between P and NP. CD2 and CD3D, markers of T-cell activation (Fig. 127.11), were expressed at low levels in both groups, with a slight, nonsignificant increase in the percent of CD2-positive cells in P women (1.6 fold; P median = 0.59%, NP median = 0.31%; $P = .156$). The overall percentage of CD3D-positive cells was higher (0.6%–9.4%), with a statistically significant 2-fold increase in the percent of CD3D-positive cells in the P breast (P median = 3.28%, NP median = 1.62%, $P = .006$) (see Fig. 127.11). Comparison of CD2- and CD3D-positive cells between P women with TSLP of 5 or less and greater than 5 revealed a slightly larger number in TSLP of 5 or less, but this was not statistically significant (CD2 $P = .16$, CD3D $P = .09$).

KEY POINTS

- Gene expression differences in the parous (P) and nonparous (NP) breast revealed 43 differentially expressed genes.[83] Evaluation of expression differences between NP and P as a function of time since last pregnancy identified 238 up- and 48 downregulated genes in the P breast. Downregulated genes fell into two patterns (transient and long-term), while upregulated genes fell into three patterns (transient, long-term changing, and long-term constant). Through Gene Ontology enrichment analyses, genes whose expression was transiently increased after pregnancy were mainly related to immune response. Long-term changing genes included immune- and development-related genes, while genes categorized as long-term constant were mainly involved in cell differentiation and developmental processes.

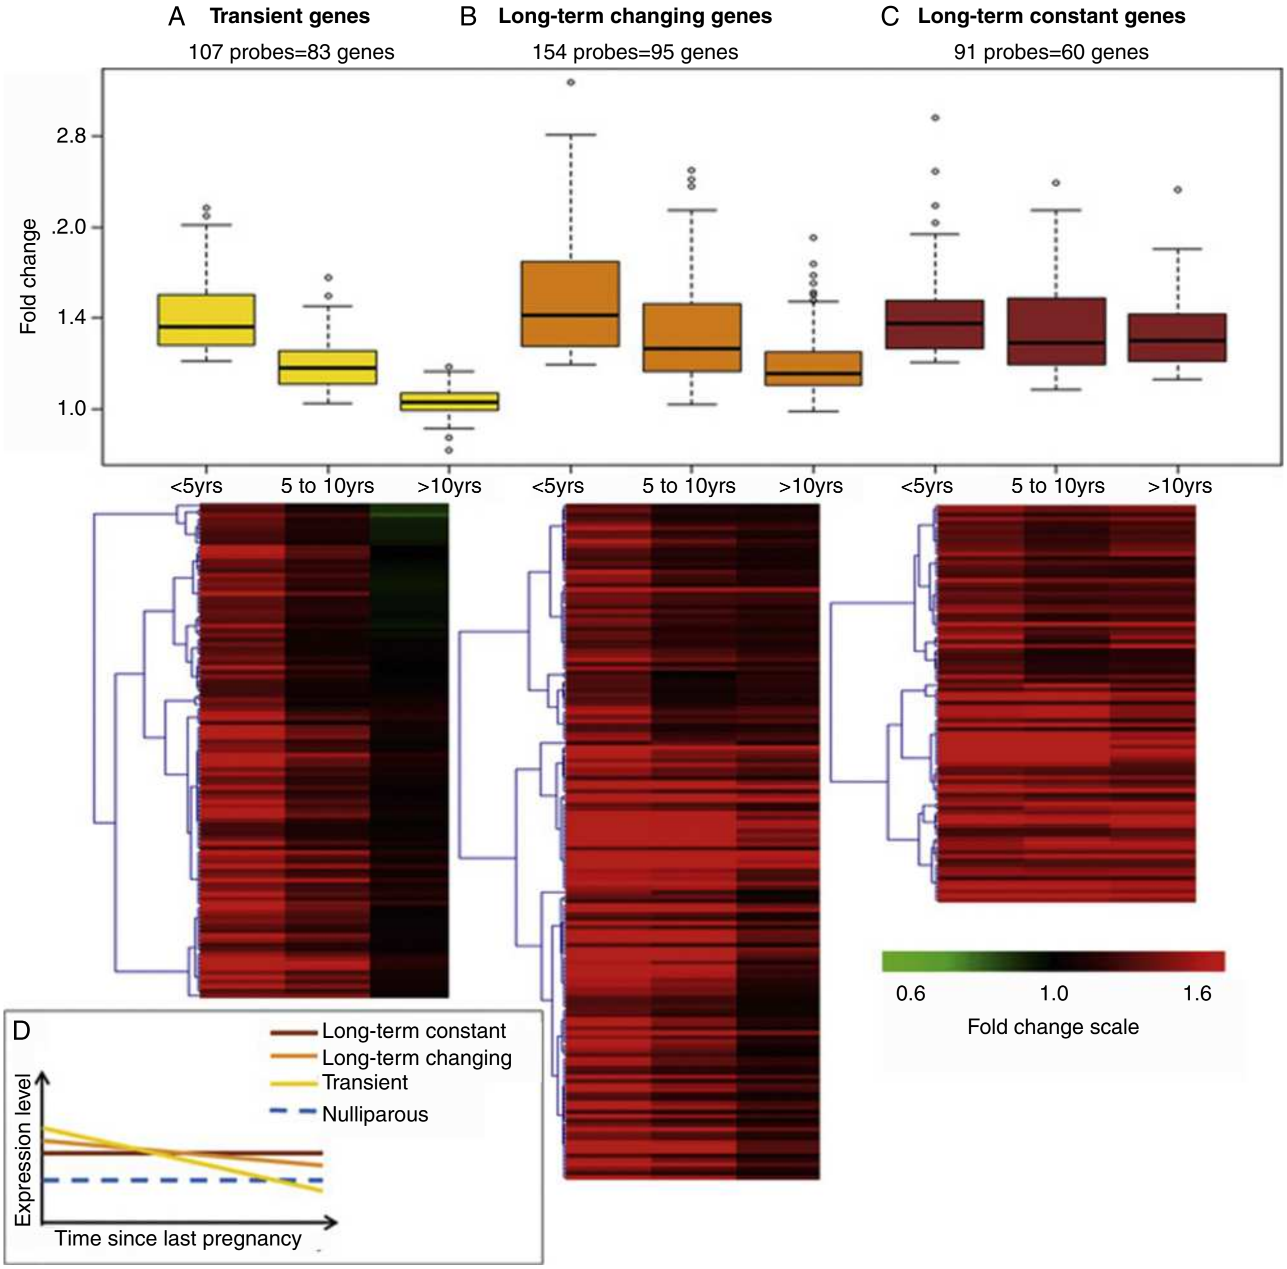

Fig. 127.7 Three expression patterns were identified among the upregulated genes. In the top, the graph shows the fold change ranges of each cluster: **A,** transient; **B,** long-term changing; and **C,** long-term constant, according to time since last full-term pregnancy (<5 years, 5–10 years, and >10 years). Heatmaps show the expression patterns of each cluster. **D,** Schematic representation of the expression levels of each cluster in function of time since last pregnancy. (From Santucci-Pereira J, Zeleniuch-Jacquotte A, Afanasyeva Y, et al. Genomic signature of parity in the breast of premenopausal women. *Breast Cancer Res.* 2019;21:46.)

THE MENOPAUSAL BREAST

Menopause occurs at an average age of 51 years, when the ovaries stop synthesizing E2 and amenorrhea ensues, and the years leading up to the final menstrual period constitute the perimenopause, wherein irregular ovulation is common (see Chapter 122). After menopause, the breast regresses in both NP and P women.[10] This involutionary process is manifested by an increase in the number of type 1 lobules and a concomitant decline in type 2 and type 3 lobules. At the end of the fifth decade of life, the breasts of both NP and P women contain predominantly type 1 lobules (see Fig. 127.3). Understanding breast development requires a longitudinal timeline in which all the phases of growth are considered, as analysis of breast structures at a single point (e.g., age 50 years) may lead to the conclusion that breasts of NP and P women are identical (see Fig. 127.3). From a quantitative perspective, however, breast regression at menopause differs in NP and P women. The predominant structure in NP breasts is the type 1 lobule (65%–80% of the total number of lobule-type components), independent of age. Type 2 lobules represent 10% to 35%, and type 3, 0% to 5%. In breasts of premenopausal P women, however, the type 3 lobule comprises 70% to 90% of the total lobule component. At menopause, type 3 lobules have declined, and the relative proportions of the three lobule types are similar to those in NP women. These observations led us to conclude that early P women undergo lobule differentiation, which was evident at a younger age; whereas NP women seldom reached the lobule type 3 stage and never reached the lobule type 4 stage (see Fig. 127.3).

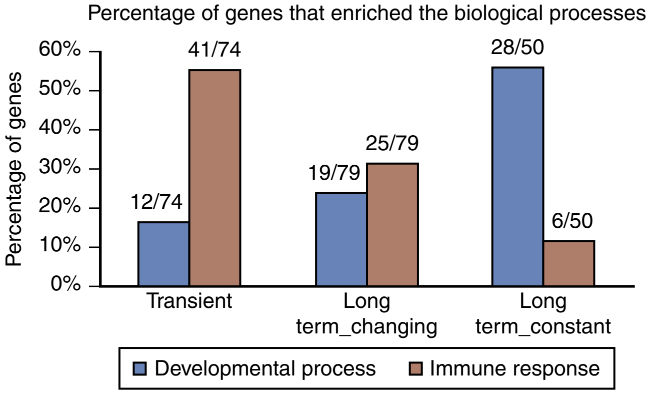

Fig. 127.8 Graph shows the percentage of genes associated with Gene Ontology (GO) terms related to developmental processes *(red)* and immune response *(blue)* for each of the three clusters. The values 74, 79, and 50 are the total number of genes associated at least with one GO term for each cluster. (From Santucci-Pereira J, Zeleniuch-Jacquotte A, Afanasyeva Y, et al. Genomic signature of parity in the breast of premenopausal women. *Breast Cancer Res*. 2019;21:46.)

Notably, beyond morphology, accumulating genomic evidence (see later) suggests that prior pregnancy can permanently alter breast biology, not morphologically identifiable, and predispose to neoplastic development.

Genomic Differences in Nulliparous and Parous Breasts at Menopause

KEY POINTS

- Premenopausal and menopausal breast transcriptomic signatures differ from one another.
- Genomic signatures are distinct in the premenopausal breast after first full-term pregnancy compared with nulliparous women
- Pregnancy history (parity and nulliparity) profoundly affects these signatures at menopause, which is related to breast cancer risk.

An early first FTP imprints a specific transcriptomic signature in involuted breast lobules of postmenopausal P women free of breast cancer that significantly differs from P women with cancer and NP women with or without the disease. cDNA microarray analysis of epithelial RNA of completely involuted lobules (lob 1), obtained by laser capture microdissection, revealed that these cells express a signature that comprises 232 deregulated genes, representing 18 functional categories. Compared with gene expression in NP control and case groups and P case groups, the P control group had 126 genes upregulated, verified by RT-PCR. In all, 103 genes were downregulated.[84] Unsupervised hierarchical clustering using expression profiles of 2541 globally varying genes across the NP and P data sets revealed that samples clustered primarily on the basis of parity status. This observation suggested that parity-induced gene expression changes conserved among these highly divergent groups could represent a powerful approach to define parity- and cancer risk–related gene expression signatures. Results of clustering the combined dataset indicate that combined parity and absence of breast cancer generated a distinct transcriptomic profile that differed versus the breast cancer groups, irrespective of parity, and from the NP cancer-free group, which has been identified traditionally as a high-risk group.[84]

We measured the relevance of GO terms in the breast epithelium of P women and analyzed the biological significance of those terms found to be deregulated in response to an early reproductive event.[84] Among the 18 categories identified to contain deregulated genes, the most highly represented and statistically significant biological process was gene transcription, in which 21 genes (64%) were upregulated, and 12 genes (36%) were downregulated. Higher gene expression was observed in 11 processes that included proteolysis and ubiquitination, cell adhesion, response to exogenous agents, metabolism, DNA repair and replication, RNA processing, apoptosis, miscellaneous processes, antiapoptosis, and chromatin modification, in which the ratios of upregulated to downregulated genes ranged from 1.75 to 11.[84]

Numerous genes with low expression were observed in seven processes: cell transport, protein biosynthesis and metabolism, cell signaling–signal transduction, biological process unknown, and biological process and molecular function unknown.[84] Among genes significantly upregulated in the P breast epithelium, 23 belonged to the categories of transcription and chromatin modification—an indication that modifications in epigenetic and transcriptional activity during pregnancy play an important role in and become a permanent component of the genomic signature imprinted by this physiologic process in the postmenopausal breast epithelium. Altogether, an early first FTP induces in the breast epithelium a specific genomic profile in the postmenopausal breast, indicating that these epithelial cells differ from those in NP women and P women with breast cancer. This signature allowed us to evaluate at a genomic level the degree of mammary gland differentiation induced by pregnancy. We postulate that it identifies Stem Cell 2,[85-88] can predict in which women parity has been protective and could be used as an intermediate surrogate biomarker to evaluate preventive strategies. Data obtained to date support our working hypothesis that the lifetime reduction in breast cancer incidence conferred by an early pregnancy is the result of complete differentiation of the breast. This process leads to the replacement of Stem Cell 1, which is a component of the lob 1 present in the NP breast and is the site of origin of ductal breast carcinoma by Stem Cell 2, which is characterized by a specific genomic signature.[86-89] It is important to emphasize that, even though differentiation significantly reduces cell proliferation in the mammary gland, the mammary parenchyma that has regressed after delivery and weaning remains capable of responding with proliferation to given stimuli, such as a new pregnancy. Stem Cell 2 is hypothesized to fulfill these characteristics, because it has been primed by the first cycle of differentiation and thus is able to metabolize carcinogens and repair DNA damage more efficiently than Stem Cell 1 of the NP gland, and therefore is less susceptible to carcinogenesis. However, if the shift from Stem Cell 1 to Stem Cell 2 has not been completed before a carcinogenic stimulus affects the breast, a neoplastic process could be initiated successfully. This may explain cases in which breast cancer develops in spite of the history of early pregnancy, which could be represented by the P cases in our study.[84] The greater breast cancer risk associated with late pregnancy, especially that occurring after 30 years of age, may result from an accumulation of genetic or epigenetic damage during the broadened “high susceptibility” or “high-risk” window noted between menarche and first FTP, as demonstrated in experimental animal models.[80]

Defining the Genomic Signature of Breast Cancer Prevention in Parous Women

More than 300 years have elapsed since a striking excess in breast cancer mortality was reported in nuns, in whom the increased risk was attributed to their childlessness[90] until MacMahon et al.,[91] in a landmark case-control study, found an almost linear relationship between a woman’s risk and the age at which she bore her first child. Numerous studies have examined how dramatic modifications that occur during pregnancy in the pattern of lobular development and differentiation, cell proliferation, and steroid hormone receptor content of the breast[92] influence cancer risk. Global genome-wide analyses, using different platforms, have confirmed the universality of this phenomenon in various strains of rats and mice.[92-97] We recently performed cDNA array

analyses of breast core biopsies of postmenopausal NP and P women[84,98-99] and identified 305 differentially expressed probe sets (208 genes) between P and NP women. Of these, 267 were upregulated, and 38 were downregulated. GO enrichment analysis revealed biological processes including RNA metabolic processes, differentiation and development of epidermis and ectoderm, and cell-substrate junction assembly, in agreement with pregnancy hormone–induced differentiation of mammary epithelial cells.[100] We found that genes pivotal to anchoring epithelial cells to the basement membrane, hemidesmosome, and cell-substrate junction assembly, such as *KRT5, LAMA3,* and *LAMC2*, were upregulated in the P group.

Among the downregulated genes, *IGF-1* was enriched in 19 biological processes that comprised cell proliferation, regulation of IGF-like growth factor receptor signaling, somatic stem cell maintenance, muscle cell differentiation, and apoptosis, among others.[98]

We used gene set enrichment analysis to compare differentially expressed genes from this study of 3717 curated gene sets of specific pathways, processes, and profiles from previous profiling experiments obtained through MsigDB.[100] Pathways enriched in upregulated genes included breast cancer estrogen signaling, cell communication, and mRNA processing.[99] The breast cancer estrogen signaling pathway encompassed a set of genes dysregulated in ER-dependent breast

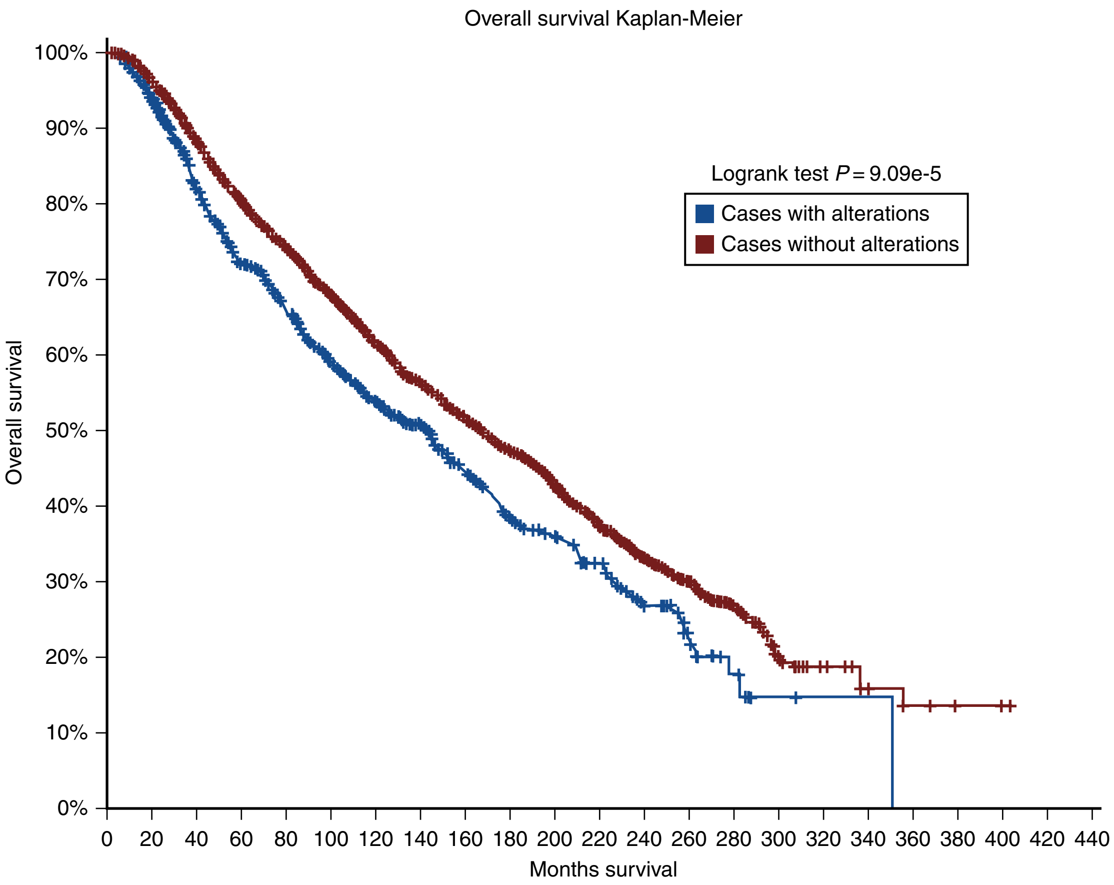

Fig. 127.10 Analyses of the parous differentially expressed genes in breast cancer patients. Genes that were selected for real-time polymerase chain reaction validation were also used for evaluation of breast cancer patients using the cBioPortal tool (http://www.cbioportal.org/). Overall Kaplan–Meier survival curve comparing cases with and without alterations in these genes. Patients who carried alterations had a median of 143.13 months' overall survival, while patients without alteration in these genes had median overall survival of 168.3 months (logrank test $P = 9.09e{-5}$). (From Santucci-Pereira J, Zeleniuch-Jacquotte A, Afanasyeva Y, et al. Genomic signature of parity in the breast of premenopausal women. *Breast Cancer Res.* 2019;21:46.)

cancers. Among these were *SCGB2A1, SCGB2A2, GATA3, TP53, TFF1, STC2, SerpinB5,* and *SerpinA3*. Because FTP involves influx of several hormones, including estrogens, we postulated that several downstream targets of estrogen would be coregulated in P subjects. Other pathways enriched by upregulated genes were cell communication and the mRNA processing reactome.[99] Among key pathways enriched by downregulated genes, the most significant were insulin signaling, MAPK, cytokine-cytokine receptor interaction, and Wnt signaling.[98,99] Using RT-PCR we validated numerous genes ($P < .05$) upregulated in P women, including *CCNL2*. IHC confirmed expression and localization of *CCNL2* in NP and P breasts,[99] with CCNL2 protein significantly overexpressed in the nucleus of epithelial cells of type 1 lobules of the P breast compared with similar structures in the breast of NP women. These observations confirm the localization of this protein in the splicing factor compartment (nuclear speckles).[101,102]

The main components of the spliceosome machinery, including RNA and proteins that undergo dynamic changes during the splicing reaction, were upregulated in the P breast. Among them were the heterogeneous nuclear ribonucleoproteins (HNRPs) that include HNRPA3, HNRPA2B1, HNRPD, and HNRPU,[103] which are implicated in the regulation of mRNA stability, as well as other functions, such as mammary gland involution,[104] negative regulation of telomere length maintenance,[105] and regulation of mRNA trafficking from the nucleus to distal processes in neural cells.[106] Although further studies are needed to define their precise functional roles in the postmenopausal breast, we postulate they play an important function as transcriptional regulators. In addition, posttranscriptional methylation of internal adenosine residues in eukaryotic mRNAs by methyltransferase like 3, which is upregulated in the P breast, could play a role in the efficiency of mRNA splicing, transport, or translation in the differentiated breast epithelium. Other members of the spliceosome complex are the proteins encoded by the genes *SF3B1, SFRS2, SFRS7, SFRS8, SFRS14, SFRS16, SNRP70, SNRPB, SNRPA1, PRF3*, and *PHF5A*, all of which are overexpressed in the P breast. In the case of the small nuclear ribonucleoproteins, there is evidence they suppress tumor cell growth and may have major implications as cancer therapeutic targets. Pre-mRNA splicing factors are enriched in nuclear domains termed interchromatin granule clusters or nuclear speckles. *CCNL1* and *CCNL2* are upregulated in the P breast, and the CCNL2 protein is also overexpressed in the nucleus of breast epithelial cells, as described earlier. CCNL1 and CCNL2 are transcriptional regulators[25-28] that modulate the expression of critical factors leading to cell apoptosis through the Wnt signal transduction pathway,[107-109] which is enriched by downregulated genes in the P breast. In our previously published preclinical and clinical studies,[39,99,110] we reported that pregnancy confers protection from breast cancer development by inducing gland differentiation, which imprints a specific and permanent genomic signature in this organ. A similar phenomenon was demonstrated in the involuted breast of postmenopausal P women.[100] We previously reported a small case-control study of transcriptomic analysis of normal breast tissues obtained from P and

NP women free of breast pathology and P and NP women with history of breast cancer that served as controls and cases, respectively.[84] To investigate commonality between the previous case-control and the subsequent study, we applied GO enrichment analysis to the gene lists generated from both studies and found that processes involved in RNA metabolism and RNA processing were similar in both studies.[99]

A number of noncoding RNAs, including XIST, MALAT-1 (NEAT2), and NEAT1, were upregulated in the P breast. Upregulation of XIST occurs upon cell differentiation, whereas failure to express XIST is seen in malignancies and in early embryogenesis.[111] Our findings are supported by recent reports suggesting that XIST is expressed in well-differentiated adult cells to maintain gene repression.[111-115]

Oxytocin, a neurotransmitter that acts through its specific receptor OXTR and is overexpressed during lactation, upregulates expression of MALAT-1, a highly conserved noncoding RNA.[116,117] Interestingly, both MALAT1 and OXTR remain overexpressed in the breast of postmenopausal P women. NEAT1 and NEAT2 localize to the periphery and to the interior of the spliceosome assembly factor SC35 domains or speckles. Our observation that, in breast epithelial cells, CCNL2 is highly enriched in nuclear speckles, indicates that CCNL2 may colocalize with NEAT1 and NEAT2. Downregulation of NEAT1, NEAT2, and XIST in the breast of NP women, in whom this organ never reaches a stage of complete differentiation similar to that achieved after completion of pregnancy and lactation, suggests that the undifferentiated breast is not actively involved in the RNA metabolism that is necessary for maintaining a state of differentiation.

Several genes directly or indirectly regulated by ER were up- or downregulated in the P breast and were enriched in the breast cancer estrogen signaling gene set. Among them, *GATA3*, an important component of this set, is crucial to mammary gland morphogenesis and differentiation of progenitor cells. GATA3 has been suggested to be a tumor suppressor,[118] a fact that is supported by observations that induction of its expression in *GATA3*-negative undifferentiated carcinoma cells is sufficient to induce tumor differentiation and inhibition of tumor dissemination.[118-121] Downregulation of RAS, dexamethasone-induced 1 (RASD1), a potential miR-375 target that negatively regulates ERa expression in breast cancer,[122] further confirms that the genes involved in the ER-regulated pathways could be under permanent transcriptional modification as a manifestation of a higher degree of cell differentiation of the P breast, in spite of the lack of transcriptomic differences in this receptor's levels between P and NP breast tissues.

Cell communication, a key element in cell and organ differentiation, is well represented in the breast of P women. The P breast exhibits upregulation of desmocollin (DSC3), a calcium-dependent glycoprotein that is a member of the desmocollin subfamily of the cadherin superfamily. These members of the desmosomal family, along with the desmogleins, are found primarily in epithelial cells, where they constitute the adhesive proteins of the desmosome cell-cell junction and are required for cell adhesion and desmosome formation. In addition, upregulation of matrix Gla proteins (MGP), laminins (LAMA3 and LAMC2), and keratin 5 (KRT5) in the P breast is an indication that they reflect a greater differentiated state of the breast epithelial cells. This concept is supported by the observation that the loss of MGP expression is associated with tumor progression and metastasis.[123,124]

Our findings that IGF-1 is downregulated in the P breast are consistent with published data reporting overall lower levels of IGF-1 in P than in NP women[125] and support the association of IGF-1 with increased breast cancer risk.[126] It is known that IGF-1 stimulates mitosis and inhibits apoptosis, playing a significant role in signaling pathways involved in the pathogenesis of breast cancer. Downregulation of IGF-1 in the P breast, in association with the significant downregulation of SOX6, early B-cell factor 1 (EBF1), ABHD5, RASD1, and RALGAPA2, could represent a significant driving force in the reduction of breast cancer risk conferred by pregnancy.

Chromatin Remodeling and Prevention of Human Breast Cancer

We have demonstrated, using detailed histological, cytological, IHC, and transcriptomic analyses of breast samples from NP and P postmenopausal women, that differentiation of the breast induced by an early pregnancy imprints a specific phenotypic and genotypic signature that can be detected in postmenopausal women.[127,128] Our observations that, during the postmenopause, the breast of both P and NP women contains preponderantly lob 1, and the fact that NP women are at higher risk of developing breast cancer than P women indicate that lob 1 in these two groups of women either differ biologically or exhibit different susceptibility to carcinogenesis.[127] The breast tissues of P and NP women contain ducts and lob 1, which have been reported to contain 11.2 ± 6.3 ductules per lobular unit. Each ductule is composed of an external layer of myoepithelial cells and a monolayer of cuboidal epithelial cells lining a lumen that contains proteinaceous material. IHC staining revealed that epithelium lining both ducts and ductules consisted of basal cells showing positive reactivity for keratin 5/6 and myoepithelial cells reacting positively with SMA; these two markers had similar reactivity in both P and NP breasts. Hematoxylin and eosin-stained tissues reveal two populations of luminal cells lining ducts and lob 1 characterized by their nuclear appearance: one containing large and palely stained nuclei with prominent nucleoli, and another containing small, hyperchromatic nuclei. The pale staining of the large nuclei in the former population is a feature indicative of a high content of noncondensed euchromatin; these nuclei were called euchromatin-rich nuclei (EUN) or Stem Cell 1. The hyperchromasia observed in the latter nuclei was indicative of chromatin condensation and high content of heterochromatin; these nuclei were identified as heterochromatin-rich nuclei (HTN) or Stem Cell 2.[128] The analysis of the distribution of HTN and EUN cells in histological sections of the breast core biopsies revealed that EUN are more abundant in NP than in P breast tissues, whereas the inverse was true for the HTN; these differences were statistically significant[128] (Fig. 127.12). We have confirmed the differences between the HTN and EUN using a quantitative image analysis system. The nuclear size (diameter, area, and perimeter) of the EUN as a whole was significantly higher ($P < .05$) than that of the HTN in both NP and P women.[119] Differences were also found to be statistically significant ($P < .05$) regarding the nuclear shape (nuclear feret ratio) in the breast of NP women, indicating that, in these breasts, the nuclei of the HTN had a more elongated ellipsoidal shape than the EUN. The light absorbance (mean gray values/nucleus) was always greater for EUN than for HTN of both NP and P breasts, either considered as two groups or individually, an indication that, in densitometric terms, HTN are always more densely stained than EUN. Comparison of the EUN of NP versus P breasts revealed significant differences in nuclear size, stainability, and densitometric energy, leading us to conclude that epithelial cell nuclei were larger, less stainable, and with smaller regions with uniform densitometric intensity in NP breasts. Comparison of the HTN of NP versus P breasts revealed significant differences in nuclear diameter, perimeter, shape and stainability; cell nuclei showed larger contours and more elongated ellipsoidal shape and they were more stainable in NP breasts. These observations indicated that a shift of the EUN cell population to a more densely packed chromatin cell (HTN) had occurred in association with the history of pregnancy as a distinctive pattern of the postmenopausal P breast.[127]

Because chromatin condensation is part of the process of chromatin remodeling towards gene silencing that is highly regulated by methylation of histones, we verified this phenomenon by IHC, incubating NP and P breast tissues with antibodies against histone 3 dimethylated at lysine 9 (H3K9me) and trimethylated at lysine 27 (H3K27me[3]). The IHC staining revealed that methylation of H3 at both lysine 9 and 27 was increased in the HTN epithelial cells of the P breast[128] compared with the EUN of the NP breast. In the NP breast the reactivity in individual cells was less intense, and the number of positive cells was significantly lower (Fig. 127.13). These variations in chromatin reorganization were supported by the upregulation of the *CBX3*, *CHD2*, *L3MBTL*, and *EZH2* genes controlling this process.[128]

Transcription regulation and chromatin organization were also highly represented in the P breast by the upregulation of *CBX3*, *EBF1*, *GATA3*, *RBBP8*, *CCNL1*, *CCNL2*, *CDCA7*, *EZH2*, *FUBP1*, *NFKBIZ*,

RUNX3, *ZNF107*, *ZNF207*, *ZNF692*, *ZNF711*, *ZNF789*, *CDCA7*, and *ZNF692.*[128] The P breast also exhibits upregulation of expression of six noncoding regions that included *XIST*, *MALAT-1* (*NEAT2*), and *NEAT1*[127] (Fig. 127.14).

KEY POINTS

- Transcriptionally active chromatin is mianly expressed in the euchromatin-rich nuclei of the breast of nulliparous women.
- Transcriptionally inactive chromatin is more frequently found in heterochromatin-rich nuclei of the parous breast and is associated with histone 3 methylation at lysines 9 and 27, as well as transcriptional silencing in heterochromatin complexes.
- Mechanisms for decreased risk of developing breast cancer in parous versus nulliparous women are complex and likely involve molecular, structural, genomic, and epigenomic changes that have the potential to be mined for future breast cancer prevention strategies.

We demonstrated that the changes in cell types and increases in chromatin condensation are novel markers for defining the concept of differentiation in the adult breast. These findings confirm the universality of histone 3 methylation at lysines 9 and 27 during differentiation, as a similar phenomenon has been described to occur during embryonic stem cell differentiation.[129,130] The observed chromatin changes in P epithelial cells are complemented by the expression of genes related to increasing cell adhesion and differentiation. In contrast to the findings of Asztalos et al.[131] of downregulation of the expression of ERa following recent (<2 years) and distant (5–10 years) pregnancies in premenopausal women, our current genomic and IHC study did not reveal differences in ERa expression in epithelial cells of ducts and lob 1 between P and NP postmenopausal women. Nevertheless, numerous genes that are regulated downstream by the ERa were found to be upregulated in the P breast, supporting a parity-mediated protective effect evident in younger P women[129] but lasting until menopause, as described earlier.

Studies of breast development under the influence of parity in women and in animal models are in agreement on the pregnancy-induced

differentiation of the breast, a process that ultimately manifests as a specific genomic signature in the mammary gland.[84,97,131-134] Although variations in gene expression among different studies and species are expected, an increase in immune activity, including overexpression of lipopolysaccharide-binding protein has been reported in the postpregnancy breast of premenopausal women[131] and in the mammary gland of four different strains of rats.[97] Interestingly, this response observed in recently pregnant and distant pregnant groups was not observed in the postmenopausal group in this study. These discrepancies may indicate that upregulation of immune response–related genes persists during postpartum involution but wanes after menopause begins. However, the possibility that cyclic hormonal changes occurring during the menstrual/estrus cycle that influence the genomic profile of the breast activating pathways that greatly differ from those expressed in the postmenopausal P women cannot be ruled out.

We found a shift in the cell population of the postmenopausal breast as a manifestation of the reprogramming of the organ after pregnancy. These observations are in agreement with what is observed in the rat mammary gland, which also contains two types of luminal epithelial cells, designated dark (DC) and intermediate (IC) cells, in addition to the myoepithelial cells (see earlier).[132] The DC and IC cells are equivalent to the HTN and EUN cells described earlier. DCs increase after pregnancy and lactational involution (Stem Cell 2); whereas the ICs (Stem Cell 2) significantly outnumber the DCs in ductal hyperplasias and ductal carcinomas.[134,135] Our analysis of nuclear ultrastructural and morphometric parameters of rodent ICs have allowed the differentiation of mammary progenitor stem cells from cancer stem cells.[128,134,135] Nuclear morphometric analysis of breast and ovarian carcinomas has confirmed the predictive value of nuclear grade for the progression of premalignant lesions to invasiveness.[136-138] Our present findings of a significant decrease in the number of EUN (Stem Cell 1) with a subsequent increase in the number of HTN cells (Stem Cell 2) expressing specific biomarkers identified at the chromatin and transcriptional levels support the value of morphometric analysis as an adjunct to molecular studies. These data clearly indicate there are morphological indications of chromatin remodeling in the P breast, such as the increase in the number of epithelial cells with condensed chromatin and increased reactivity with anti-H3K9me and anti-H3K27me[3] antibodies. Histone methylation is a major determinant for the formation of active and inactive regions of the genome and is crucial for the proper programming of the genome during development.[139] In the P breast, there is upregulation of transcription factors and chromatin remodeling genes such as *CHD2* and *CBX3*, whose products are required for controlling protein/protein or DNA/protein interactions. *CBX3* is involved in transcriptional silencing in heterochromatin-like complexes and recognizes and binds H3 tails methylated at lysine 9, leading to epigenetic repression (see Fig. 127.14). Two other important genes related to the polycomb group (PcG) protein that are upregulated in the P breast are *L3MBTL* and *EZH2*. Members of the PcG form multimeric protein complexes that maintain the transcriptional repressive state of genes over successive cell generations. *EZH2* encodes an enzyme that acts mainly as a gene silencer, performing this role by the addition of three methyl groups to lysine 27 of histone 3, a modification that leads to chromatin condensation.[128,138-141]

RNA molecules recruit PcG complexes to the locus of transcription or to sites located elsewhere in the genome. An important role has been attributed to noncoding RNAs (ncRNAs).[142] It can be postulated that the increased chromatin condensation in the P breast reported herewith could have been initiated by ncRNAs, which is supported by the observed upregulation of several ncRNAs that included nuclear paraspeckle assembly transcript 1 (*NEAT1*), *MALAT-1* (*NEAT2*), and *XIST*,[143,144] all critical components of the speckles. These observations indicate that, in P women, the breast remains actively involved in the RNA metabolism that is necessary to maintain a state of differentiation. A ncRNA transcribed from a portion of the *XIST* gene locus forms hairpin structures that recruit the PRC2 complex to the X-inactivation center *X(ic)*,[145] and transcription of full-length *XIST* RNA, which forms the same hairpin structures, leads to further PRC2 recruitment and the spread of PcG-mediated repression across the inactive X chromosome. *XIST* repression, often seen in malignancies, also occurs in early embryogenesis and during the acquisition of pluripotency in undifferentiated embryonic stem cells by the binding of *NANOG*, *OCT4*, and *SOX2* directly to the chromatin of the *XIST* gene.[110] It is possible that, in the postmenopausal NP breast, the upregulation of *DDX*, *SOX1*, *SOX6*, and *SOX17* play a direct pivotal role in the repression of *XIST* transcription. Although this needs to be functionally verified, it is possible that these genes play a role in controlling *XIST* in the P breast. Upregulation of *XIST* has important implications in the understanding of the differentiation pattern of the P breast. In recent studies it has been shown that the reprogramming of X-chromosome inactivation during the acquisition of pluripotency *in vivo* and *in vitro* is accompanied by the repression of *XIST*.[141-143] Reprogramming experiments have further reinforced the concept that X-chromosome inactivation is intimately linked to differentiation and support our findings that *XIST* is expressed in well-differentiated adult cells, participating in the maintenance of gene repression.[112,143-146]

Our work demonstrates that the breast of P postmenopausal women exhibits a specific signature that has been induced by a FTP. This signature reveals, for the first time, that the differentiation process is centered on chromatin remodeling and the mRNA processing reactome, which emerge as important regulatory pathways induced by pregnancy. The biological importance of the pathways identified in this specific population cannot be sufficiently emphasized, because of the fact that the upregulation of the noncoding sequences that control gene repression and of the genes that control the spliceosomes could represent a safeguard mechanism at genomic and posttranscriptional levels that maintain the fidelity of the transcription process, a phenomenon that could be the ultimate step mediating protection of the breast from malignant transformation conferred by FTP.

Female sexual health is complex and involves numerous physiologic pathways that are relevant to the practicing endocrinologist. Female sexual problems associated with distress include problems with desire, arousal, and orgasm. They affect up to 12% of adult women, while sexual pain prevalence has been reported to be as high as 33%.[1,2] While the seat of reproduction is in the reproductive tract, external genitalia, and gonads, the locus of nearly all sexual response is in the brain, and, as such, psychosocial, developmental, behavioral, and cultural factors all play important roles. The pathways that mediate these brain responses involve neurotransmitters and hormones and can be impacted by nearly every endocrinologic system. Furthermore, female sexuality, while rooted in biology, cannot exist in the absence of the psychological and social context. In this chapter, however, we will focus primarily on the biology of female sexual health and its relevance to endocrinology.

NORMAL FEMALE SEXUAL RESPONSE

Neurotransmitters of Desire and Arousal

Normal female sexual response is a complex process that starts in the brain and is mediated by many well-known neurotransmitters. What is key about these neurotransmitters is that they may play an excitatory or inhibitory role in the promotion of desire and arousal and, as will be discussed later, are strongly influenced by hormones.

Evidence supports that the main sexual excitatory neurotransmitter is dopamine. Exposure to dopamine has been shown in animal models to enhance desire, excitement, and continuation of sexual activity.[3] Neuroimaging and animal modeling have shown multiple brain regions responsible for desire and arousal, including the ventral tegmental area, which is the primary source of dopamine to the mesolimbic and mesocortical pathways. The nigrostriatal system promotes somatomotor activity; the mesolimbic system subserves numerous types of motivation; and the medial preoptic area (MPOA) focuses the motivation onto specifically sexual targets, increases copulatory rate and efficiency, and coordinates genital reflexes. These actions are universally mediated by dopamine (Fig. 128.1).[4] Clinically, this is evidenced by data showing that excess dopamine can lead to increased and hypersexual behaviors.[5]

Another excitatory neurotransmitter involved in female sexual response is norepinephrine. Norepinephrine has been shown to play a key role in both central and peripheral regulation of sexual response. Centrally, it has been shown to promote sexual arousal, while peripherally it controls the autonomic components of sexual response (Fig. 128.1).[3]

The main inhibitory neurotransmitter in sexual desire and arousal is serotonin.[6] Pharmacologic data have demonstrated repeatedly that excess serotonin can lead to diminished sexual response, and lab data suggest this is likely mediated by inhibition of dopaminergic pathways.[4,7]

Other neurotransmitters purported to affect desire and arousal include endogenous opioids, melanocortins, and oxytocin, which more likely modulate the intensity of a perceived sexual experience and play a large role in the rewards centers that are central in mediating sexual response, in addition to pair bonding (oxytocin) (Figs. 128.1 and 128.2).[3]

Endocrinology of Desire and Subjective Arousal

The two best-known hormones related to the sexual response are estrogen (specifically, estradiol) and testosterone. Whether these hormones act individually or synergistically, or actually mediate the same actions in both the female and male brain, has been the subject of debate for many years.[8]

Among the four forms of estrogen (estrone, estradiol, estriol ,and estetrol),[9] the most abundant and relevant to the female sexual response is estradiol. Estradiol has been shown to have a direct role in the female sexual response, mainly for its effects on genital vasodilation and lubrication. Centrally, however, estrogen's main role is to stimulate the key neurotransmitters involved in sexual response at the level of the hypothalamus and limbic system, as noted earlier (Fig. 128.2).[8] The role of testosterone and other androgens has long been known to be important

in the male sexual response. This is also true for women. Testosterone likely influences the expression of nitric oxide synthase, which increases the production of nitric oxide, which then leads to the release of the neurotransmitters central to the female sexual response.[6] Animal studies demonstrate that androgens rather than estrogens are linked to targeting of dopaminergic pathways in the prefrontal cortex.[10] Human studies demonstrating the sexual benefits of testosterone are limited to clinical supplementation with androgens in women with sexual dysfunction.[11] These studies suggest that it is androgens alone, rather than estrogens, that mediate sexual response in women (Fig. 128.2).[6]

It is well established that androgen levels decrease across the lifetime of women.[12] While there are weak associations between lower androgen levels and lower sexual desire, there is no defined cutoff concentration associated with low sexual desire.[13] There has been significant research into the effects of supplemental testosterone on female sexual dysfunction, the details of which will be discussed later in this chapter.

Interestingly, animal research (primarily in rodents) has indicated that, in females only, circulating estradiol is predictive of sexual response.[3] In contrast in humans, there is considerable debate regarding the specific role(s) of the different sex steroids and their effects on sexual desire and arousal, namely whether androgens or estrogens are responsible for these responses. In a well-designed study examining daily sexual desire and hormone levels, only estradiol reliably predicted desire, while progesterone had a negative effect, and testosterone concentrations were not as predictive as estradiol.[14] Additionally, it has been demonstrated that testosterone levels decrease more rapidly in the fourth decade of life in women, rather than in menopause, and circulating estradiol levels in this age group have been shown to be more relevant to lower sexual desire than circulating androgens.[15] However, clinical data have not reliably demonstrated that supplementing women with estradiol leads to increased desire.[8] This is not the case for testosterone, as will be addressed in later sections.

KEY POINTS

- Dopamine is the key neurotransmitter regulating sexual desire.
- Both estradiol and testosterone modulate dopamine and improve all aspects of the female sexual response.
- Both local and systemic estrogens and testosterone can maintain vulvar, vestibular and vaginal health.

ENDOCRINOLOGY OF OBJECTIVE AROUSAL

Normal Vulvar and Vaginal Anatomy and Role of Hormones

Historically, the hormone focus regarding vulvar and vaginal health has been on the degree of estrogenic stimulation. It is well established that there are receptors for estradiol throughout the vagina, vulva, and urethra, and even in the trigone of the bladder.[15,16] The roles of estrogen are numerous, including maintaining blood flow to the vulvovaginal tissue, the collagen within the epithelium, and the hyaluronic acid

Changes in cellular function caused by sex steroid hormones can result in changes to:
Non-vascular smooth muscle:
(i) Growth or atrophy
(ii) Response to neurotransmitters
Epithelial cells:
(i) Mucification
(ii) Keratinization
(iii) Permeability
Blood vessels:
(i) Growth or atrophy
(ii) Vaso-reactivity
Lubrication and blood flow
Neurons:
(i) Distribution pattern
(ii) Synthesis and/or release of neurotransmitters

Figure 128.3 Estrogen plays a role in supporting the microbiome and protecting the tissue from pathogens.

and mucopolysaccharides within the moistened epithelial surfaces. Estrogen also plays a role in supporting the microbiome and protecting the tissue from pathogens (Fig. 128.3).[17] Although estrogen is important in maintaining vulvovaginal health, there are emerging data that androgens also have an important role.[16] All three layers of the vagina have been shown to have androgen receptors; in addition, androgens have been shown in animal models to stimulate nerve fibers, as well as mucification of the vaginal epithelium.[16] Furthermore. it appears that androgens are likely derived from the conversion of circulating dehydroepiandrosterone (DHEA) entering the cells of the vulvar and vaginal tissue.[18] Androgens maintain nonvascular smooth muscle function in the vagina and vascular smooth muscle in the clitoris and also have a stimulatory effect on vaginal nerve density.[16,19,20]

This critical role of sex steroids in the vulva and vagina is important for normal female sexual response. Physiologic arousal derives from increased blood flow to the clitoris, labia, vulva, and vagina, which results in vasocongestion as well as lubrication.[21,22] As in male genitals, the basic mechanisms of these processes are mediated through adrenergic and nitric oxide signaling, although modulation by the sex steroid hormones themselves is also involved.[19,23]

Testosterone and estradiol regulate their own receptors and can also cross-regulate the other receptors.[24] Estradiol modulates genital blood flow and is related to the density of collagen fibers in the lamina propria. In addition, estradiol moderates muscular thickness in the vagina and vasorelaxant mechanisms of the clitoris involved in arousal.[15,25] Vaginal lubrication is a combination of basal mucin production and vaginal vascular transudate.[20] Sex steroid hormones regulate mucification, keratinization, and the permeability of the vaginal epithelium (Fig. 128.3).[19] Mucification of the vaginal epithelium is a result of androgens, while proliferation of the vaginal epithelium is related to the effects of estrogens.[15,20] Therefore, mucin production is regulated by androgen, whereas vaginal vascular transudation is an estrogen-dependent effect. Thus, together both androgens and estrogens play a role in objective arousal physiology.

DEFINITIONS AND DIAGNOSIS OF SEXUAL DYSFUNCTION

Definitions of female sexual dysfunctions are based primarily on clinical manifestations and patient report rather than pathophysiological etiology. Current definitions are closely tied to the evolution of the Diagnostic and Statistical Manual of Mental Disorders (DSM), the diagnostic classification system of the American Psychiatric Association.[26] The DSM-IV definition of hypoactive sexual desire disorder (HSDD) states that a woman has to have persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity. The judgment of deficiency or absence is made by the clinician, taking into account factors that affect sexual functioning, such as age and, importantly, the context of an individual's life. The disturbance must cause marked distress or interpersonal difficulty in order to be considered a disorder, and the sexual dysfunction *cannot* be better accounted for by another axis 1 disorder (except another sexual dysfunction). Most critical, especially for the non–sexual medicine expert, is that the disorder is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication such as an selective serotonin reuptake inhibitors [SSRI], an antihypertensive, etc.) or a general medical condition. The diagnosis additionally segregates the disorder into the categories of acquired versus lifelong, and situational versus generalized.[27] The other categories of female sexual dysfunction in the DSM-IV included arousal disorder, aversion disorder, orgasmic disorder, and two different sexual pain disorders: vaginismus and dyspareunia.

The more recent DSM-V, published in 2013, eliminated many of these definitions.[28] It merged "desire" and "arousal" into one entity called "sexual interest/arousal disorder." The diagnosis depends on a patient having three of the following symptoms:

a. Absent or decreased interest in sexual activity
b. Absent or decreased sexual or erotic thoughts and fantasies
c. No or decreased initiation of sexual activity and lack of receptivity to a partner's attempts to initiate
d. Absent or decreased sexual excitement or pleasure during sexual activation in almost all or all (75%–100%) sexual encounters
e. Absent or decreased sexual interest or arousal in response to any internal or external sexual or erotic cues
f. Absent or decreased genital or nongenital sensations during sexual activity in almost all or all (75%–100%) sexual encounters

In DSM-V, the female orgasmic disorder was defined as "marked delay in, marked inadequacy of, or absence of orgasm" and eliminated the prior requirement of "following a normal sexual excitement phase."

Furthermore, the sexual pain disorders were combined into "genito-pelvic pain/penetration disorder," defined as persistent or recurrent difficulties with at least one of the following characteristics:

a. Vaginal penetration during intercourse
b. Marked vulvovaginal or pelvic pain during vaginal intercourse or penetration attempts
c. Marked fear or anxiety about vulvovaginal or pelvic pain during or in anticipation of vaginal penetration
d. Marked tensing or tightening of the pelvic floor muscles during attempted vaginal penetration

The DSM definitions are a mainstay of mental health practice in the United States and around the world, and thus play a large role in research, evaluation, and clinical management of women with female sexual dysfunction. However, there is a great deal of controversy regarding these definitions, especially regarding combining desire and arousal disorders, and genital pain and penetration disorders. Additionally, no compelling evidence exists that suggests that a duration of 6 months has better diagnostic validity than a duration of 3 months, but the former would certainly delay the establishment of a diagnosis and the availability of reimbursement for therapy. Similarly, the DSM-V rules also require a rubric that the symptoms must be present "in almost all or all (75%–100%) occasions of sexual activity." These definitions and percentages are not evidence-based and may not correlate in any way to a patient's distress level.[29]

International Classification of Diseases. The International Classification of Diseases (ICD) codes comprise a worldwide health information standard developed and published by the World Health Organization for coding mortality and morbidity, signs, symptoms, reasons for encounter, and external causes of both injury and disease. This classification system has been used throughout the world as a standard diagnostic and coding tool and incorporates many of the diagnoses seen in the DSM.[30] The most current version is the ICD-11, published in 2018; however, the ICD-10 is still in worldwide use and includes disorders of desire, aversion, genital response, dyspareunia, and vaginismus. The new ICD-11 has expanded the definitions greatly and addressed some of the concerns with the DSM-V definitions noted previously. For example, ICD-11 takes into account associated conditions and nonnormative sexual practices, reflecting a broader understanding of sexual dysfunctions, and continues to separate desire, arousal, and genital pain disorders as the DSMIV-TR did.[31]

Other Schemata. Given ongoing developments in sexual health research and knowledge, there have been additional approaches to nomenclature and diagnosis proposed by leading researchers and academic groups to expand the nomenclature and definitions of female sexual dysfunction, including desire, arousal, and sexual pain.[29,32-34] These definitions take into account the many associated factors, associated pathophysiology, and nuances in the diagnoses of sexual disorders.[35-37]

Screening Tools. Most screening tools focus on HSDD. Provider interviews are necessary to elucidate many of the nuances as well as the psychosocial factors that are critically involved in all sexual dysfunctions. However, there can be much benefit from selected screening tools and surveys focusing on patient-reported outcomes (PROs). Most clinical studies on treatment for HSDD require specific endpoints related to these PROs, but they can also be used in the office by clinicians and include the Elements of Desire Questionnaire and Decreased Sexual Desire Screener.[33] The Female Sexual Function Index (FSFI)[38] and Brief Index of Sexual Functioning for Women (BISF-W)[39] have domains related to pain, orgasm, and arousal and can thus help incorporate all aspects of female sexual dysfunction into one screening tool, although these are most commonly used in research studies.[38,39]

Similarly, for pain disorders, there are numerous tools to assess the degree of pain and its clinical manifestations. These also are different tools focused for the research versus clinical environments.[40] For many clinicians, using a visual analog scale can be most useful in a busy clinical setting, and testing external and internal genitalia is necessary to elucidate the source and severity of the pain.

Distress. As noted previously, reduced scores on tests of desire, arousal, pain, and so on do not rise to the diagnosis of a disorder unless accompanied by clinically meaningful and measurable distress. Most patients do not use the word "distress" in their vocabulary defining their sexual dysfunction. One of the most used terms closest in sentiment to distress is "bother." Distress is commonly measured by a short questionnaire, the Female Sexual Distress Scale–Revised.[33] This validated tool has been paired with the FSFI and the BISF-W in multiple investigations and is commonly used by regulators in their assessment of new therapies.

PATHOPHYSIOLOGY OF FEMALE SEXUAL DYSFUNCTION

Hypoactive Sexual Desire Disorder

Sexual desire is regulated by key regions in the brain through the action of various effects on resident neurotransmitters. Dopamine, norepinephrine, melanocortin, and oxytocin mediate sexual excitation, whereas opioid, serotonin, endocannabinoid, and prolactin mediate sexual inhibition. HSDD occurs in premenopausal women with normal menstrual function, despite the hormonal fluctuations in the cycle. It happens in women who are menopausal, with or without hormone "replacement" therapy, including with or without the addition of testosterone. Although the underlying biological causes of HSDD remain unknown, HSDD likely involves the effects of inhibitory processes or neuroadaptations that result in decreased excitation, increased inhibition, or a mixture of the two.[32] Based on this understanding, there are numerous medical conditions that would thus affect and be associated with HSDD. The most well-known and understood comorbidity in HSDD is depression, but other medical conditions like diabetes, obesity, incontinence, and especially surgical menopause play a role.[32] Furthermore, there are numerous medications that can also affect sexual desire, based on known alterations in excitatory and inhibitory neurotransmitters and hormones. SSRIs are the most commonly recognized medications, but other psychiatric medication, blood pressure medication, and especially hormonal contraception can contribute as well.[32] A thorough psychosexual history is also necessary, given that the psychosocial component of HSDD cannot be ignored. It should be noted that there are neuroimaging studies that demonstrate differential brain activity patterns in women with and without HSDD,[41] suggesting that alterations in brain function and structure may be additionally modulated or reinforced by experience and behavior, which has been characterized as experience-based neuroplasticity.[42] This can then further propagate the HSDD condition.

Sexual Arousal Disorders

We have already established that sexual arousal is distinct from desire, and there are also differences between genital arousal and subjective, or cognitive, arousal.

In terms of genital arousal disorder, the pathophysiology is often related to changes in the local hormonal and/or vascular environment, as seen in the menopause, pregnancy, and postpartum. It should be noted that there are medications that can alter the hormonal environment of the vagina and vulva.[43] Any assessment of a woman with genital complaints requires a thorough history and medication history to assess for risk factors for hormonal or vascular changes. The most common are aromatase inhibitors for the treatment and prevention of hormone-sensitive breast cancer, but an often-overlooked group of medications are combined hormonal contraceptives or any contraception that decreases follicle-stimulating hormone and luteinizing hormone, and thus estradiol and testosterone.[44,45] There are other etiologies that can affect local genital response as well. These include nerve injuries, as well as medications that can blunt or overstimulate the local genital response.[46,47] Vascular disorders can also blunt the female sexual response due to changes in blood flow and sensation.[48] There are data that suggest sustained exercise, presumably leading to local nerve injury, can also blunt the genital response, as bicycle riders report significantly higher rates of genital numbness.[49]

Female cognitive arousal disorder is a distinct entity characterized by a lack of mental engagement and focus in response to sexual stimuli.[37] There is much research demonstrating that subjective and genital arousal may not happen simultaneously and may in fact be dyssynchronous.[50] Most research on subjective arousal is focused on use of PROs and is often combined with HSDD research. Evidence distinguishing the pathophysiology of subjective arousal from that of HSDD is limited. Many of the same neurotransmitters, hormones, medical conditions, and medications involved in the pathophysiology of desire play a central role in arousal, but their effect on a woman's subjective arousal is often distinct from her subjective desire. However, the ultimate effect is an imbalance of inhibition and excitation that leads directly to alterations in subjective arousal.

Orgasmic Disorder

Among all established sexual health conditions, orgasmic disorder is likely the least well understood, likely because of the lack of knowledge of the fundamental physiology, purpose, and control of female orgasmic function. Women who have difficulty reaching orgasm sometimes show decreased sexual desire and/or inadequate arousal, suggesting a problem with the desire and arousal phases rather than with the orgasm phase *per se*.[51,52] Numerous biological factors can account for disorders of orgasm in women. General medical conditions, such as heart or kidney disease, multiple sclerosis, fibromyalgia, thyroid disorders, weakened pelvic floor, and menopause have been associated with all female sexual dysfunctions, including anorgasmia. The literature on the orgasm-inhibiting effects of SSRIs is particularly abundant and dates back almost two decades. Anorgasmia is reported in at least one third of patients who receive SSRIs, in a dose-dependent manner.[53] Alcohol and other drugs also have been shown to interfere with orgasm. Most importantly, psychosocial factors cannot be overlooked and likely play a significant role; these factors include, but are not limited to, age, education, social class, cultural background, relationship conflicts, and shame or embarrassment about sexuality due to religious beliefs or familial inhibitions.[54] A distinction between primary/lifelong orgasmic dysfunction and secondary/acquired dysfunction may provide the practitioner with both a clue to the cause and the pathway toward treatment. Generally, primary/lifelong orgasmic dysfunction has been the purview of psychosocial practitioners, while secondary/acquired dysfunction has been attributed to a biological source.

Sexual Pain Disorders

Sexual pain disorders encompass a wide variety of conditions. As with all sexual disorders, the importance of psychological and social assessments/treatments must be taken into account, but it is important to remember that women who are experiencing pain will likely have a physical/biological cause underpinning their pain. Often, it is important to assess the psychological and social effects of that biological condition. For example, the patient with deep endometriosis may have severe sexual pain, but the barriers caused by the endometriosis pain's impact on intimacy may create psychological and social effects for the patient, the partner, or the couple taken together.

Common gynecological causes of sexual pain include endometriosis and pelvic floor muscle dysfunction.[55] Pelvic floor muscle overactivity or hypertonicity are commonly overlooked causes of sexual pain. Prolonged use of these muscles, "clenching against the pain," can result in decreased tissue oxygenation, muscle overactivity, shortening of sarcomeres, and the development of myofascial trigger points. Hypertonicity of the muscles that insert at the posterior vestibule—the pubococcygeus, puborectalis, and superficial transverse perinei—can lead to allodynia (as seen in vestibulodynia) in the posterior vestibule. Hypertonicity of deeper muscles (e.g., ileococcygeus, coccygeus, and obturator internus) can lead to vaginal or deep thrusting dyspareunia. In addition, overactivity of the bulbocavernosus and ischiocavernosus is associated with clitorodynia. Many women with pelvic floor hypertonus may also have chronic constipation and elements of urinary retention.[55]

Many women with genital pain have a local component confined to the vulvar vestibule, and this is mediated by hormonal, neurological, and inflammatory conditions,[55] which we will focus on here. As noted earlier, the tissues of the vulva and vagina are both responsive and dependent on sex steroid hormones for proper health and function (Fig. 128.3). There are many causes of decreased sex steroids, both natural and iatrogenic, that can lead to dyspareunia. The most common cause of decreased sex steroids in women is menopause. Other physiologic causes include anovulation secondary to lactation, anorexia, hypothalamic amenorrhea, excessive physical activity or physiological stress, and hyperprolactinemia. Iatrogenic causes of decreased circulating sex steroids include oophorectomy, which leads to immediate menopause, hysterectomy (without oophorectomy), and commonly prescribed medications, such as combined hormonal contraception (CHC).[55] CHC use leads to a reduction in serum estradiol and free testosterone by decreasing ovarian production of estrogen and total testosterone based on negative feedback and by inducing the liver to produce increased levels of sex hormone–binding globulin (SHBG). SHBG binds both free circulating testosterone and estradiol, with higher affinity for testosterone. In addition, some CHCs contain synthetic progestogens that act as testosterone antagonists at the androgen receptor, most notably drospirenone, which is an analog of spironolactone. It has been shown that CHCs cause histopathologic changes in the vestibular epithelium (the embryologic equivalent of the male penile urethra), thereby increasing vulnerability to mechanical strain and decreasing mechanical pain thresholds. Preliminary evidence suggests that women with provoked vestibulodynia may have alterations in their androgen receptor leading to reduced sensitivity to lowered androgen environments.[56] Given their effects on sex steroids, it is perhaps not surprising that studies have shown that CHCs are associated with an increased risk of vestibulodynia.[57]

Inflammation plays a central role in vestibulodynia as well. Although both women with vestibulodynia and healthy women have inflammatory cells in the vestibular epithelium, the relative abundance and organization of these cells may differ between women with and without vestibulodynia. Several controlled studies have demonstrated that women with vulvodynia have evidence of central sensitization.[58] These results suggest that women with vulvodynia have an increased perception of nonpainful and painful stimulation to the vestibule.

KEY POINTS

- Sexual desire disorder is distinct from sexual arousal disorder.
- Sexual pain can be related to conditions that affect the vulva, vulvar vestibule, vagina and internal pelvic organs.
- Most female sexual dysfunctions are associated with other comorbidities and can be caused by both endocrinopathies and their treatments.

TREATMENTS FOR SEXUAL DYSFUNCTION

Hypoactive Sexual Desire Disorder

HSDD is the most common sexual dysfunction in women, and, as outlined earlier, is often associated with poor medical and psychological states. All treatments for HSDD should begin with education, adjustment of potentially modifiable factors, and, if needed, provision of additional therapeutic interventions. The choice of therapeutic intervention should be made in conjunction with the patient (and potentially her partner), based on her/their preferences and goals. The International Society for the Study of Women's Sexual Health has developed a comprehensive process of care for management for women with HSDD. Many of their suggestions are incorporated in this chapter (Fig. 128.4).[35]

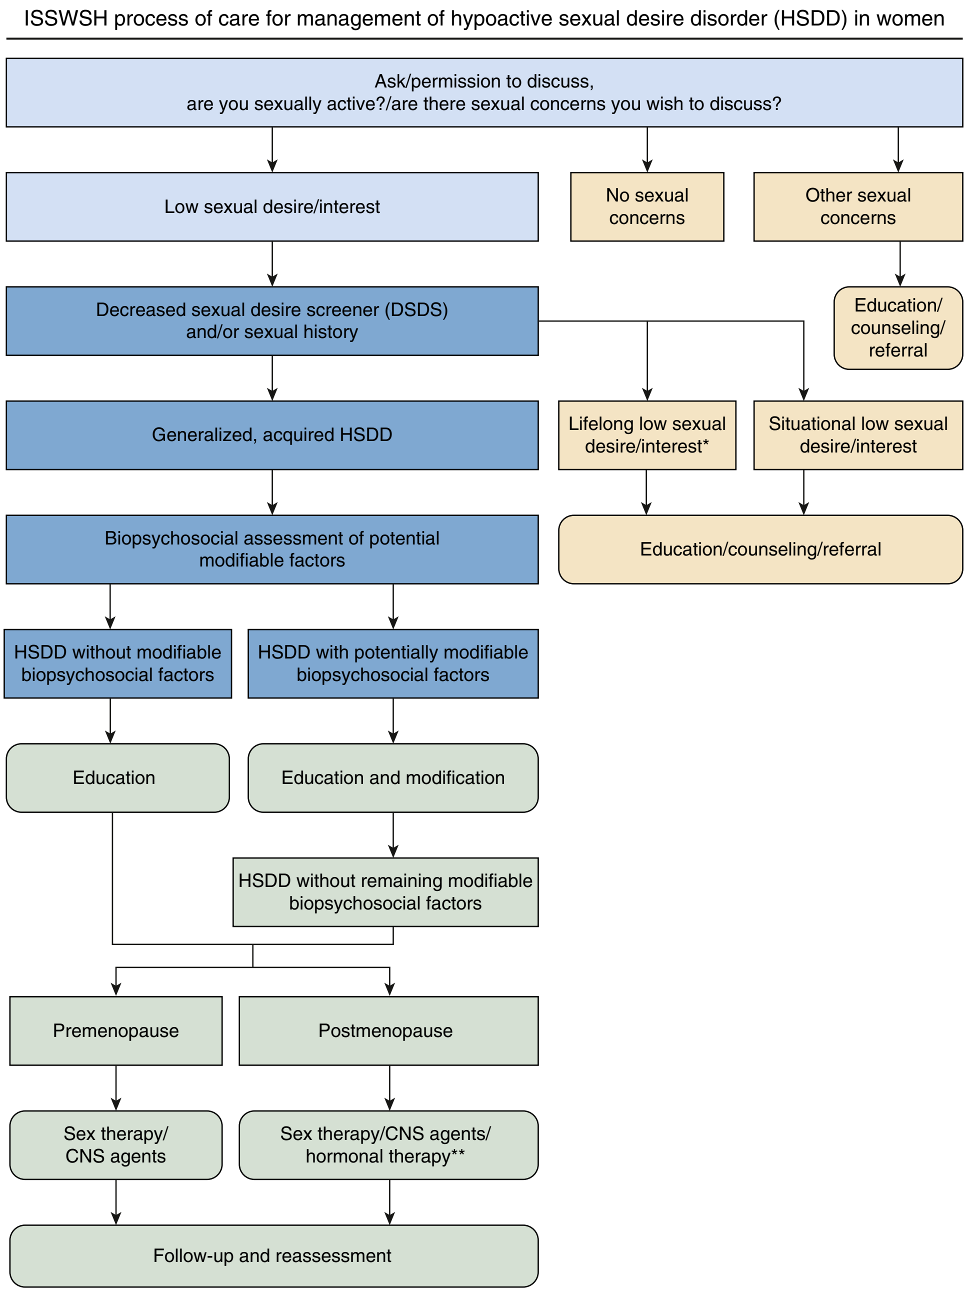
Nonhormonal Treatments

The first US Food and Drug Administration–approved treatment for generalized, acquired HSDD in women was flibanserin (August 18, 2015). Flibanserin (100 mg nightly) is a nonhormonal, centrally acting, daily, oral, serotonin agonist and antagonist. Flibanserin works by enhancing 5-HT1A activity and inhibiting 5-HT2A activity. Between the two actions, serotonin production is heavily downregulated. This, in turn, leads to changes in dopamine and norepinephrine in the brain.[59] Over 3000 women were initially studied in the three original, pivotal trials, which revealed changes in sexual desire (increase), sexual distress (decrease), and satisfying sexual events (increase) versus placebo as endpoints.[60] There is evidence that demonstrates the efficacy and safety of flibanserin in postmenopausal women as well, but flibanserin is not approved for postmenopausal women in the United States.[60] Approximately 50% of women with HSDD respond to flibanserin, and it may take up to 8 weeks for efficacy to emerge. The most common adverse events (AEs) in premenopausal women are dizziness (9.2%), somnolence (8.3%), nausea (6.5%), and fatigue (3.7%)· It should be noted that placebo-corrected efficacy rates are similar to those seen with other central nervous system (CNS)-active agents (i.e., for depression). In the pivotal clinical trials, the rate of discontinuation due to AEs was 13% in premenopausal women treated with flibanserin compared with 6% treated with placebo.[62]

Flibanserin's original labeling carried a boxed warning that concomitant alcohol use is contraindicated, and providers had to become certified to prescribe the medication as part of a risk evaluation and mitigation strategy (REMS) with elements to assure safe use program. This was based on the results of an alcohol challenge study that found an increase in sedation, syncope, and hypotension in the treatment group (23 men and two women) when flibanserin was coadministered with alcohol. Of note, alcohol use was not restricted and did not increase such AEs over placebo in the three major pivotal trials, which were limited to premenopausal women. A series of postapproval alcohol interaction studies, for example one performed in 96 women (≤45 years old), revealed no effect of a combination of ethanol for blood pressure, vertigo, or syncope.[63] The boxed warning has since been removed, and there is no longer a REMS certification requirement for prescribers and pharmacies to educate patients to avoid alcohol. The remaining warning is to take flibanserin at bedtime and 2 or more hours following the last consumption of alcohol. If that timing is not possible, then patients are advised to skip that night's dose of flibanserin.

The second nonhormonal medication to be FDA-approved for premenopausal women is bremelanotide (1.75 mg subcutaneous as needed), a melanocortin-4 receptor agonist. Its mechanism of action is also believed to be downstream stimulation of dopamine receptors in the MPOA following melanocortin-4 receptor binding (Figs. 128.1 and 128.2).[64] The efficacy of bremelanotide was shown in two phase III randomized placebo-controlled trials showing improvement in sexual desire and decrease in sexual distress, but notably not affecting the number of satisfying sexual events.[65] Its use "as desired" is seen as a possible mechanism for the absence of this agent's impact on satisfying sexual events. Bremelanotide comes in a single-use insulin-like pen autoinjector and is approved for "as needed" use only. Bremelanotide's main AEs (vs. placebo) are nausea (40.0% vs. 1.3%), flushing (20.3% vs. 0.3%), injection site reactions (13.2% vs. 8.4%), headache (11.3% vs. 1.9%), and vomiting (4.8% vs. 0.2%). All side effects (except for injection site reactions) tended to decrease with additional use beyond the first dose. Whether this improvement in AE experience was due to reduced associated anxiety or tachyphylaxis is unknown. There is no boxed warning or REMS program for bremelanotide. While not tested in its current formulation, a nasal formulation (not FDA-approved) demonstrated efficacy in postmenopausal women.

There are other CNS agents that are used off label for HSDD. Bupropion (300–400 mg/day) is the only one studied with sexual desire as a clinical endpoint, and did show efficacy, but the one study of this subject did not enroll enough patients to meet statistical significance.[66] The evidence for adding bupropion for people with antidepressant-induced HSDD is mixed.[67,68] Buspirone is another antidepressant and anxiolytic agent that has been used for HSDD, and did show efficacy in improving desire in clinically depressed patients, but there is no study on this drug where HSDD is the primary clinical endpoint.[69] Trazodone, a phenylpiperazine compound of the serotonin antagonist and reuptake inhibitor class, is commonly prescribed as a sedative, anxiolytic, and antidepressant. However, it also has efficacy in post-traumatic stress disorder, alcohol dependence, and so on. It is known to bind to several serotonin receptors in the 5HT1 and 5HT2 families, like flibanserin, as noted earlier. Trazodone is known to have sexual side effects at high doses that include priapism/clitorism. Recent research demonstrates efficacy for decreased sexual desire (i.e., HSDD) without priapism/clitorism when used at doses as low as 3.5 mg/d.[70]



ISSWSH process of care for management of hypoactive sexual desire disorder (HSDD) in women
Ask/permission to discuss, are you sexually active?/are there sexual concerns you wish to discuss?
Low sexual desire/interest
No sexual concerns

The International Society for the Study of Women's Sexual Health Process of Care for Management of Hypoactive Sexual Desire Disorder in Women. Copyright Elsevier 2018.)

Hormonal Management of Hypoactive Sexual Desire Disorder

Estrogens. While most focus on hormones and HSDD is on the effects of testosterone, we have already demonstrated that some testosterone is converted to estradiol, and there is evidence that estradiol mediates sexual desire in women. It would thus make sense that estradiol supplementation may improve HSDD in women. However, nearly all research focused on this subject has taken place in postmenopausal women who are being given estrogen supplementation for bothersome menopausal symptoms (vasomotor, sleep, and vulvovaginal complaints), including low desire. It is not recommended to treat premenopausal women with estrogen for low sexual desire.

There is research that demonstrates that women on menopausal hormone therapy with estradiol have improved sexual function compared with placebo.[71] Other data have demonstrated that ultralow dose supplementation does not improve function, along with other menopausal symptoms.[72] Further evidence shows that the route of estrogen administration is likely most critical when using postmenopausal estrogen therapy for HSDD. A well-designed randomized clinical trial (RCT) demonstrated that transdermal, but not oral, estrogen replacement was associated with improved sexual function, primarily in the pain and lubrication domains.[73] This difference related to route of estrogen administration may be mediated by the liver "first-pass" increase in SHBG that occurs with oral estrogens, but not transdermal preparations. Increased SHBG during oral estrogen administration has the potential to decrease circulating free testosterone, again suggesting the role of testosterone in sexual function. Thus, if considering systemic estrogen treatment for low sexual desire in postmenopausal women, preference should be focused on nonoral delivery (patches, lotions, gels, vaginal rings, etc.)

Testosterone and Low Desire. We have already established how testosterone mediates sexual desire through effects on the neurotransmitters responsible for excitation and inhibition (Figs. 128.1 and 128.2). As such, there has been consistent evidence from placebo-controlled RCTs that testosterone therapy is more effective than placebo for the treatment of HSDD in postmenopausal women[74,75] when delivered at physiologically normal doses. Furthermore, such doses have demonstrated safety when used short-term, typically 6 months. Initially, testosterone treatments were in the form of oral testosterone and testosterone implants.[76-79] In order to maintain a more consistent and safer level of testosterone while continuing to avoid first-pass metabolism in the liver, transdermal formulations were developed. These included a transdermal testosterone patch releasing 300 mcg of testosterone/day or a cream delivering 5 mg testosterone in 0.5 mL (10 mg/mL) daily.

There are data on the efficacy of using patch-delivered transdermal testosterone for menopausal women with or without concomitant estrogen and progesterone/progestogen for low desire. It also can be used as a single treatment, improving satisfying sexual events, arousal, orgasm frequency, pleasure, responsiveness, and self-image.[80,81] There is likewise a small dataset demonstrating efficacy in late premenopasual women, but this is mainly limited to women closer to the menopasual transition (mean age 39.7 years).[82] A recent metaanalysis demonstrated the need for further research to determine the efficacy of testosterone therapy for premenopausal women with HSDD.[81]

The main concern with testosterone is in regard to safety, both in the short and long term.

Testosterone preparations, specifically intramuscular preparations, subcutaneous implants, and oral formulations (methyltestosterone 1.25–2.5 mg or testosterone undecanoate 40 mg), have wide variation in serum concentrations and limited short- and long-term safety data in women,[11] most of whom were postmenopausal in studies that have been completed. The main side effects of testosterone supplementation (all forms) are acne, hirsutism, and balding, as well as weight gain. Lipid and lipoprotein effects included reduction in total cholesterol, high-density lipoprotein cholesterol, and triglyceride levels along with a statistically significant increase in low-density lipoprotein cholesterol with oral, but not transdermal, testosterone preparations.[81,83]

A major concern is the potential for testosterone to increase the risk of breast cancer, principally through its aromatization to estradiol. Although the data are limited, a metaanalysis of data from over 3000 women using transdermal testosterone, with or without concomitant estrogen and progestin hormone therapy, found that breast density (a surrogate marker for cancer risk) did not change with transdermal testosterone treatment in several small trials with insufficient data to assess long-term breast cancer risk.[81,83]

Long-term safety data are limited. One 4-year study of open-label extension of two, 6-month clinical trials of 300 mcg/day transdermal testosterone patch in 967 women with oophorectomy treated with estrogen therapy showed no increase in the rate of serious AEs.[84] In 2008 a testosterone gel phase II cardiovascular and breast safety RCT required by the FDA to establish safety enrolled 3656 postmenopausal participants over the age of 50 years who had at least two cardiovascular risk factors at baseline (e.g., hypertension, dyslipidemia) and a clinical diagnosis of HSDD.[85] After 4 years, with over 7300 women-years of exposure, the company (BioSante Pharmaceuticals, Inc, Lincolnshire, IL) reported 53 adjudicated cardiovascular events, a lower than anticipated rate, and a low breast cancer rate, which is reassuring. However, although the study was reviewed by an independent data safety and monitoring board that allowed the trial to continue, the data have never been peer reviewed or published.[86] It has been determined that, despite these reassuring outcomes, long-term (beyond 2 years) safety data, particularly regarding breast cancer and cardiovascular events (acute myocardial infarction, stroke, deep vein thrombosis, and death), are limited and inconclusive.[11,81,87,88] To fully satisfy the medical and regulatory agencies' concerns with these important questions would likely require a billion dollars of funding over a decade, which thus severely limits the ability of any naturally occurring product (i.e., testosterone) to be brought to market.[89]

It is recommended that, should a patient and her healthcare provider decide on a therapeutic trial of testosterone, baseline total testosterone should be evaluated.[90] Normal testosterone ranges have been reported for women of different age groups, but there is no minimal value for any androgen that can be used to identify women with HSDD.[13,35] Women using testosterone should have regular follow-up blood testosterone measurements to ensure that supraphysiologic therapy and serum levels are avoided.[11]

Testosterone formulations for women are not globally available, so clinicians are commonly limited to prescribing compounded formulations of 1%, or testosterone formulations for men modified to much lower administered doses (usually one tenth of the male dose). Current guidelines recommend using male formulations, given the reliability of their concentrations.[11]

Other hormonal treatments have been proposed and developed for HSDD. DHEA is a prohormone that is widely available as a supplement. It is converted into testosterone and estrogen *in vivo*.[90] While it has been promoted as improving sexual well-being, and small studies have suggested beneficial effects, systematic reviews and metaanalyses have failed to show this effect.[91-93] Tibolone is a synthetic orally active steroid that is weakly androgenic and lowers SHBG, resulting in an increase in endogenous free testosterone. The data for its efficacy in treating low sexual desire are somewhat limited, with small clinical trials showing efficacy for this endpoint but a larger metaanalysis demonstrating that it is not more effective that placebo.[94]

Genital Arousal and Sexual Pain

Genital arousal and sexual pain are often mediated by local hormonal and inflammatory markers, as mentioned earlier. There is a paucity of data showing the efficacy of any individual treatment for these conditions, with the exception of local hormone therapy for genitourinary syndrome of menopause (GSM).[95,96] GSM is covered elsewhere in this textbook, and thus this section will focus on treatments related to sexual arousal and pain.

There are several nonhormonal treatments that can be used to address sexual arousal disorders. Many of the HSDD medications mentioned earlier have been shown to improve arousal disorders in women, likely through central mechanisms affecting subjective desire. For genital arousal disorders, the main focus of research has been in increasing blood flow and sensation to the local tissue. This can be accomplished via vasodilators, including L-arginine, yohimbe, and sildenafil.[97,98] While these products usually can be compounded, there are over-the-counter formulations that have shown modest benefits (Zestra)[99]

For sexual pain, nonhormonal treatments usually include local neuropathic pain medication, such as lidocaine 2% to 5%, compounded gabapentin 6%, ketamine 10%, and local tricyclic antidepressants (amitriptyline or nortriptyline, 2%–5%), as well as capsaicin.[100] It should be noted that women with sexual pain disorders that are neuropathic in nature also may benefit from systemic treatment with gabapentin, pregabalin, or tricyclic antidepressants, but the data for efficacy are lacking.[101,102]

All women should be counseled about proper use of lubricants for sexual activity. Water-based lubricants are the most common, but may not be the most effective, particularly in circumstances where prolonged duration of sexual activity may require reapplication. Silicone-based lubricants last longer, as do oil-based lubricants, although they may not be safely combined with latex condoms, depending upon the specific active agents. Additionally, there are numerous vaginal moisturizers (typically hydrophilic agents) that purport to improve symptoms of dryness, and thus pain, and while few have actually been studied in rigorous trials, it is well-established that there is no regulation, and indeed very little consistency, in ensuring that both lubricant and moisturizers are pH- and osmolality-balanced for the vagina. [03]

Hormones for Local Vaginal Pain. Given the known sensitivity of vaginal and vulvar tissue to hormonal fluctuations, it is not surprising that local hormone therapy can be effective for sexual pain disorders that are not related to menopause. Separate from menopause-related GSM, many women, both pre- and postmenopausal, suffer from provoked vestibulodynia. This disorder, confined to the vaginal vestibule, is thought to arise in tissues derived from embryonic endoderm. Such tissues may lack androgen sensitivity.[104] As such, this vestibular tissue may require the addition of androgens for pain relief.[44] There are published data supporting the use of both estradiol (0.0%–-0.03%) and testosterone (0.1%) for vestibulodynia.[44] This is first-line therapy for provoked vestibulodynia that can be attributed to hormonal changes, such as that produced by long-term combined hormonal contraceptives, but can also be used for women with other types of provoked vestibulodynia. There is significant evidence for the use of prasterone (DHEA) for dyspareunia, but the research has focused on dyspareunia due to GSM rather than provoked vestibulodynia.[16]

KEY POINTS

- There are two FDA approved treatments for sexual desire disorder in premenopausal women, both targeting neurotransmitters. These treatments also benefit postmenopausal women.
- Testosterone has strong published data documenting benefits for low sexual desire for postmenopausal women, side effects are mainly limited to acne and hirsutism.
- Long-term safety data are limited There are no commercially available testosterone treatments for sexual dysfunctions in women outside Australia; treatment must be with male formulations at reduced doses or compounded therapies.

PERSISTENT GENITAL AROUSAL DISORDER

The final and most unrecognized sexual dysfunction is an entity known as persistent genital arousal disorder (PGAD)/genitopelvic dysethesia (GD). This condition is characterized by persistent sensations of genital arousal in the absence of sexual stimulation or emotion that are considered unwanted and cause the patient at least moderate distress.[46] The proposed etiologies of this condition are plentiful and may involve a range of psychologic, pharmacologic, neurologic, and vascular causes, including medication cessation, genital hormonal changes, local genital masses, and spinal masses.[46] The treatments depend on the etiology, and a detailed history and physical exam, as well as imaging that may involve spinal MRI, are warranted. This condition can lead to significant distress, is often misdiagnosed, and has even been associated with suicide, and should be taken seriously by the evaluating clinician.

CONCLUSION

Female sexual dysfunction is a highly complex set of disorders with multiple etiologies. The practicing endocrinologist may see a range of female sexual health complaints. Each woman should be evaluated from a biopsychosocial perspective to assure incorporation of the many factors that may play a role in a particular patient's presenting symptoms. Once a detailed history is obtained, many women will require a physical exam. The most common sexual dysfunctions are low desire and sexual pain. Sexual arousal and orgasmic disorders and PGAD/GD should be considered. Each of these has specific treatment options depending on a patient's specific complaints, exam findings, and comorbidities. Female sexual health is highly correlated to overall health and well-being and should be considered crucial to any clinical evaluation, and promotion of sexual wellness should be incorporated into any treatment plan for endocrinologic disease.

Pregnancy is a state in which one or more fertilized eggs is retained within the uterus and provisioned with oxygen and nutrients for the specific amount of time required to complete the embryonic/fetal development program. Pregnancy ends by the process of parturition, whereby the products of conception (i.e., the embryo/fetus and extraembryonic tissues) are expelled from the uterus. Hormone signaling networks control pregnancy and parturition by:

- Creating a suitable intrauterine environment to enable attachment and implantation of the embryo.
- Signaling the presence of a viable embryo to sustain a propregnancy uterine phenotype and maternal physiology.
- Controlling implantation of the embryo into the uterine wall and the formation of a placenta.
- Modulating maternal physiology to supply oxygen and nutrients to the conceptus.
- Blocking the process of parturition and physically accommodating the conceptus for a gestational period needed for fetal growth and maturation.
- Triggering parturition at a time when the fetus is sufficiently mature to survive as a neonate.
- Establishing maternal lactation and behaviors required to protect and nurture the newborn.

The hormones of pregnancy include multiple proteins, lipids, and steroids acting in endocrine and/or paracrine modes. This chapter will focus on key hormonal signals that control and coordinate the establishment and maintenance of human pregnancy and the timing and process of parturition.

KEY POINTS

- Pregnancy follows a maturational process leading to delivery of a fetus able to survive in the extrauterine environment.

ESTABLISHMENT OF PREGNANCY

Pregnancy is established by implantation of the developing embryo into the uterine wall. This requires synchrony between a receptive endometrium and a competent embryo. For implantation, the competent embryo, usually at the blastocyst stage, first adheres to luminal epithelial cells of the endometrium and then invades into the uterine wall, where it forms a physical and functional attachment. The process includes development of the placenta to establish a biochemical and physiologic link with the mother.

Preparation of the Endometrium

The uterus is prepared for implantation by the ovarian steroid hormones estradiol and progesterone that induce cyclic changes in morphology and function of the endometrium as part of the menstrual cycle. During the follicular phase of the ovarian cycle, estradiol promotes proliferation and thickening of the functionalis layer of the endometrium. During the postovulatory luteal phase, progesterone induces differentiation of the functionalis into a glandular, secretory, and highly vascularized tissue that is receptive to embryo implantation. In women, the progesterone/estradiol-primed endometrium is most receptive to embryo implantation between days 20 and 24 of the menstrual cycle (i.e., 6–10 days after ovulation).[1] The probability of embryo implantation before and after this time window is low.

KEY POINTS

- Ovarian estrogen and progesterone prepare the endometrium for implantation of the blastocyst 6–10 days after ovulation.

Embryo Competency

Upon fertilization and syngamy, the nascent embryo, while transiting the fallopian tube toward the uterus, undergoes an intrinsic program of cell division and differentiation to become a ball of cells known as a morula, encapsulated by the remnant of the oocyte zona pellucida. At around the fifth day postsyngamy (around day 19 of the menstrual cycle) the morula enters the uterine cavity, where it floats freely for several days. As the number of cells in the embryo increases, differentiation occurs to produce two distinct cell types: (1) the outer trophectoderm composed of trophoblast cells that will differentiate into the extraembryonic tissue (placenta and chorionic membrane), and (2) a cluster of inner cells, referred to as the inner cell mass, that will give rise to the embryo/fetus. Differentiation of the two cell types is influenced by multiple transcription factors, especially members of the homeobox family. A critical step is expression of the NANOG homeobox protein, which drives the differentiation of inner cells to acquire a pluripotency phenotype necessary to give rise to the embryo/fetus.[2] Cells on the surface of the morula do not express NANOG and differentiate to form trophoblast cells that will give rise to the placenta and chorionic membrane.

KEY POINTS

- Cells on the surface of the morula do not express the homeobox protein NANOG and become the trophectoderm that forms the placenta. Inner cells do express NANOG and form the inner cell mass that develops into the embryo.

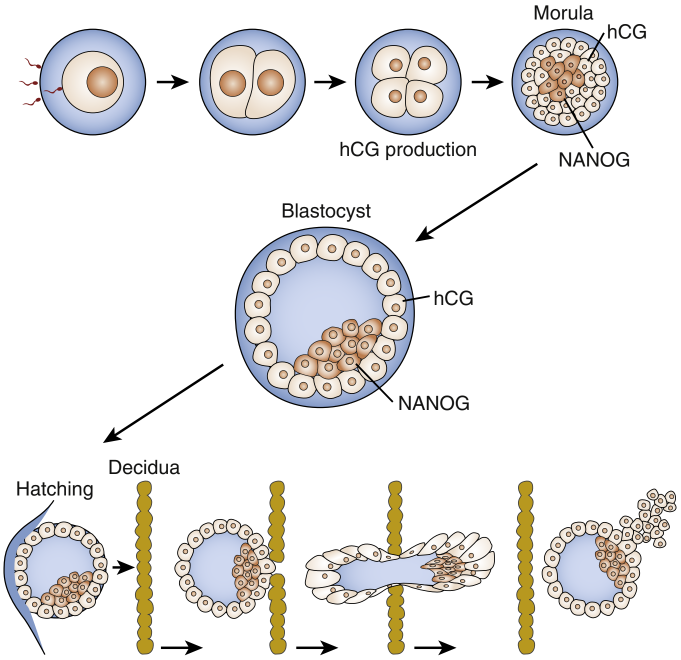

Fig. 129.1 **Formation of the morula with production of human chorionic gonadotropin (*CG*), the first signal to the mother of the presence of pregnancy. As cell division occurs, CG production increases.** The outer cells cease to express homeobox protein NANOG, which is required for totipotency, and form the trophectoderm and later the placenta. These cells transport fluid in an inward direction, leading to the formation of the blastocyst. The central cells, which continue to express NANOG, retain totipotency and form the inner cell mass of the blastocyst and later the embryo. Before attachment of the blastocyst to the endometrial lining of the uterus, the blastocyst hatches from the zona pellucida. The blastocyst then penetrates the decidualized endometrium, and the trophectoderm begins to invade.

At around day 7 the zona pellucida degenerates, and the embryo "hatches" to allow direct contact of trophectoderm with endometrial epithelial cells. At this stage the embryo develops a fluid-filled cavity and is referred to as a blastocyst. At the same time luminal endometrial epithelial cells produce chemokines and cell adhesion molecules that attract the blastocyst to domelike structures known as pinopodes, to which trophoblast cells adhere and produce proteases that degrade the endometrial extracellular matrix (ECM), opening a path for the embryo to migrate into the uterine wall (Fig. 129.1).

Decidualization of the Endometrium

Late in the luteal phase, in fertile and nonfertile cycles, progesterone and increased intracellular cyclic adenosine monophosphate (cAMP) in stromal cells of the endometrium induce changes collectively referred to as decidualization, which includes proliferation and hypertrophy of stromal fibroblasts, formation of a network of contact processes between neighboring stromal fibroblasts, shrinkage and altered secretory activity of glandular epithelial cells, and infiltration of specific leukocytes including natural killer (NK) cells, T-cells, and macrophages.[3-5] Increased cAMP is stimulated by chorionic gonadotropin (CG) secreted by the trophoblast cells of the blastocyst.[6,7] Endometrium in this state is referred to as the decidua. Decidualization begins during the latter part of the luteal phase at endometrial stromal cells adjacent to spiral arterioles. If embryo implantation occurs, the decidualization reaction spreads to include the entire endometrium.

KEY POINTS

- Chorionic gonadotropin secreted by the trophectoderm and progesterone secreted by the maternal ovary transform the endometrium into the decidua that is receptive to implantation.

The decidua facilitates deep implantation and placentation of the embryo and is essential for the establishment and maintenance of human pregnancy. ECM produced by decidualized endometrial stromal cells guides and promotes trophoblast invasion, and the stromal cells provide nutritional support for the implanting blastocyst. However, the dense cellular matrix of the decidua also restricts *de novo* embryo implantation, thus closing the implantation window.[3,5] During pregnancy the decidua exists as three types, determined mainly by anatomy: (1) the basalis that lies directly adjacent to the implantation site and, eventually, the placental disc; (2) the capsularis that surrounds the embryo to separate it from the uterine cavity; and (3) the parietalis that comprises the remainder of the endometrium. The capsularis eventually fuses with the parietalis when the embryo/fetus grows to occupy the entire uterine cavity. Formation and maintenance of the decidua is dependent on progesterone in conjunction with intracellular cAMP in decidual stromal cells.

Implantation and Placentation

The process of implantation and placentation is controlled primarily by paracrine signaling between the embryo and endometrial cells involving multiple hormones including chemokines, cytokines, cell adhesion molecules, matrix metalloproteinases and their inhibitors, *HOX* gene products, and various growth factors and angiogenic factors.[8] These molecules are thought to mediate the effects of progesterone and CG to produce a receptive endometrium and an intrauterine milieu conducive to embryo survival. Locally acting cytokines, especially in response to progesterone, are also thought to condition maternal immune cells resident in the decidua to tolerate the semiallogeneic conceptus.[9]

Trophoblast cells, upon adhesion to pinopodes, produce proteases that degrade the proximate ECM to produce a pathway for invasion of the embryo into the endometrial stroma. Trophoblast cells then divide

Maternal uterine vein
Endothelial cells
Brush border
Syncytiotrophoblast nuclei
Cytotrophoblasts on basement membrane

Fig. 129.2 Cytotrophoblasts grow into the maternal decidua from a basement membrane. The cytotrophoblasts differentiate into several cell types. Some form dense columns of cells that form anchoring villi that attach the placenta to the lining of the uterus, others erode into the maternal spiral arteries and transform into an endothelial phenotype that lines these vessels, and an additional group fuses to form the syncytiotrophoblast layer that lines the villus space.

and differentiate into an invasive phenotype, referred to as cytotrophoblasts, that form columns that penetrate into the uterine wall to anchor the blastocyst deep in the endometrial stroma. Some cytotrophoblasts invade beyond the endometrial basement membrane and through to the inner third of the myometrium toward uterine spiral arterioles, where changes in oxygen tension cause expression of genes that alter their cell phenotype toward that of endothelial cells. The modified cytotrophoblast cells then invade into the arterioles, where they replace the vascular endothelial lining and destroy the arterial smooth muscle. Elimination of endothelial and musculoelastic tissue increases the diameter of the spiral arteries, which significantly increases flow of maternal arterial blood to the conceptus (based on Poiseuille's law: flow through a cylinder is proportional to the fourth power of the radius of the cylinder). This process is critical to ensure an adequate supply of maternal oxygen and nutrients to the developing conceptus, especially in the later stages of pregnancy. Shallow or defective cytotrophoblast invasion into spiral arterioles during implantation is thought to restrict subsequent blood flow to the conceptus and induce a compensatory increase in maternal blood pressure to ensure adequate flow to the placenta. This compensatory mechanism may lead to preeclampsia and/or intrauterine growth restriction.[10,11]

At the same time as vascular cytotrophoblasts invade into the spiral arterioles and disrupt the arterial-venous connection, other cytotrophoblasts fuse to form a multinucleated cell, referred to as the syncytiotrophoblast. At this stage the developing inner cell mass is surrounded by an outer syncytiotrophoblast with a layer of underlying proliferating trophoblast cells, and the embryo is anchored to the uterine vasculature and completely surrounded by endometrial stroma. During embryo invasion, the syncytiotrophoblast forms trabeculae that create fluid-filled spaces, known as lacunae, between the eroded spiral arterioles and associated veins. At the same time cytotrophoblast cells underlying the syncytiotrophoblast proliferate to form finger-like protrusions containing mesenchymal cells from the inner cell mass that eventually form interconnected blood vessels linked to the developing fetal cardiovascular system. The finger-like chorionic villi are the basic units for gas exchange between maternal and fetal blood and for nutrient transfer from the maternal compartment. The entire maternal-facing surface of the chorionic villi network is covered by the syncytiotrophoblast (Fig. 129.2).

During the first trimester vascular cytotrophoblasts occlude the uterine spiral arteries and limit maternal blood flow to the developing embryo. Consequently, early embryo development and organogenesis, especially fetal blood vessels forming in the chorionic villi, occur in a relatively hypoxic state. At weeks 10 to 12 of gestation the vascular plugs of cytotrophoblast cells deteriorate, leading to maternal blood entering the lacunae, where it bathes the network of chorionic villi. At this stage maternal blood directly contacts the syncytiotrophoblast. This form of placentation is referred to as a hemochorial, denoting direct contact of maternal blood with placental cells. The hemochorial arrangement of the human placenta allows the syncytiotrophoblast to secrete hormones directly into maternal blood. Consequently, the endocrine milieu of human pregnancy is dominated by hormones produced by the placental syncytiotrophoblast.[12,13] Cytotrophoblast cells in the amnion-chorion membrane also produce hormones that affect adjacent maternal cells and tissue. Most placental hormones are identical to the non-placental hormones that affect major homeostatic systems. These include hypothalamic-pituitary-adrenal and gonadal hormones, hormones that control metabolism and energy utilization, and hormones involved in the response to stress and the control of lactation. Some placental hormones are close analogs of adult hormones and serve functions specific to pregnancy. In general, placental hormones act to modulate maternal physiology in favor of maintaining pregnancy and provisioning the fetus with oxygen and nutrients.

KEY POINTS

- In the first trimester, cytotrophoblast plugs in maternal arteries maintain the developing embryo in a hypoxic environment. At the end of the first trimester these plugs dissolve, allowing maternal arterial blood to come into direct contact with the syncytiotrophoblast of the placenta. The syncytiotrophoblast layer secretes multiple hormones directly into the maternal blood that reprogram maternal metabolism to direct nutrients to the fetus.

Immune Tolerance of the Conceptus

As an immunologically foreign allograft, the conceptus is potentially at risk from attack by the maternal immune system. For the establishment and maintenance of pregnancy the maternal immune system must tolerate the semiallogeneic conceptus.[14] Several mechanisms have been proposed to explain this effect, each involving paracrine signaling by hormones and cell surface proteins between the syncytiotrophoblast, extravillous trophoblasts, decidual cells, and maternal immune cells at the maternal-fetal interface.

The syncytiotrophoblast and extravillous trophoblasts may camouflage themselves from maternal immune attack. Major histocompatibility complex (MHC) molecules are required for immune recognition and activation of a response to antigens. The usual MHC class I molecules, HLA-A and HLA-B and MHC class II antigens, are not expressed on the syncytiotrophoblast and cytotrophoblast cell surface.[15] However, trophoblasts express classic HLA-C and nonclassic HLA-E and HLA-G. The absence of MHC class I HLA-A and -B molecules prevents cytotoxic CD8 T-cell responses. HLA-C molecules down-regulate NK cell responses towards a tolerogenic state,[16-18] and HLA-G, a unique nonpolymorphic HLA, inhibits decidual NK (dNK) cell activation[19-22]. Syncytiotrophoblast and extravillous cytotrophoblasts also may inhibit proliferation of maternal T-cells in the decidua by catabolizing tryptophan, an essential amino acid for rapidly dividing T-cells.[23,24]

Activity of maternal immune cells at the maternal-fetal interface is also thought to be influenced by progesterone as part of its progestation actions, although the mechanism is not clearly understood. Maternal immune cells have low or undetectable expression of the nuclear progesterone receptor (PR), and as such progesterone actions are not considered to be mediated directly by PRs in immune cells. Instead, progesterone could act indirectly via PR-mediated effects in decidual stromal cells. For example, in decidual stromal cells progesterone stimulates the production of Fas-ligand that induces apoptosis in activated T-cells.[25-27] Progesterone may also induce chemokine activity in decidual cells to recruit dNKs with attenuated cytotoxic activity and increased immunosuppressive activity to the maternal-fetal interface.[28-30] It is also possible that progesterone affects immune cells directly via its interaction with the glucocorticoid receptor (GR). Indeed, the level of progesterone at the maternal-fetal interface (decidua basalis) at term is high (~5 μM) and likely sufficient to activate the GR.[31] Progesterone, likely via the GR, may increase the pool of regulatory T-cells (Tregs) that inhibit inflammatory Th17 cells to promote tolerance to nonself antigens.[32]

The human placental trophoblast cells are remarkable in that they expresses multiple segments of endogenous retrovirus DNA that incorporated into the hominid genome millions of years ago.[33] One particular endogenous retrovirus gene encodes syncytin-1, a placental protein that promotes syncytialization and formation of the syncytiotrophoblast that is crucial for development of the placenta.[34] Placental syncytin-1 protein contains an immunosuppressive domain that may also promote immune tolerance at the maternal-fetal interface.[35,36]

KEY POINTS

- The placental syncytiotrophoblast creates maternal immune tolerance for the semiallogeneic fetus through multiple mechanisms, including production of endogenous immunosuppressive retroviral proteins.

PREGNANCY MAINTENANCE

Placental hormones drive dramatic changes in maternal physiology that favor the developing fetus. For the fetus, early gestation is characterized by differentiation of tissues and organogenesis. From midgestation onward, the focus shifts to accumulation of nutrients, further tissue growth, and the functional maturation of organ and regulatory systems in preparation for its transition to postnatal life. In the mother, early pregnancy is a time of nutrient storage, whereas following midgestation, provision of nutrients to the fetus becomes the primary goal. In addition, the uterus must be maintained in a relaxed, closed, and quiescent state to accommodate and gestate the conceptus. These maternal adaptations are controlled mainly by hormones produced by the fetal-placental unit, the net effect of which is to favor pregnancy and supply the fetus with oxygen and nutrients to complete its developmental program. In this context fetal-placental hormones are allocrine factors, because they are produced by one organism, the fetus, to elicit a response in another organism, the mother.

The human fetal-placental unit produces a wide range of hormones, most of which are identical or close analogs of neuropeptides, hypothalamic-pituitary hormones, steroid hormones, and growth factor and cytokine protein hormones (Table 129.1).[13,37] The hormones are synthesized and released by the syncytiotrophoblast directly into the maternal circulation to act on the same receptors as their maternal counterparts. By this arrangement the placenta becomes an endocrine control center. Some hormones produced by the placenta such as corticotropin-releasing hormone (CRH) are also released into the fetal circulation.

Chorionic Gonadotropin

One of the most important hormones produce by the early embryo that is essential for the establishment of pregnancy is CG (also known as hCG). In a nonfertile cycle the maternal corpus luteum (CL) regresses late in the luteal phase, leading to a decrease in circulating progesterone. Loss of progesterone causes inflammation, vascular remodeling, and necrosis and breakdown in the luteal phase endometrium, which leads to its shedding as menses. The endometrium is then renewed from the remaining endometrial layer in response to estradiol in the following cycle. For pregnancy to occur menstruation must be prevented. To this end, in a conception cycle the early embryo produces CG, a glycoprotein hormone that is structurally and functionally analogous to pituitary luteinizing hormone (LH) (the β-subunits of LH and CG differ, and the α-subunits are identical). CG prevents regression of

TABLE 129.1 Hormones Produced by the Human Placenta

Neuropeptides	Corticotropin-releasing hormone, thyrotropin-releasing hormone, gonadotropin-releasing hormone, melatonin, cholecystokinin, metenkephalin, dynorphin, neurotensin, vasoactive intestinal peptide, galanin, somatostatin, calcitonin gene–related peptide, neuropeptide Y, substance P, endothelin, atrial natriuretic peptide, renin, angiotensin, urocortin, kisspeptin
Pituitary hormones[46]	Adrenocorticotropic hormone, thyroid-stimulating hormone, placental growth hormone, placental lactogen, chorionic gonadotropin, lutenizing hormone, follicle-stimulating hormone, β-endorphin, prolactin, oxytocin
Adipokines	Adiponectin, leptin, resistin, visfatin, ghrelin
Growth factors[46]	Insulin-like growth factor-1, insulin-like growth factor-2, vascular endothelial growth factor, epidermal growth factor, activins, inhibins, follistatin
Cytokines	Interleukin-1, interleukin-2, interleukin-6, interleukin-8, interferon-α, interferon-β, interferon-γ, tumor necrosis factor
Steroids	Progesterone, estradiol, estrone, estriol, estetrol, 2-methoxyestradiol, allopregnanolone, pregnenolone, 5α-dihydroprogesterone
Monoamines	Epinephrine, norepinepherine, dopamine, serotonin, adrenomedullin
Lipids	Prostaglandin-F$_{2\alpha}$, prostaglandin-E$_2$, prostaglandin-I, thromboxane$_{A2}$

the CL and stimulates its continued production of progesterone, maintaining the endometrium and thus preventing menstruation.

Production of CG by the embryo begins at the eight-cell stage under drive from the endogenous retrovirus protein syncytin-1 and is subsequently produced by the syncytiotrophoblast.[38] Blastocyst implantation is associated with the first detectable levels of CG (indicated by levels of the unique β-subunit of CG) in the maternal circulation and urine, and is used as a diagnostic test for pregnancy. During the first trimester, CG in maternal blood increases almost exponentially, doubling every 2 to 3 days in the first 3 weeks of pregnancy. CG levels peak by week 10 to 12 of gestation, and thereafter maternal CG levels decrease to a plateau for the remainder of pregnancy.

As well as affecting the maternal CL, CG also acts on endometrial stromal cells via its interaction with LH/CG receptors to increase intracellular cAMP and sensitize the cells to progesterone. Progesterone in concert with cAMP induces expression of multiple genes in the endometrial stroma to induce decidualization. Thus, one of the earliest endocrine/paracrine signaling events in pregnancy is the production of CG that serves to maintain exposure of the uterus to progesterone, prevent menstruation, and promote decidualization.

Gonadotropin-Releasing Hormone

The human placenta also produces gonadotropin-releasing hormone (GnRH) that is identical to that produced by the hypothalamus.[39] Placental GnRH may regulate CG—as hypothalamic GnRH regulates LH production by the anterior pituitary—in an autocrine/paracrine manner. Levels of circulating GnRH correlate with CG and are highest during the first trimester, and *in vitro* studies show that GnRH stimulates CG production by placenta cells.[40,41]

Proopiomelanocortin-Derived Hormones

The human syncytiotrophoblast expresses proopiomelanocortin (POMC) that serves, as it does in the pituitary, as a precursor via its enzymatic cleavage, for the adrenocorticotropin (ACTH)-endorphin family of peptides: ACTH, β-lipotrophic hormone (β-LPH), α-melanocyte-stimulating hormone (α-MSH), and β-endorphin (β-EP).[42-45] Enkephalins and dynorphins are also produced by the human placenta.[46] The role of placental POMC-derived proteins is unclear. Marked changes in the maternal hypothalamic-pituitary-adrenal (HPA) axis occur during pregnancy, mediated mainly by placental ACTH and possibly other POMC derivatives. Placenta ACTH appears to function primarily in the maternal compartment, because is not sufficient to prevent adrenal hypoplasia in fetal hypopituitarism due to anencephaly. Production of α-MSH is thought to increase skin pigmentation and induce melasma, the mask of pregnancy.[47]

Corticotropin-Releasing Hormone

Production of CRH by the placental syncytiotrophoblast is unique to primates and, within the order, the pattern of production across pregnancy varies. In New World and Old World monkeys, placental CRH production peaks at midpregnancy.[48,49] In contrast, in great apes, including humans, placental CRH production progressively increases around the end of the first trimester and follows an exponential trajectory thereafter, peaking at term.[50] The contribution of the maternal hypothalamus to circulating CRH levels during pregnancy is negligible compared with that of the placenta, and as such maternal CRH levels directly reflect placental CRH synthetic activity. Great apes, including humans, also produce a circulating CRH-binding protein (CRHBP) that is thought to limit CRH bioavailability.[51] For most of pregnancy, CRHBP is present in excess of CRH in maternal blood.[52] A fall in CRHBP levels late in pregnancy is thought to increase bioactive CRH.[53,54] Actions of CRH are mediated by two CRH receptors, CRH-R1 and CRH-R2.[55,56]

CRH attributable to placental secretion can be detected in the maternal blood beginning at around the fifteenth week of gestation. Placental CRH production is modified by estrogen, progesterone, and nitric oxide, which are inhibitory, and by a range of neuropeptides, which are stimulatory.[57-60] Placental CRH production may also be linked to placental development and syncytiotrophoblast size and intrinsic and extrinsic stressors. Placental CRH levels in the maternal circulation increase almost exponentially after the fifteenth week of gestation, with the steepest incline occurring in the 5 weeks before parturition.[61] Late in pregnancy CRH levels in the maternal circulation are approximately 1000-fold higher than in nonpregnant women,[62] and placental CRH is principally responsible for the hyperactivity of the maternal HPA axis and the hypercortisolism that occurs at this time. Maternal hypercortisolism could contribute to the changes in maternal metabolism that promote nutrient transfer, notably by increasing production of glucose transporters in the placenta.[63] The fetus is protected from maternal hypercortisolemia by the 11β-hydroxysteroid dehydrogenase enzyme in the placenta, which converts cortisol to the inactive glucocorticoid cortisone.[64] Alterations in the expression of this enzyme may modulate fetal growth and fetal stress.

The control of placental CRH secretion is complex and includes factors that stimulate CRH expression and release by the hypothalamus.[57] A major difference between placental and hypothalamic CRH secretion is that, unlike the hypothalamus, production of CRH by placental cells is increased by cortisol.[65-67] *In vitro* studies suggest that a positive feedback loop exists whereby placental CRH stimulates ACTH production by the fetal pituitary that increases cortisol production by the fetal adrenal glands that then stimulates further placental CRH production. This positive feedback effect is thought to produce the exponential rise in placental CRH secretion and maternal CRH levels during human pregnancy.[52,68,69] CRH also preferentially increases the production of dehydroepiandrosterone sulfate (DHEA-S) by fetal and

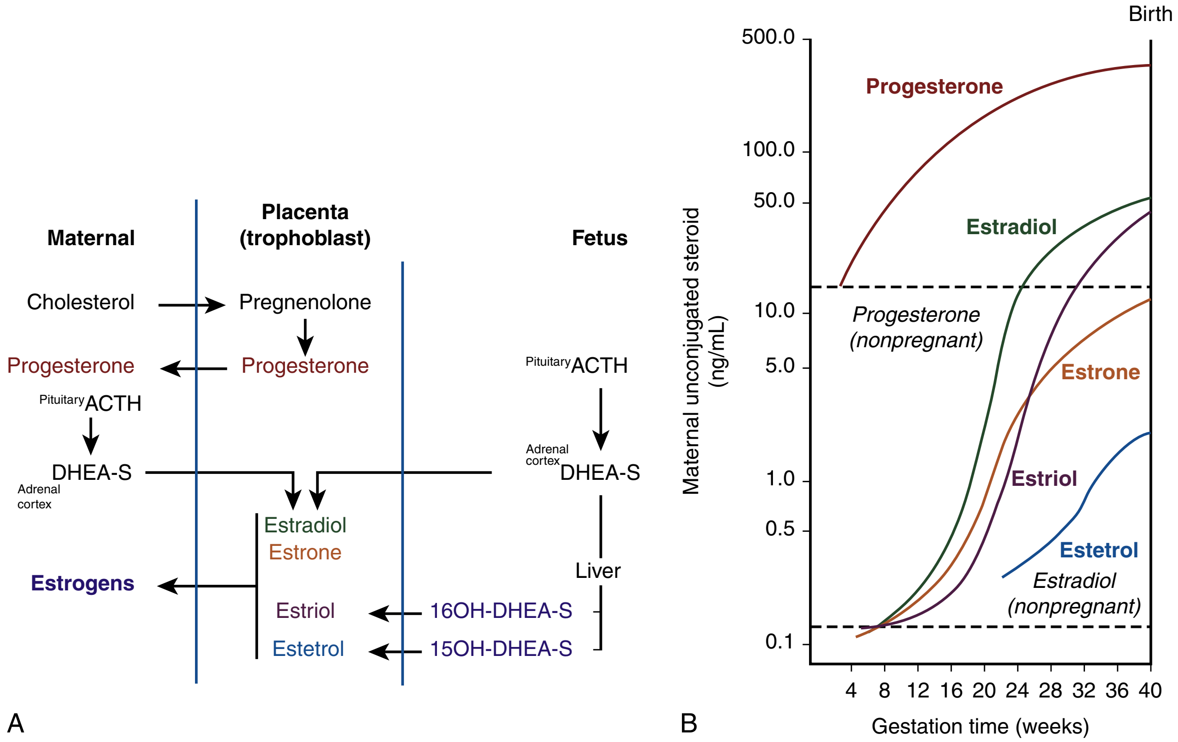

Fig. 129.3 A, Biosynthesis of progesterone and estrogens by the human fetal-placental unit. Progesterone is produced mainly from maternal cholesterol. Estrogens are biosynthesized from C19 androgen precursors (mainly DHEA) produced by the maternal and fetal adrenals. B, Levels of progesterone and estrogens (estrone, estradiol, estriol, and estetrol) in maternal blood during human pregnancy compared with average levels in normal cycling women. Estriol and estetrol are derived from 16OH- and 15OH-DHEA produced by the fetal liver.

adult adrenal cortical cells.[66,70-72] Fetal adrenal DHEA-S is converted to estrogens by the placental cells (see later). Interestingly, the marked rise in placental CRH during the final 10 weeks of pregnancy coincides with increased cortisol production by the fetal adrenals and correlates with increases placental estrogen production during the third trimester. This endocrine loop is thought to play a role in the hormonal control of parturition (discussed later; Fig. 129.3).

Placental Lactogen and Placental Growth Hormone

The human placenta expresses genes encoding members of the growth hormone (GH)/prolactin family. The proteins are encoded by a gene cluster on chromosome 17 that comprises *GH1*, *GH2*, *CSH1*, *CSH2*, and *CSHL1*.[73] *GH1* encodes pituitary GH and is expressed exclusively by pituitary somatotrophs. *GH2* is expressed only by the syncytiotrophoblast and extravillous cytotrophoblasts and encodes a placental GH (PGH) variant that differs from pituitary GH at 13 amino acids. *CSH1* and *CSH2* are duplicated genes exclusively expressed by the syncytiotrophoblast and cytotrophoblasts that encode placental lactogen (PL) that has homology with prolactin and shares some functions with GH. *CSHL1* is a pseudogene that does not produce a protein product. Thus, PL is derived from expression of *CSH1* and *CSH2*.[74]

PGH and PL exert somatogenic and lactogenic activity mediated by the GH and prolactin receptors, respectively. PL is predominantly a lactogen acting via the prolactin receptor, and has weak GH receptor–mediated activity.[74-76] Like pituitary GH, PGH and PL stimulate insulin-like growth factor-1 (IGF-1) production and have similar effects on growth and metabolism.[77]

PL is preferentially secreted into the maternal compartment, is detectable in the maternal circulation early in gestation and rises up to 6000 ng/mL late in the third trimester. Levels of PL in the fetus are 1/100 of the maternal concentration. PGH is only secreted into the maternal compartment, where it becomes detectable at the seventh week of gestation, peaks by the thirty-sixth week, and replaces pituitary GH as the major stimulus to maternal IGF-1 production.[78]

The roles of PGH and PL in the physiology of human pregnancy and parturition are not clearly defined. Fetuses with mutations in the GH/prolactin cluster that causes complete deficiency in PL and GH (PGH and pituitary GH) have severe growth restriction in an otherwise normal pregnancy. In contrast, fetal growth and development, and pregnancy in general, are normal in fetuses with mutations causing complete PL deficiency.[79] Pregnancies bearing mutations causing deficiency in PGH alone have not been identified. Taken together, the experiments of nature suggest that PGH is necessary for fetal growth and that PL is not necessary for normal pregnancy and may function in a redundant manner with PGH. As PGH is secreted into the maternal compartment, it is likely to affect fetal development via actions on maternal cells and tissues. A likely mechanism is that PGH (and PL) modulate maternal energy homeostasis to meet fetal needs, and that disruption of this endocrine axis starves the fetus of energy sources and nutrients, leading to growth restriction. PL and PGH also may affect maternal behavior to facilitate protection and nurturing of the neonate.[80,81]

Modulation of Maternal Energy Homeostasis

The developing fetus must signal its nutrient needs to the mother in step with its growth and development trajectory. This requires changes in maternal food intake and energy handling. In early pregnancy, maternal insulin secretion increases, with minimal alteration in insulin sensitivity. In contrast, insulin resistance is a characteristic feature of late pregnancy and changes maternal metabolism from fuel storage to fuel availability. In normal pregnancy a 50% reduction in insulin-mediated glucose disposal is observed in late gestation.[82,83] The placenta plays a key role in establishing appropriate maternal metabolic adaptations to sustain pregnancy and provide the fetus with nutrient and energy resources. Upon delivery of the placenta, maternal insulin sensitivity reverts to the nonpregnant state.

The genesis of insulin resistance during pregnancy has been attributed to placental hormones; although the exact contribution of specific placental hormones to maternal metabolism is not fully defined. PGH appears to be a major player. In mice, overexpression of human PGH to levels comparable with those in women during the third trimester induces significant peripheral insulin resistance.[84] PGH increases the expression of the p85α subunit of PI3 kinase in skeletal muscle. This acts as a dominant-negative competitor, preventing p85-p110 heterodimers from binding to insulin receptor substrate 1 (IRS-1), effectively producing a postreceptor defect in insulin signaling.[85] Levels of p85α are elevated in human pregnancy.[86]

The extent of insulin resistance during pregnancy does not correlate with maternal plasma levels of estradiol, progesterone, prolactin, or PL.[87] The strongest predictor of insulin sensitivity in pregnant women is instead tumor-necrosis factor-α (TNF-α), a potent proinflammatory cytokine that negatively correlates with insulin sensitivity in early and late pregnancy, even after adjusting for maternal fat mass and body mass index.[88] TNF-α is thought to induce insulin resistance by increasing phosphorylation of IRS-1, impairing downstream signaling from the insulin receptor. The placenta synthesizes and releases TNF-α predominantly into the maternal circulation, and plasma TNF-α concentrations rise by approximately 45% during late pregnancy.[87]

The human placenta also produces the adipokines leptin, adiponectin, resistin, ghrelin, and visfatin, each of which contributes to the control of maternal metabolism, and especially insulin sensitivity.[89] Leptin produced by the placenta is secreted mainly into the maternal circulation to achieve relatively high levels. Pregnancy is, however, associated with leptin resistance, with effects of leptin on eating behavior, satiety, and metabolic activity becoming uncoupled from its circulating levels. Nonetheless, it appears to promotes insulin resistance and fatty acid mobilization from adipose tissue, each of which would favor mobilization of energy sources for fetal use.[90] Leptin levels decline to normal nonpregnant values within 24 hours of delivery.[91] Adiponectin, resistin, ghrelin, and visfatin produced by the placenta and secreted into the maternal compartment likely have similar effects.

Growth Factors and Cytokines

Multiple growth factors and cytokines are produced by the placenta and affect fetal and maternal physiology. The IGFs are important regulators of fetal and placental growth. The IGF system is composed of three ligands (IGF-1, IGF-2, and insulin) that bind to four receptors: the type 1 IGF receptor (IGF-1R), the hybrid insulin/IGF-1R receptor, the mannose-6 phosphate/IGF-2 receptor, and the insulin receptor. Six IGF-binding proteins (IGFBPs) further modulate IGF activity. In particular, IGFBP-1 regulates the action of IGFs in pregnancy by limiting their availability for binding to cognate receptors. Proteases that cleave IGFBP-1 (e.g., pregnancy-associated plasma protein-A) therefore have promitogenic effects by increasing IGF bioavailability.[92] In addition, phosphorylation of IGFBP-1 increases its affinity for IGF-1. Levels of nonphosphorylated IGFBP-1 increase during pregnancy, and large amounts of nonphosphorylated IGFBP-1 in fetal serum have growth-promoting effects.[92] IGFBP-3 is the major carrier of IGF-1 and IGF-2 in the circulation to form a reservoir for IGFs. IGFBP-3 is regulated by GH and increases during pregnancy.[93]

Synthesis of maternal IGFs is modulated by PL and GH. PGH becomes the primary regulator of maternal IGF production as pregnancy advances. Although there is no placental transfer of IGFs, maternal IGFs affect fetal growth by influencing placental structure and function and diverting maternal nutrients to the fetus. Fetal pituitary GH does not control fetal growth, but growth is directly influenced by fetal IGFs and binding proteins, which in turn are regulated by fetal nutrition, insulin, and PL levels. Fetal tissue production of IGFs regulates placental growth.[94] IGF-1 and IGF-2 are expressed in the fetus, but IGF-1 predominates after birth under the stimulus of neonatal GH.[95] Fetal pituitary GH may have a small impact on fetal growth late in the third trimester, as evidenced by the lower birth size of neonates with hypopituitarism or GH insensitivity.[96,97] The placenta is exposed to both maternal and fetal IGFs and synthesizes many components of the IGF system that have roles in trophoblast growth, turnover, and placental exchange.[98]

The syncytiotrophoblast and cytotrophoblast cells express the epidermal growth factor (EGF) family of hormones that includes EGF, heparin-binding EGF-like growth factor, amphiregulin, betacellulin, epiregulin, and transforming growth factor-α.[99] The EGF family of growth factors play key paracrine roles in implantation and trophoblast invasion. Deficiency in EGF expression and/or signaling is associated with preeclampsia and fetal growth restriction.[100,101]

The fibroblast growth factor (FGF) family comprises 23 members (FGF-1 to FGF-23). The human placenta expresses FGF-2 and FGF-10, which are produced by cytotrophoblasts and connective tissue stroma of placental villi.[102,103] FGFs stimulate angiogenesis by affecting endothelial cell proliferation and migration via four high-affinity cell surface FGF receptors (FGFR-1 to -4). In the human placenta, FGFRs are expressed by the mononuclear phagocytic Hofbauer cells,[103,104] and FGF induces Hofbauer cells to produce multiple growth factors and cytokines involved in tissue repair. FGF via Hofbauer cells is thought to promote placental tissue repair and syncytiotrophoblast bud formation that is essential for placental development and growth.

Growth of the placenta with advancing gestation requires coordinated angiogenesis and remodeling of uterine vasculature, and especially the blood supply to the decidua basalis. These processes are affected by the vascular endothelial growth factor (VEGF) family of angiogenic growth factors. Cytotrophoblasts, the syncytiotrophoblast, and villous stromal cells produce VEGF (five isoforms are generated by alternative splicing from a single gene) and placenta growth factor (PLGF; four splice variants)[105-109] that promote formation of new blood vessels and increase vasodilatation and microvascular permeability to enhance tissue perfusion.[110,111] The actions of these factors are mediated by two receptors: FMS-like tyrosine kinase-1 (FLT1) and kinase insert domain receptor (KDR),[112-114] which are present on endothelial cells.[115-117] FLT1 also circulates as a soluble form, sFLT1, that binds and inhibits the angiogenic actions of circulating VEGFs and PLGFs.[118] The etiology of preeclampsia is thought to involve disruption of the VEGF/PLGF system, leading to adverse effects on maternal hemodynamics.[119] Preeclampsia is thought to derive from shallow invasion of trophoblasts into the maternal spiral artery endothelium and muscle walls during early placental development that decreases placental perfusion later in pregnancy.[120,121] Decreased perfusion causes hypoxia that increases VEGF and PLGF production by cytotrophoblasts and the syncytiotrophoblast that, via KDR on endothelial cells, increases release of sFLT1 that is thought to disrupt function of the maternal endothelium and cause hypertension and proteinuria, the typical signs of preeclampsia.[122]

KEY POINTS

- Peptide hormones released by the placenta promote maternal nutrient transfer to the fetus by increasing maternal insulin resistance, but this process predisposes the pregnant woman to gestational diabetes.
- Abnormalities of trophoblast invasion leads to increased release of vasotoxic factors that predispose to preeclampsia.

Steroid Hormones

In all viviparous species examined so far, progesterone is essential for the establishment and maintenance of pregnancy, and its withdrawal or disruption of its biological activity ends pregnancy by triggering parturition.[123] It is aptly referred to as the hormone of pregnancy. During the luteal phase of the menstrual cycle, progesterone prepares the uterus for pregnancy by affecting endometrial growth and function to create an intrauterine environment and endometrial phenotype conducive to embryo survival and implantation. Progesterone induces decidualization of the endometrial stroma that is critical for implantation. It also promotes growth and relaxation of the myometrium and maintains rigidity and closure of the cervix.

Progesterone needed to establish and maintain human pregnancy is initially provided by the maternal CL in response to CG. Removal of the ovaries during the first 6 to 10 weeks of pregnancy leads to abortion.[124] However, at around week 10 of gestation the syncytiotrophoblast of the placenta begin producing progesterone *de novo* from maternal cholesterol, and thereafter become a major source of progesterone. Initiation of the placenta as a source of progesterone is referred to as the luteal-placental shift. After this occurs, pregnancy persists even if the maternal ovaries are removed. Placental progesterone production increases for the remainder of pregnancy and late in third trimester is around 250 mg per day.[125] Consequently, levels of progesterone in maternal blood increase with advancing gestation and during the second and third trimesters are 10- to 20-fold higher than during the luteal phase.[126]

Actions of progesterone to maintain pregnancy are mediated by the nuclear PR isoforms, PR-A and PR-B, present in myometrial, cervical, and decidual cells. The PRs function mainly as ligand-activated transcription factors to affect target cell function by regulating expression of specific genes. That elimination of progesterone (e.g., by ovariectomy before the luteal/placental shift) or treatment with the PR antagonist mifepristone (also known as RU486)[127-129] end pregnancy by inducing parturition reflects the importance of progesterone/PR signaling for the maintenance of pregnancy. Through this signaling pathway, progesterone is thought to affect the expression of genes in myometrial, cervical, and decidual cells whose products promote a uterine phenotype—myometrial relaxation and quiescence, cervical rigidity and closure, and inflammatory quiescence at the chorion-decidual interface—that sustains pregnancy. In the myometrium, progesterone/PR signaling affects expression of genes encoding factors collectively referred to as contraction-associated proteins (CAPs). Progesterone inhibits expression of stimulatory CAPs and increases expression of relaxatory CAPs. Important stimulatory CAP genes include *GJA1,* which encodes connexin-43, a gap junction protein that forms connections between myometrial cells to synchronize contractions, *PTGS2,* which encodes prostaglandin (PG) synthase type 2 that increases local levels of the potent uterotonin, $PGF_{2\alpha}$, and *OXTR,* which encodes the oxytocin receptor to increase responsiveness of myometrial cells to oxytocin, another potent uterotonin. Progesterone/PR signaling also decreases responsiveness of uterine cells to estrogens by inhibiting expression of *ESR1*, which encodes estrogen receptor-α (ERα).[130] This indirectly promotes quiescence by inhibiting estrogen/ERα-induced expression of genes encoding stimulatory CAPs. Progesterone/PR signaling in uterine cells also exerts antiinflammatory effects by decreasing responsiveness to proinflammatory/prolabor stimuli.[131] This is important because proinflammatory stressors may induce parturition via tissue-level inflammation in the myometrium, cervix, and decidua.[132] Thus, progesterone acting via the PRs in myometrial, cervical, and decidual cells maintains pregnancy by promoting a quiescent and compliant uterine phenotype conducive to housing the conceptus, blocking parturition by inhibiting the expression of genes encoding stimulatory CAPs, suppressing responsiveness to estrogen/ERα, and decreasing responsiveness to proinflammatory/prolabor stimuli.

During the menstrual cycle, estrogens (mainly estradiol) stimulate regrowth of the functionalis layer of the endometrium and increase myometrial cell proliferation. Estradiol also increases uterine growth and blood flow to the endometrium and promotes milk gland development in the mammary ductal epithelium in preparation for lactation. During pregnancy estrogens (estrone, estradiol, estriol, and estetrol) increase uteroplacental blood flow via actions mediated by locally produced growth factors and angiogenic factors.[133] Thus, as with progesterone, estrogenic actions also favor pregnancy.

The syncytiotrophoblast of the human placental produces estradiol, estrone, estriol, and estetrol beginning at around week 10 to 12 of gestation.[134] Placental estrogen production increases almost exponentially for the remainder of pregnancy. The syncytiotrophoblast lacks the full set of steroidogenic enzymes to produce estrogens *de novo* from cholesterol but has the capacity to produce estrogens from C19 steroids. The main substrate for placental estrogen formation is DHEA-S produced by the maternal and fetal adrenals in response to ACTH and placental CRH. The syncytiotrophoblast has high levels of sulfatase activity, which converts DHEA-S to DHEA, 3β-hydroxysteroid dehydrogenase activity, which converts DHEA to androstenedione, aromatase activity, which converts androstenedione to estrone, and 17β-hydroxysteroid dehydrogenase activity, which converts estrone to estradiol. The fetal liver also metabolizes DHEA-S to 16-hydroxy-DHEA-S and 15-hydroxy-DHEA-S, which serve as substrates for the synthesis of estriol and estetrol, respectively. Thus, the large amounts of estrogens produced by the human placenta for most of pregnancy are dependent on a supply of C19 steroid, mainly from the fetal adrenal cortex (see Fig. 129.3).

The role of placental estrogens in the physiology of human pregnancy and parturition remains unclear. One conundrum is why large amounts of estrogens are produced by the placenta. Pregnancy and parturition appear normal in cases where placental estrogen production is significantly increased (10- to 100-fold) above the normal range. This is apparent in congenital adrenal hyperplasia, in which the fetal adrenal glands fail to produce cortisol, leading to increases ACTH release (due to loss of cortisol-mediated negative feedback) that increases the supply of DHEA-S to the placenta. Pregnancy and parturition also are normal in cases in which placental estrogen production is significantly decreased (e.g., placental aromatase deficiency; placental sulfatase deficiency; anencephaly; congenital adrenal lipoid hyperplasia). Apart from virilization in the mother and female fetus due to adrenal androgen excess, pregnancy appears to be unaffected by placental estrogen deficiency. This, however, does not exclude a role for estrogens in the control of human pregnancy and parturition, because estrogens from maternal sources (e.g., aromatization of adrenal androgens by adipocytes) are unaffected in cases of placental estrogen deficiency. In fact, in cases of placental aromatase deficiency, maternal estrogen levels were at a physiologically significant range (1–1.6 nmol/L) comparable with levels during the mid and luteal phases of the menstrual cycle.[135,136]

Conditions in which human pregnancy exists in the complete absence of estrogens have not been identified, suggesting that a minimal level of estrogenic drive is necessary for human pregnancy and parturition. In this case the remarkable capacity of the human placenta to convert C19 androgens to estrogens may be important to prevent virilization of the female fetus.

Under the influence of rising estrogen levels produced by the placenta, maternal pituitary lactotrophs increase prolactin production leading to concentrations in maternal serum of 200 to 300 ng/mL at term.[137] This is thought to contribute to mammary gland development in preparation for lactation.

KEY POINTS

- Progesterone is the primary hormone that maintains pregnancy by suppressing the expression of genes encoding contraction-associated proteins such as connexin 43 and cyclooxygenase 2, and by maintaining a closed rigid cervix.

PARTURITION AND BIRTH TIMING

Parturition, the process of birth, is controlled by hormonal signals that affect the contractile state of the uterine smooth muscle, as well as the mechanical integrity of the uterine cervix and the fetal membranes Clinical labor is defined as painful and rhythmic uterine contractions, softening and dilation of the cervix, and weakening/rupture of the fetal membranes. For parturition, the myometrium transforms from a quiescent, relaxed, and compliant phenotype to a highly contractile and excitable state to become the engine for birth, producing the rhythmic, coordinated, and forceful contractions of labor. At the same time, the uterine cervix, which is closed and rigid for most of pregnancy, softens and dilates in response to increased intrauterine pressure caused by the contractions of labor, to eventually expand enough to allow the fetus to be forced into and through the birth canal. In addition, tissue level inflammation in the decidua causes weakening of the adjacent amnion-chorion that leads to rupture of the fetal membranes to liberate the fetus from the amniotic sac. Labor is also associated with tissue-level inflammation that involves the infiltration of activated immune cells into the myometrium and cervix. Thus, the cell targets for the hormonal control of parturition are the smooth muscle cells in the myometrium, cervical stroma cells, and decidual stromal cells at the maternal-fetal interface, and, in each tissue, infiltrating and resident immune cells. In this arrangement, labor status is controlled by the balance between hormonal signals affecting each uterine tissue/cell type that promote labor (i.e., induce myometrial contraction, cervical softening, decidual inflammation/membrane weakening, and tissue-level inflammation) and those that block labor (i.e., promote myometrial relaxation and compliance, cervical rigidity and closure, and decidual immune quiescence and tolerance and prevent tissue-level inflammation). In addition, the hormonal control of human parturition involves factors that initiate the process at a specific stage of gestation that is usually linked with fetal-placental development. Although the hormonal control of this complex process involving multiple tissue and cell types and two organisms, the fetus and the mother, is not yet fully elucidated, several hormones are known to play pivotal roles, including: (1) progesterone, and specifically withdrawal of its propregnancy and labor-blocking effects; (2) estrogens and activation of prolabor estrogenic actions; (3) placental CRH and its effects on fetal adrenal steroidogenic and placental estrogen production; and (4) uterine tissue-level inflammation and net inflammatory stress on the gravid uterus leading to increased production of locally acting prolabor cytokines.

Evolutionary Perspective

Evolution is driven by the natural selection of traits based on the extent to which they benefit reproductive efficiency. The success of pregnancy significantly impacts reproductive efficiency, and therefore the hormonal control of pregnancy and parturition was likely subjected to intense selective pressure. This would explain much of the variation around the common theme of viviparity; e.g., singleton versus polytocus pregnancy; seasonal/cyclic versus continuous fertility; and altricial versus precocial neonates. The appropriate timing of birth is critical for the success of pregnancy, and therefore reproduction, in viviparous species. Preterm birth of an immature fetus imparts major risk for pregnancy failure, with the burden assumed by the immature neonate. Prolonged pregnancy and postterm parturition imparts risk for maternal and fetal survival due to the physical inability to birth an overgrown fetus. Pregnancy in general also confers survival risk on the female, and as such a maternal trigger for parturition likely evolved to end pregnancy to favor survival of the mother and her potential for future pregnancies. In this way, the interests of the female to pass her genes to the next generation via future pregnancies are balanced with those of the fetus, which include the interests of paternal genes, in the current pregnancy. Thus, it has been proposed that extant physiology is the result of evolutionary conflict between the interests borne in maternal and fetal/paternal genomes that significantly impacted the selection of hormonal control mechanisms to regulate the pregnancy and the timing of parturition.[138]

This concept is exemplified by the obstetric dilemma hypothesis that posits that hominid birth timing was impacted by the selective pressures caused by the evolution of bipedalism (obligate bipedal locomotion) and encephalization (increased complexity and relative size of the brain).[139] Obligate bipedalism in hominids began around 3 million years ago and involved changes in the size and shape of the pelvis to increase the efficiency of locomotion. Although this change decreased the size of the obstetric outlet, it likely had little impact on the success of pregnancy until brain and head size began increasing through the process of encephalization around 1 million years ago.[140] Human brain size has remained relatively constant for at least the last 100,000 years.[141] The obstetric dilemma hypothesis posits that increased fetal head size eventually confounded the birth process, requiring selection of traits that trigger parturition before the fetal head becomes larger than the pelvic outlet, a trait that appears to be unique to human lineages. The benefits of continued encephalization would eventually be limited by the reproductive cost of failed pregnancy (i.e., maternal and fetal loss) associated with the difficulty of birthing a large-headed fetus. In this context, encephalization likely exerted strong selective pressure on the hormonal control of birth timing such that gestation was shortened. Among primates, the problems imposed by cephalopelvic disproportion appear to be unique to humans. Comparative studies of neonatal brain size to body size across primate species, and the fact that human neonates are altricial, with a significant amount of brain growth occurring in the first 6 to 12 months after birth, suggest that evolution favored the shortening of human gestation.[142,143] This may have occurred by the selection of specific hormonal interactions to control the timing of parturition leading to birth of an altricial neonate. Successful encephalization also required sufficient energy to facilitate rapid growth of the fetal brain. This could have been achieved by the evolution of deep placentation and invasion of the uterine spiral arteries to maximize access to maternal blood and the secretion of placental hormones such as PL and PGH that induce maternal insulin resistance to increase the supply of glucose for the fetus. A metabolic basis for human altriciality has been proposed that argues that birth occurs when the metabolic demands of the fetus exceed maternal capacity to supply oxygen and nutrients.[144] Although this model challenges the obstetric dilemma, it is feasible that both hypotheses are valid.

Framing the hormonal control of human pregnancy and parturition in the context of the unique natural history puts into perspective extant pathophysiology. Natural selection operates at the population level to reconcile the benefits and costs of traits over multiple generations. With regard to the obstetric dilemma and metabolic constraint hypotheses, both solved the problem of favoring the benefits of encephalization in the context of obligate bipedalism with maternal survival and successful pregnancy. Extant pathophysiologies of pregnancy (e.g., preterm birth, preeclampsia), most of which are unique to humans occur at the individual level and may arise from inefficiencies in hormonal systems that were selected based on net effects at the population level and over multiple generations.

KEY POINTS

- In humans the evolution of bipedalism led to a narrowing of the pelvis. Concurrently the ecological niche occupied by humans favored increased brain size, which became limiting for delivery of the fetus. This resulted in shortening of gestation so that birth occurs before the fetal head becomes larger than the pelvic outlet, resulting in a relatively immature neonate compared to other primates.

Fetal Maturation

Under normal circumstances birth occurs when the fetus is sufficiently mature to survive as a neonate. This involves coordination between functional development of vital organ systems such as the lungs, the immune system, neuroendocrine control axes (especially the HPA axis), and the capacity to regulate energy use and storage and nutrient absorption and utilization. To this end, hormonal signals from the fetal-placental unit feed into the parturition control mechanism such that initiation of labor is synchronized with development. This is achieved by glucocorticoid (cortisol in the human) and is exemplified by parturition in sheep that is triggered by a surge of cortisol produced by the fetal adrenals 1 to 2 weeks before labor that stimulates functional maturation of fetal organs (especially the lungs) and triggers parturition by inducing progesterone withdrawal. Thus, parturition in sheep is controlled by activity of the fetal HPA axis and its production of cortisol, ensuring that birth and fetal maturation are linked. Promotion of fetal maturation by glucocorticoid appears to be a conserved trait across viviparous species, with variation in the source (e.g., fetal or maternal) and type of glucocorticoid (e.g., cortisol or corticosterone), the upstream hormonal axes that control its production, and the stringency with which it is linked to the parturition trigger mechanism. Synthetic glucocorticoid therapy is widely used to promote fetal organ (especially the lungs) maturation in women presenting with preterm labor and threatened preterm birth.

Unlike in sheep, cortisol does not appear to be a trigger for human parturition. Parturition in women occurs normally at term in pregnancies with fetuses that cannot produce cortisol due to anencephaly or the inability to synthesize cortisol due to deficiency in the 21-hydroxylase enzyme.[145,146] Also unlike sheep, administration of synthetic glucocorticoid (usually compounds that are not metabolized by the placenta) to women presenting with threatened preterm birth does not advance the parturition process. Nonetheless, as with other species, cortisol plays a key role in maturing the fetal lungs; hence the success of glucocorticoid therapy to promote fetal lung maturation in cases of threatened preterm birth. However, the fetal adrenals are not the exclusive source of cortisol for fetal maturation. In human pregnancy cortisol from the maternal compartment contributes to promoting fetal maturation. Evidence for this is that late in the third trimester maternal estriol levels are inversely associated with circadian maternal cortisol levels, suggesting that some maternal cortisol leaks through the placenta to suppress the fetal HPA.[147] Thus, the hormonal control of human parturition is not dependent on activity of the fetal HPA axis and may involve redundancy to ensure that parturition and fetal maturation occurs even if the fetal HPA axis, and especially production of fetal cortisol, is disrupted.

Progesterone Withdrawal

Clinical and animal data support the general consensus that, for most of pregnancy, progesterone actively blocks parturition, and loss of this activity induces changes in the uterine tissues to initiate the parturition cascade. The progesterone withdrawal trigger for parturition can occur by two mechanisms: (1) systemic or local decreases in bioavailable progesterone, and (2) desensitization of uterine target cells to the labor-blocking actions of progesterone. In animals in which the maternal CL is the exclusive source of progesterone throughout pregnancy (e.g., mouse, rat, rabbit), parturition is triggered by CL regression leading to systemic progesterone withdrawal. In other animals (e.g., sheep) in which progesterone is supplied by the placenta, parturition is induced by a prepartum surge in fetal adrenal cortisol that decreases placental progesterone secretion by inducing its conversion to estradiol.[148] The coordinated systemic progesterone withdrawal and increased estradiol transforms the uterine tissues to the labor state.

Human parturition occurs without a systemic progesterone withdrawal. Circulating levels of progesterone are high (compared with midluteal-phase levels) for most of pregnancy and persist during parturition, decreasing only after delivery of the placenta.[149] In this scenario progesterone withdrawal could be induced by loss or disruption of progesterone/PR signaling. Indeed, clinical and animal data show that the PR antagonist mifepristone promotes labor and, in most cases, induces the full parturition cascade at any stage of pregnancy, despite high circulating levels of progesterone.[150] Thus, human parturition is likely induced by functional rather than systemic progesterone withdrawal that involves physiological controlled changes in PR transcriptional activity in uterine cells.

Uterine cell responsiveness to progesterone is mediated by the relative abundance and transcriptional activities of the PR isoforms, PR-A and PR-B, that function as ligand activated transcription factors. *In vitro* studies have revealed possible molecular mechanisms by which progesterone/PR signaling in myometrial cells blocks labor. The data suggest that progesterone via PR-B decreases responsiveness to estrogens by inhibiting estrogen receptor expression,[130] decreases expression of genes encoding prolabor CAPs by increasing expression of transcriptional repressors such as ZEB1,[151] and inhibits responsiveness to proinflammatory/prolabor stimuli.[131,132] The PR-mediated functional progesterone withdrawal trigger for parturition centers on inhibiting these, and likely other, actions of progesterone/PR-B signaling in uterine cells. Several mechanisms have been proposed (Fig. 129.4). In most progesterone-responsive cells, PR-A inhibits the transcriptional activity of PR-B and this is considered to be a mechanism for target cell autoregulation of progesterone responsiveness, such that progesterone/PR transcriptional activity is inversely related to the PR-A/PR-B ratio.

KEY POINTS

- The onset of human labor is associated with a functional withdrawal of progesterone action caused by various mechanisms including increased transrepressive activity of PR-A and increased intracellular metabolism of progesterone.

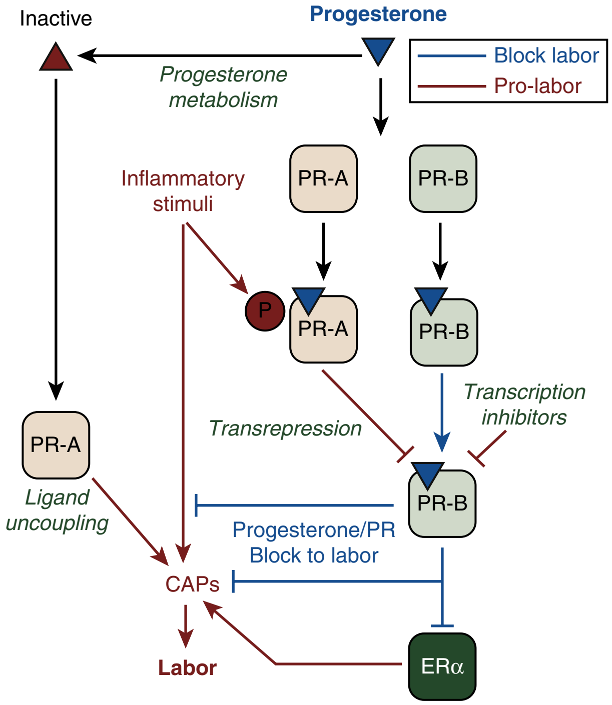

Fig. 129.4 Possible mechanisms for progesterone withdrawal in human pregnancy and mechanism for the progesterone block to labor. Upon ligand binding, progesterone receptors (PRs) dimerize and become activated as transcription factors. For most of pregnancy, progesterone acting via PR-B exerts anti-inflammatory activity to block inflammation-induced labor, inhibits contraction-associated protein gene expression, and inhibits responsiveness to estradiol by inhibiting expression of estrogen receptor-α. Functional progesterone withdrawal could be mediated by (1) increased PR-A transrepressive activity via phosphorylation of PR-A; (2) increased transcriptional repressor activity; (3) local metabolism of progesterone to an inactive form; that (4) generates unliganded PR-A, which increases expression of prolabor-associated genes in myometrial cells.

The onset of labor in women at term is associated with increased abundance of PR-A compared with PR-B in the myometrium,[152] and PR-A transrepressive activity in myometrial cells is induced by proinflammatory/prolabor stimuli via site-specific serine phosphorylation of PR-A.[153] This effect of PR-A may inhibit the capacity for progesterone/PR-B to block labor. PR-B transcriptional activity could also be inhibited by increased expression and activity of corepressors and reduced interaction of PR-B with DNA elements.[154-156] It is also possible that target cells metabolize progesterone to a form that fails to activate PRs causing a localized progesterone withdrawal.[157,158] *In vitro* studies in myometrial cells suggest that progesterone metabolism produces unliganded PR-A that directly induces expression of genes encoding stimulatory CAPs.[159] Thus, a significant body of data suggests redundancy in the mechanisms for the functional progesterone withdrawal trigger for human parturition. This is consistent with the importance of this process for the success of pregnancy.

Stress and Tissue-Level Inflammation

Human parturition is considered an inflammatory event that involves localized inflammation in the uterine tissues characterized by activation of resident tissue immune cells and the infiltration of activated immune cells.[160-162] Studies in mice and rhesus macaques show that the onset of labor is preceded by inflammation in the uterine tissues,[163,164] and parturition is induced by intrauterine administration of proinflammatory stimuli.[165-167] In women, preterm birth is closely associated with intrauterine infection, clinically silent upper genital tract infection, and bacterial vaginosis.[168-175] One hypothesis derived from those observations is that human parturition is triggered by inflammatory stress load impacting the uterine effector tissues (myometrium, decidua, and cervix). In this scenario, an inflammatory load threshold exists, above which various mechanisms for localized progesterone withdrawal are induced (Fig. 129.5). One mechanism by which progesterone/PR signaling maintains pregnancy is to inhibit the responsiveness of uterine cells to proinflammatory stimuli (i.e., an antiinflammatory effect). Studies in myometrial cells suggest that the inhibitory actions of PR-A are induced by site-specific serine phosphorylation in response to proinflammatory stimuli.[153] Based on those data it is proposed that for most of pregnancy progesterone/PR-B signaling in uterine cells blocks labor by exerting anti-inflammatory effects and that an inflammatory load threshold exists, above which specific protein kinase activity is activated that phosphorylates PR-A to induce its transrepressive effect on progesterone/PR-B anti-inflammatory activity. Inflammatory stimuli coupled with loss of progesterone/PR-B anti-inflammatory activity causes tissue-level inflammation and the production of cytokines, especially PGs, that transform the myometrium and cervix to the labor state. Inflammatory drivers of human parturition could be intrinsic (e.g., fetal maturation, uterine wall distention, maternal nutritional stress) or extrinsic (e.g., intrauterine infection; maternal environmental, and psychosocial stress) and involve numerous local and endocrine hormones that converge on the activation of PR-A transrepressive activity in uterine cells to cause progesterone withdrawal.

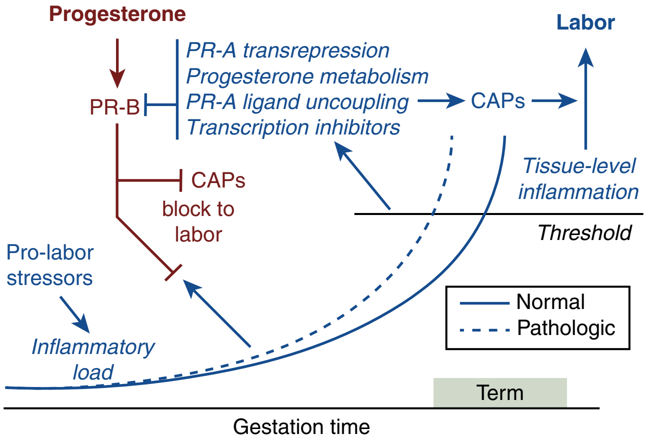

Fig. 129.5 Threshold-limited mechanism for inflammation-induced parturition by induction of progesterone withdrawal in response to net inflammatory load impacting progesterone/PR target cells in the gravid uterus. According to this model the timing of parturition is determined by the inflammatory load trajectory and the threshold for inflammation-induced progesterone withdrawal.

Progestin Therapy to Prevent Preterm Birth

The use of progesterone supplementation as a strategy to prevent preterm labor and preterm birth was proposed soon after progesterone was identified and isolated in the early 1930s. The core assumption is that risk for preterm birth derives from a deficiency of progesterone, and that this can be corrected by progesterone supplementation. The fact that circulating levels of endogenous progesterone in women throughout pregnancy are high and remain elevated even during labor and delivery (this was not known in the 1930s) challenges the biological plausibility for progesterone supplementation.

Nonetheless, in the 1950 (when sufficient stocks of purified progesterone became available for clinical studies) trials of progesterone were conducted. Administration of progesterone as a high-concentration (~1 g) intravenous or intraamniotic bolus in laboring women had no tocolytic activity.[176,177] Subsequent trials focused on prophylactic progesterone supplementation to reduce risk for preterm birth. During the 1960s to 1980s, small clinical trials of progesterone and 17-hydroxyprogesterone-caproate (17HPC) prophylaxis indicated a beneficial effect in reducing risk for preterm birth.[178,179] This led to larger trials in the 1990s that also indicated that progestin supplementation reduces the risk for preterm birth; but only in women with elevated risk for preterm birth.[180,181] More recent clinical trials,[182,183] however, have produced negative outcomes, and consequently progestin prophylaxis to prevent preterm birth remains controversial.[178-180] However, subsequent larger trials[182,183] however, have produced negative outcomes, and consequently progestin prophylaxis to prevent preterm birth remains controversial.

Estrogens

Estrogenic actions on the gravid uterus are generally thought to promote labor by increasing expression of genes encoding prolabor CAPs (e.g., *GJA1*, *OXTR*). In most species maternal estrogen levels increase during the prelude to parturition. Human pregnancy is characterized by a highly estrogenic state beginning at around the end of the first trimester, when the fetal adrenal-placenta steroidogenic axis produces large amounts of estrone, estradiol, estriol, and estetrol (see earlier). Thus, for most of human pregnancy the uterine tissues are exposed to high levels of estrogen, yet effects to promote labor appear to be blocked. One possible reason for this is that progesterone inhibits expression of *ESR1* (which encodes ERα) in uterine cells, thus suppressing the capacity for estrogens to promote labor. This effect decreases upon progesterone withdrawal, which releases the inhibition of *ESR1* expression allowing ERα to mediate prolabor estrogenic effects. Interestingly, abnormalities that compromise placental estrogen production (e.g., placental aromatase deficiency) do not affect the timing of birth, suggesting that the high estrogen levels are not necessary for normal parturition.[135,136,184] In all cases of placental estrogen deficiency, however, the gravid uterus was exposed to estrogens produced in the maternal compartment. Experiments of nature in which human pregnancy exists in the complete absence of estrogens have not been reported. Thus, it appears that relatively little estrogen is required for normal human parturition. Parturition is also normal in pregnancy with abnormally high estrogen levels due to congenital adrenal hyperplasia.[145] These observations suggest that estrogen effects in human parturition are not dependent on circulating levels, provided a minimal amount exists, but are instead controlled by increased uterine tissue estrogen responsiveness (i.e., functional estrogen activation) that may be induced by progesterone withdrawal.

KEY POINTS

- Increased estrogenic activity at term drives increased expression of genes encoding contraction-associated proteins. The increased estrogenic activity is mediated by alterations in estrogen receptor–mediated signaling pathways.

Integrative Role of Placental Corticotropin-Releasing Hormone

The timing of human parturition is associated with the rate of increase in circulating CRH production during the course of pregnancy[52,68] (Fig. 129.6). Levels of placental CRH in maternal blood follow an exponential function. The rate of exponential increase in circulating CRH beginning at around the end of the first trimester correlates with birth timing. The rate of increase in maternal CRH during the second and third trimesters is greater in women destined to deliver before term compared with women who deliver at term, and lowest in women who deliver postterm. Small changes in the exponential function early in pregnancy lead to large differences between different women later in pregnancy that are associated with pre- and postterm birth. Given the large variations among individuals, it is likely that the rate of rise of maternal concentrations of CRH reflects physiologic changes that lead to labor, and as such is a predictor of birth timing, and that this is determined during the first trimester.[52,185] The exponential increase in maternal plasma CRH also reflects the increasing volume of the syncytiotrophoblast and the exponential increase that occurs in syncytiotrophoblast nuclei with advancing gestation that is in part controlled by syncytin-1–induced fusion of cytotrophoblasts with the syncytiotrophoblast. Thus, the rise in maternal CRH concentrations may also be viewed as a developmental process within the placenta leading to delivery. In this context, placental CRH production may be part of a clock mechanism that links placental development to gestational length,[52] all driven by an endogenous retrovirus.

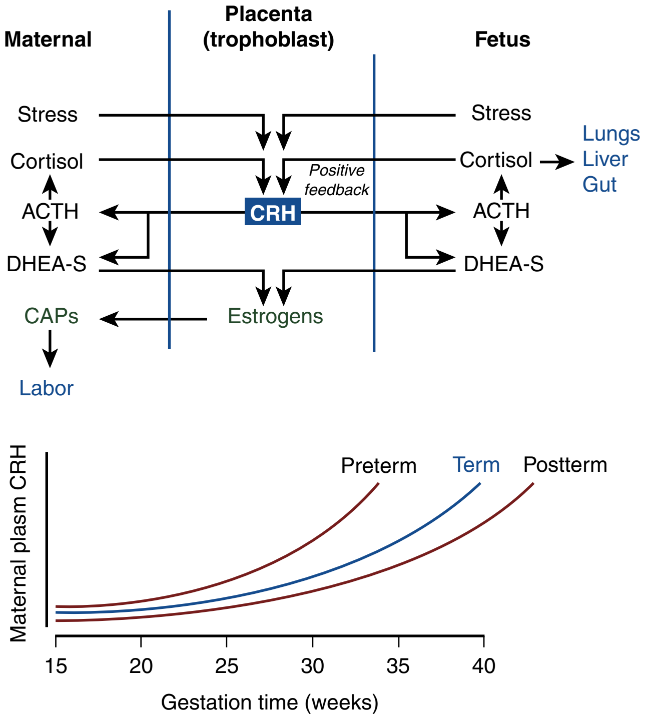

Fig. 129.6 Top: Central role of placental corticotropin-releasing hormone (*CRH*) in controlling fetal organ system maturation via fetal cortisol and parturition via estrogen production by the fetal-placental unit. Placental CRH stimulates adrenal cortical steroidogenic activity either directly (for DHEA) or via adrenocorticotropin. Cortisol exerts positive feedback on placental CRH production and stimulates functional maturation of fetal organ systems. Bottom: Maternal blood CRH levels in human pregnancy increase exponentially after midgestation. The rate of increase is associated with the timing of parturition.

Placenta CRH may influence birth timing by affecting maternal and fetal physiology. Although it is secreted predominately into the maternal blood, physiologically relevant amounts are also released into the fetal circulation. In the mother, CRH receptors are present in the pituitary and the myometrium. In the fetus, CRH receptors are present in the pituitary and in the adrenal cortex and lung.[186] In the mother, placental CRH increases ACTH production by the pituitary, which in turn increases cortisol production by the adrenals. Consequently, maternal cortisol levels increase during the course of pregnancy in concert with CRH levels, although the effect of CRH is moderated by the circulating CRHBP and desensitization of CRH receptors by continuous exposure to high concentrations of CRH.[187,188] Nonetheless, increased levels of CRH and ACTH promote cortisol and DHEA-S production by the maternal adrenals, with DHEA-S serving as a maternal-derived substrate for placental estrogen synthesis. CRH may also directly affect contractility of the myometrium. For most of pregnancy, myometrial cells express mainly CRHR1, a Gs-coupled receptor linked to adenylate cyclase that, in response to CRH, increases formation of cAMP, which promotes relaxation of the myometrium.[189]

Placental CRH is also released into the fetus, and although circulating fetal CRH concentrations are lower than in the maternal circulation, they still rise with advancing gestation. In the fetus, CRH receptors are present on the pituitary[190] and on the cells that form the fetal zone of the adrenal cortex.[191] Stimulation of the fetal pituitary by CRH increases ACTH production and consequently increases the synthesis of cortisol and DHEA-S by the fetal adrenal glands. One possible hormonal cascade initiated by placental CRH is that rising fetal cortisol concentrations induce maturation of the fetal lung. This in turn is associated with increased production of surfactant protein A and phospholipids that have proinflammatory actions in the myometrium and fetal membranes that increases production of prostaglandins in those tissues that act locally to induce the labor phenotype.[192] CRH may also directly stimulate fetal lung development and surfactant phospholipid synthesis.[186] CRH also directly promotes the production of DHEA-S by fetal zone cells in the fetal adrenals, therefore increasing placental estrogen production.[191]

In summary, positive feedback systems in the mother and fetus drive an exponential increase in placental CRH production as pregnancy advances. Increasing placental CRH affects fetal and maternal adrenal steroidogenesis to increase cortisol and estrogen (via increasing adrenal DHEA-S) production. Cortisol promotes fetal organ maturation, especially the lungs (see Fig. 129.6). Thus, placental CRH may be a link between placental development and its response to physiologic stressors that influences multiple hormonal pathways, each contributing to the coordination of fetal maturation with the timing of parturition.

KEY POINTS

- Placental CRH production is linked to maturational processes that lead to parturition. Increased maternal CRH concentrations are linked to preterm delivery while low levels are associated with post-dates delivery. Placental CRH production is linked to fetal adrenal androgen production and increased placental estrogen synthesis.

CONCLUSION/FUTURE DIRECTIONS

Despite meeting the significant metabolic and physical demands of the conceptus, females survive the stress of pregnancy and usually have multiple pregnancies. This finely tuned biological state is critical for species propagation, and as such extant physiology is the product of millions of years of natural experimentation and selection. The leading edge of this process is hormonal signaling between the fetal/placental and maternal compartments. Maternal adaptations to establish and maintain pregnancy, and then end pregnancy at a specific stage of gestation by the process of parturition, are mediated by multiple fetal and maternal hormones acting via endocrine and paracrine modes. We have described some of the key hormones controlling these processes. Continued research in this field will eventually reveal the specific roles of hormones and hormonal systems in the physiology and pathophysiology (e.g., pre- and postterm birth; preeclampsia; gestational diabetes) of human pregnancy and parturition and provide clinical tools (e.g., hormone levels as risk biomarkers) and therapeutic targets to promote pregnancy wellness and prevent adverse pregnancy outcomes.

Successful pregnancy involves complex genetic, cellular, and hormonal interactions facilitating implantation, placentation, fetal development, parturition, and fetal adaptation to extrauterine life. An array of signaling molecules, transcription factors, and epigenetic events program embryogenesis and fetal development, in concert with autocrine, paracrine, and endocrine networks of hormones that coordinate maternal-placental-fetal interactions. A growing understanding of the spectrum of hormones and their mechanisms of action, as well as advances in molecular genetics, has helped to elucidate the physiology of fetal endocrine systems and the pathological basis of many neonatal disorders. It is becoming clear that the intrauterine environment can also have a significant impact on the lifelong health of an individual, as well as exerting multigenerational effects. This chapter reviews our current understanding of the transplacental passage of hormones, development of fetal endocrine systems, fetal growth, and adaptations of the fetal endocrine systems to extrauterine life and endocrine disorders affecting the neonate.

OVERVIEW

The unfolding of our understanding of mammalian pregnancy and fetal development represents one of the dramatic chapters of scientific progress during the past half-century. Successful pregnancy involves complex genetic, cellular, and hormonal interactions facilitating implantation, placentation, embryonic and fetal development, parturition, and fetal adaptation to extrauterine life. The evolution of pregnancy is accompanied by dramatic changes in the hormonal milieu. This is a time of not only potential vulnerability but also tremendous plasticity. An array of signaling molecules, transcription factors, and epigenetic events program embryogenesis and fetal development, in concert with autocrine, paracrine, and endocrine networks of hormones and growth factors that coordinate maternal-placental-fetal interactions.

The placental-fetal endocrine environment includes a wide spectrum of placental hormones and growth factors and a variety of fetal endocrine adaptations to the intrauterine environment. The fetal adrenal cortex, the para-aortic chromaffin system including the paired organs of Zuckerkandl, and the intermediate lobe of the pituitary are prominent among the unique fetal endocrine tissues. Cortisol and thyroid hormones are largely inactivated during much of fetal life but are programmed to serve critical maturational events during fetal development. Vasotocin, the parent neurohypophyseal hormone in submammalian species, is expressed transiently during fetal life, and calcitonin, a largely vestigial hormone in adult mammals, plays a significant role in fetal calcium and bone metabolism. Other hormones and growth factors that play prominent roles in the fetus include catecholamines, parathyroid hormone (PTH)–related protein (PTHrP), anti-Müllerian hormone (AMH), insulin-like growth factor 2 (IGF-2), transforming growth factor-α (TGF-α), and the neuroregulins. Furthermore, hormonal programming during the fetal-perinatal period conditions the adult functional characteristics of selected endocrine systems.

At parturition, the fetus is faced with the abrupt termination of placental support and rapid transition to the extrauterine environment, in which breathing, circulatory adjustments, endogenous thermogenesis, free water conservation, and mobilization of energy substrates are required for survival. The adrenal cortex and the autonomic nervous system (ANS) play key roles in neonatal transitional physiology, but other endocrine systems are required for optimal homeostasis.

A growing understanding of the spectrum of hormones and their mechanisms of action, as well as advances in molecular genetics, has helped to elucidate the physiology of fetal endocrine systems and the pathological basis of many congenital endocrine disorders. It is becoming increasingly clear that the intrauterine environment not only enables fetal development but can also have a significant impact on the lifelong health of an individual, as well as exerting multigenerational effects.

This chapter reviews our current understanding of the transplacental passage of hormones, development and programming of the fetal endocrine systems, fetal growth, and adaptations of the fetal endocrine systems to extrauterine life and endocrine disorders affecting the neonate.

PLACENTAL HORMONE PRODUCTION AND TRANSFER

The fetal endocrine milieu is largely independent of maternal hormones because the placenta acts as a selective barrier and is impermeable to most peptide hormones. Hormones larger than 0.7 to 1.2 kD have limited or no access to the fetal compartment.[1] Steroid (cortisol), thyroid hormones (T_3, T_4), catecholamines, and estradiol do cross the placenta but are metabolized *en route*.[2–5] The placental cells contain an active 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2) that catalyzes the conversion of maternal cortisol to inactive cortisone.[3,6] This is important considering the steep gradient between maternal cortisol concentration and that of the fetus, amounting to almost a 10-fold difference. Synthetic glucocorticoids (betamethasone, dexamethasone) bypass this protective mechanism. This is utilized acutely in preterm labor to aid lung maturation; however, chronic use in rodent models has been shown to adversely affect fetal growth, as well as postnatal effects on blood pressure, glucose homeostasis, and memory.[7–10] Antenatal steroid treatment for indications other than the obstetric management of threatened preterm delivery lacks robust evidence (e.g., to reduce virilization of a fetus with congenital adrenal hyperplasia [CAH]).[11,12]

Placental production of estrogens in the form of estradiol, estrone, estriol, and estetrol is vast, and by term, the estradiol concentration is 100-fold higher and estriol is 1000-fold higher than in the nonpregnant state.[13] Placental 17βHSD catalyzes inactivation of estradiol to estrone, preventing the passage of excessive estrogens to the fetus.[4]

Transplacental passage of thyroid hormones to the fetus, particularly in the first trimester, is important for neurodevelopment. Placental tissue contains an iodothyronine inner-ring monodeiodinase, which deiodinates most of the T_4 to inactive reverse triiodothyronine (rT_3) and converts active 3,5,3'-triiodothyronine (T_3) to inactive diiodothyronine.[5,14] Nonetheless, there is some transplacental passage of T_4 to the fetus in early pregnancy and this may be of importance as observational studies have suggested altered intellectual function, albeit mild, in infants born to mothers with mild untreated or subclinical hypothyroidism (although this may also be due to placental transfer of thyroid peroxidase TPO antibodies).[15]

Catecholamine-degrading enzymes in placental tissue include both monoamine oxidase and catechol *O*-methyltransferase,[3,9] and both metanephrine and dihydroxymandelic acid metabolites of catecholamines are present in placental homogenates.[16]

In addition to this role in hormone metabolism, the human placenta subserves an important endocrine role during fetal development (see Chapter 129). The placenta is a major source of many of the hypothalamic neuropeptides. Table 130.1 summarizes the menu of placental hormones and growth factors, similar or identical to those secreted from the anterior pituitary (AP, such as placental growth hormone [GH] and placental lactogen) or other nonplacental organs. The significance of many of these remains unclear, but the overall contribution to the unique endocrine environment is substantial.

KEY POINTS

- Pregnancy produces a unique endocrine milieu.
- The fetal endocrine environment is largely independent of maternal hormones because the placenta acts as a selective barrier, impermeable to most peptide hormones.

ECTOPIC FETAL HORMONE PRODUCTION

Human chorionic gonadotropin (hCG) is produced abundantly in the first trimester by the placenta and is preferentially secreted into the maternal circulation.[17] hCG and luteinizing hormone (LH; a structural and functional homolog of hCG produced by the AP) bind to the same receptor, although hCG has a higher binding affinity. hCG is present in the fetal circulation. Kidney, liver, and testes from 16- to 20-week-old human fetuses produce immunoreactive and bioactive hCG *in vitro*.[18,19] Kidney tissue produces nearly half as much hCG per milligram of protein as placenta; liver activity is lower. hCG is also found in the fetal ovary, lung, adrenal, thymus, spleen, and muscle.[20] hCG is able to stimulate the production of dehydroepiandrosterone (DHEA) and testosterone by Leydig cells, which is important for masculinization of fetal tissues. hCG signaling in other tissues may be important for their growth and differentiation.[21,22]

Adrenocorticotropic hormone (ACTH)–like immunoreactivity is present in relatively high concentrations in neonatal rat pancreas and kidneys.[23] This hormone is presumably derived from a pro-opiomelanocortin (POMC) parent molecule. POMC is also secreted by the fetal lung and is known to alter adrenal sensitivity to ACTH. The interplay between fetal pituitary, lung, and adrenal may regulate response to stress or the onset of parturition.[24]

Ghrelin is a hormone with potent GH-releasing activity produced by human gastric endocrine cells and by the pituitary, hypothalamus, and placenta. Fetal lung is an additional source of circulating ghrelin, whose function is as yet unknown.[25,26]

Hypothalamic neuropeptides (thyrotropin-releasing hormone [TRH], corticotrophin-releasing hormone [CRH], GH-releasing hormone [GHRH]) are present in a variety of adult tissues, particularly in the pancreas and gut.[27,28] In the fetus, hypothalamic neuropeptides are also present in the gut and tissues derived from it. High concentrations of TRH and somatostatin immunoreactivity have been reported in neonatal rat pancreas and gastrointestinal tract tissues, whereas hypothalamic concentrations are low.[29,30] These neuropeptides have immunoreactive and chromatographic properties similar to those of the synthetic hypothalamic peptides. Encephalectomy does not alter the circulating TRH levels in the neonatal rat, whereas significant reductions are produced by pancreatectomy. In the sheep fetus, thyroid hormones modulate pancreatic and gut TRH concentrations, which suggests thyroid hormone control of extrahypothalamic *TRH* gene transcription or translation in the fetus.[31] TRH and somatostatin are also present in the human neonatal pancreas and in the blood of the human newborn where both hormones are derived mostly from extrahypothalamic sources.[32–35] The presence of TRH at high concentrations in fetal ovine blood and the modulation of fetal pancreatic, placental, and blood TRH levels by thyroid hormones suggests a role for extrahypothalamic TRH in the control of fetal pituitary thyrotropin secretion before the near-term maturation of hypothalamic TRH.[31] The role of extraneural somatostatin in the fetus is undefined. CRH is produced by the placenta and is identical to hypothalamic CRH. The circulating maternal concentration of CRH increases 1000-fold as pregnancy progresses, reaching 0.5 to 1 nmol/L at term. Fetal CRH concentrations are lower (50 pmol) but are still substantial compared to nonpregnant women and men (<0.01 nmol/L). Placental *CRH* expression and production are stimulated by glucocorticoids (in

Transfer and metabolism of norepinephrine studied from maternal to fetal and fetal to maternal sides in the in vitro perfused human placental life. *Am J Obstet Gynecol.* 1984;148:474–481.

contrast to hypothalamic CRH).[36] This positive feed-forward system for placental CRH is unique to pregnancy. *In vitro* placental CRH stimulates pituitary ACTH from cultured primary adrenal cells. This suggests that *in vivo* placental CRH may stimulate pituitary ACTH production, promoting fetal adrenal steroidogenesis.[37–39] The fetal adrenal is an androgen factory, producing substrate for placental estrogen synthesis. The exponential increase in maternal CRH from 35 weeks' gestation to term has led to the proposal that this acts as a biological clock, initiating the onset of parturition by increasing estrogen production.[40]

GH-V encodes placental GH, and *hPL-A*, *hPL-B*, and *hPL-L* encode placental lactogens (hPL; also called chorionic somatomammotropins [CSH]). The major circulating placental lactogens are derived from the *hPL-A* and *hPL-B* genes. *GH-V* rises sharply after midgestation to a peak at 34 to 37 weeks and, within 1 hour after delivery of the placenta, it disappears from the circulation.[41] *GH-V* is not secreted into the fetal circulation and exclusively plays a role in maternal and possibly uteroplacental physiology. hPL is structurally homologous to GH but functionally closer to prolactin (PRL) and is secreted directly into both fetal and maternal circulations. hPL is first detected in the mother at 6 weeks of gestation to reach a peak of 5000 to 7000 ng/mL at 32 to 35 weeks; fetal hPL concentrations, however, approximate 20 to 50 ng/mL at term. hPL concentrations increase with placental mass and are higher in twin than in singleton pregnancies. In the mother, lactogens affect insulin production, hypothalamic gene expression, and leptin action and so maintain metabolic homeostasis while providing the substrates for nutrition for the fetus and newborn infant. Placental GH-V is secreted into the maternal circulation and reduces insulin sensitivity in the mother and so spares glucose and other nutrients for transplacental delivery and fetal growth. As a counterbalance, insulin production and beta-cell mass increase during pregnancy.[42] At least in rodents, evidence suggests that PRL and placental lactogen signaling through the PRL receptor are essential for the increase in beta-cell mass. A surge in PRL concentration in the perinatal period parallels an increase in beta-cell replication, and a whole-body knockout of the PRL receptor reduces beta-cell mass and insulin secretion in the perinatal period.[43]

KEY POINTS

- Ectopic hormone production by the fetus is evident but often has uncertain functional significance.

FETAL ENDOCRINE SYSTEMS

Fetal endocrine systems can be classified as shown in Table 130.2. The neuroendocrine hormone systems transduce or convert neural into

  - Perinatal hormonal programming

endocrine information. These include the hypothalamic-AP system and the hypothalamic-posterior pituitary (PP) system. The insulin-glucagon and PTH-calcitonin systems function autonomously, with hormone secretion regulated largely by local feedback mechanisms. The events of parturition dispel the period of protected fetal development and precipitate a series of profound metabolic stresses. The neuroendocrine transducer systems are well developed at birth and function smoothly to defend against these stresses. The autonomous endocrine systems regulating blood glucose and calcium concentrations, however, are relatively suppressed *in utero* and must adapt rapidly to the extrauterine environment. Abnormalities related to homeostasis of blood glucose and calcium concentrations are relatively frequent in the early neonatal period, particularly in premature babies.

THE HYPOTHALAMIC-PITUITARY SYSTEMS

The pituitary is located in the midline of the brain within the sella turcica and consists of three lobes of dual embryologic origin. The adenohypophysis (anterior and intermediate lobes) originates from Rathke's pouch, an invagination of the oral ectoderm. The neurohypophysis (posterior lobe) develops from the neural ectoderm of the ventral diencephalon.[44–47]

The AP consists of five different cell lineages producing six hormones: somatotrophs (GH), gonadotrophs (follicle-stimulating hormone [FSH] and LH), corticotrophs (ACTH), thyrotrophs (thyroid-stimulating hormone [TSH]), and lactotrophs (PRL).

The intermediate lobe contains melanotrophs, which secrete POMC, a major precursor to endorphins, and α-melanocytic–stimulating hormone (α-MSH).[48] Cleavage of POMC in the anterior lobe produces corticotropin and β-lipoprotein. The human fetal pituitary contains high concentrations of compounds resembling α-MSH and corticotropin-like intermediate lobe peptide (CLIP).[49,50] The role of these peptides in the human fetus remains unclear. CLIP and α-MSH may both play a role in fetal adrenal activation, and α-MSH may influence fetal growth.[51,52] Intermediate lobe cells begin to disappear near term and are virtually absent in the adult human pituitary.[53]

The PP releases two hormones, oxytocin and antidiuretic hormone (ADH; also known as arginine vasopressin [AVP]), which are produced in the hypothalamus (supraoptic and paraventricular nuclei) and transported axonally via the pituitary stalk to be stored and released from the PP.[54]

Pituitary Development. The human fetal forebrain is identifiable by 3 weeks' gestation. The diencephalon and telencephalon can be seen by 5 weeks, and by this point, Rathke's pouch separates from the primitive pharyngeal stomodeum.[55–57] The hypothalamus, pituitary stalk, and PP are largely developed by 7 weeks' gestation, and the bony floor of the sella turcica is present separating the adenohypophysis from the primitive gut.

Pituitary development results from temporospatial interactions of transcription factors and signaling molecules. These occur in distinct and sequential developmental steps, which are critical for pituitary organogenesis. Although direct evidence in humans is lacking, the process of pituitary development is highly conserved across all vertebrate species including rodents; development of the mouse pituitary, in particular, is very well-characterized.[55]

In the mouse, the pituitary placode appears at embryonic (E) day 7.5, located ventrally to the anterior neural ridge and next to the future hypothalamo-infundibular region, which will give rise to the roof of the oral cavity (Fig. 130.1). During the next 24 hours, as the anterior neural tube bends and rapidly expands, the hypophyseal placode is displaced ventrally to become situated under, and in contact with, the prospective forebrain within the ectoderm at the roof of the future oral cavity. By E9.0, it invaginates dorsally and the rudimentary Rathke's pouch is formed.[58] The definitive Rathke's pouch, formed by E10.5, gives rise to the anterior and intermediate lobes. The posterior lobe is derived from the posterior part of the developing diencephalon. The overlying neural ectoderm evaginates to form the infundibulum (from which the PP and pituitary stalk will derive), which comes into direct contact with Rathke's pouch. The juxtaposition of Rathke's pouch and the diencephalon is maintained throughout the early stages of pituitary organogenesis. This close relationship is required for tissue interactions between neural and oral ectoderm, which are critical for the initial stages of pituitary specification. By E12.5, the pouch is completely separated from the underlying oral ectoderm; precursors of the hormone-secreting cells start to proliferate ventrally from the pouch to constitute the future AP. The lumen of the pouch persists as the pituitary cleft, separating the anterior and intermediate lobes in the mature gland. The iterative nature of the inductive interactions required for pituitary morphogenesis makes it very sensitive to both loss- and gain-of-function mutations.[59]

Hormone-producing terminally differentiated cells in the adult AP are organized in three-dimensional homotypic cell networks. In the embryo, the first differentiated cells appear as isolated cells, but rapidly aggregate with other cells producing the same hormone into strands of cells and then into three-dimensional networks. The first hormone-producing network to appear is the POMC lineage at E13 in the mouse, followed by the somatotrope/lactotrope and gonadotrope

network. A network of thyrotrope cells has not been visualized thus far.[60] Specialized AP cell types, including lactotropes, somatotropes, corticotropes, thyrotropes, and gonadotropes, can be recognized in the human AP between 7 and 16 weeks.[57]

The fetal pituitary can synthesize and secrete GH by 8 to 10 weeks' gestation. Pituitary GH increases from ~1 nmol (20 ng) at 10 weeks to 45 nmol (1000 ng) at 16 weeks. The high plasma GH concentrations after the development of the pituitary portal vascular system at midgestation may reflect unrestrained secretion.[57] Control of GH secretion matures progressively during the last half of gestation and during the first few weeks of postnatal life; the mechanisms are not yet fully understood, however, mature responses to sleep, glucose and l-dopa are present by 3 months of age. GH pulsatility is evident soon after birth in humans, but trough concentrations are higher than in later life so random GH sampling can be used to screen for GH deficiency (GHD) in the neonatal period.[61]

Fetal plasma PRL is low until 25 to 30 weeks' gestation and increases to 11 nmol/L at term. PRL increases in response to TRH and decreases in response to dopamine. Brain and hypothalamic control of PRL matures late in gestation and during the first few months of postnatal life.[57]

There is a general tendency toward hypersecretion of fetal pituitary hormones during the last half of gestation. Pituitary hormones found at high concentrations in cord blood from aborted human fetuses and premature human infants include GH, TSH, ACTH, β-endorphin, β-lipotropin, LH, and FSH.[57,62] Development of hypothalamic-pituitary control involves maturational events in the cortex and midbrain, the hypothalamus and hypothalamic-pituitary portal vascular system, peripheral endocrine systems, and perhaps placental hormone and neuropeptide production. The fetal pituitary hypersecretion appears to be related to relatively delayed maturation of the central nervous system (CNS) and hypothalamic control of secretion of the hypothalamic-releasing hormones.[57]

The fetal neurohypophysis is well developed by 10 to 12 weeks' gestation. Fetal pituitary oxytocin concentration, detectable by 11 to 15 weeks, exceeds AVP concentration by 19 weeks. In the fetus, AVP appears to function as a stress-responsive hormone. The major potential stress for the fetus is hypoxia. Plasma AVP concentrations in human cord blood are elevated in association with hypoxia, bradycardia, and meconium passage.[63] Water channel receptors (aquaporins 1, 2, 3) are present in the newborn infant to regulate free water clearance in response to volume and osmolar stimuli.[64] Lack of AVP is associated with diabetes insipidus (DI) with a failure to retain water resulting in polyuria and polydipsia postnatally. DI may be due to congenital causes such septo-optic dysplasia (SOD; a combination of pituitary, eye, and midline forebrain defects) or holoprosencephaly (HPE), or rarely be due to mutations in the *AVP-neurophysin* gene.

Hypothalamus and Pituitary Stalk Development. The anatomy of the developed hypothalamus is well understood. It extends from the anteriorly located optic chiasm to the posteriorly located mammillary body and is organized into distinct rostral-to-caudal regions: preoptic, anterior, tuberal, and mammillary. The hypothalamus is also subdivided into three medial-to-lateral regions: periventricular, medial, and lateral.[65] Contained within the medial region is the medial preoptic nucleus, anterior hypothalamus, the dorsomedial nucleus, the ventromedial nucleus, and the mammillary nuclei. The lateral zone consists of the preoptic area and hypothalamic area.[65]

As Rathke's pouch invaginates, part of the ventral diencephalon evaginates ventrally to form the infundibulum and later the PP lobe and pituitary stalk. The pituitary stalk acts as a physical connection between the pituitary gland and brain and contains the hypophyseal (hypothalamo-pituitary) portal system, as well as the neuronal connections traversing across the hypothalamic median eminence. The neurons originate from hypothalamic magnocellular bodies termed the supraoptic, suprachiasmatic, and paraventricular nuclei. The former two nuclei release AVP, while the paraventricular nuclei release oxytocin.[66] The median eminence contains a capillary bed into which parvocellular neurons, located in a variety of hypothalamic nuclei, secrete hypophysiotropic hormones, which then reach the anterior and intermediate pituitary lobes via the hypophyseal portal system. These stimulate the release of the seven anterior/intermediate pituitary lobe hormones via the hypophyseal portal system. The parvocellular neurons also secrete oxytocin and AVP, although at much lower concentrations than the magnocellular neurons, with the parvocellular-derived AVP acting synergistically with CRH in regulating ACTH release. It is therefore evident that it is the hypothalamus that is the central mediator of growth, reproduction, and homeostasis, acting through the pituitary gland.

Deciphering embryonic hypothalamic development has proved problematic, due to its anatomical complexity and highly diverse collection of cell groups and neuronal subtypes.[67] Furthermore, genetic expression studies within the hypothalamus have knock-on effects on multiple neuronal subtypes and downstream physiological processes. However, studies are slowly elucidating hypothalamic development.

The hypothalamic cell condensations, which represent the hypothalamic nuclei, and the interconnecting fiber tracts are demonstrable by 15 to 18 weeks.[57,68] Hypothalamic neurons and diencephalic fiber tracts for the neuropeptides somatostatin (SS), GHRH, TRH, and gonadotropin-releasing hormone (GnRH) are visible by this time. Concentrations of dopamine, TRH, GnRH, and SS are significant in hypothalamic tissue by 10 to 14 weeks of gestation.

Maturation of the pituitary portal vascular system continues through 30 to 35 weeks, and the system becomes functional with portal vascular extension into the hypothalamus. The definitive Rathke's pouch comprises proliferative progenitors that will gradually relocate ventrally, away from the lumen as they differentiate. A proliferative zone containing SRY (sex-determining region Y)-box 2 [SOX-2]–expressing progenitors is maintained in the mouse embryo in a periluminal area and was recently found to persist in the adult.[69–71] These progenitors are capable of giving rise to all of the cell types within the AP.

Secretory granules are present within AP cells by 10 to 12 weeks, and pituitary hormones, including GH, prolactin (PRL), TSH, LH, FSH, ACTH, oxytocin (OT), vasotocin (VT), and arginine vasopressin (AVP), can be identified by immunoassay between 10 and 17 weeks.[57,62]

Thus the anatomy and biosynthetic mechanisms that make up the hypothalamic-pituitary neuroendocrine transducer appear functional by 12 to 17 weeks of gestation.

Genes Involved in Pituitary Development and Disease. Normal pituitary development is complex, involving a cascade of signaling molecules and transcription factors that play a crucial role in organ commitment, cell proliferation, cell patterning, and terminal differentiation (Fig. 130.1).

Cells within the primordium of the pituitary are initially competent to differentiate into all cell types. Following expression of the earliest markers of pituitary gland development (e.g., homeobox gene expressed in embryonic stem cells [*Hesx1*]), further signaling pathways are established that direct these cells toward terminal differentiation. Signaling molecules and transcription factors are expressed sequentially at critical periods of pituitary development and many are subsequently attenuated (Fig. 130.2A,B). Genes that are expressed early are implicated in organ commitment but are also implicated in repression and activation of downstream target genes that have specific roles in directing the cells toward a particular fate. Extrinsic molecules within the ventral diencephalon and surrounding structures, such as bone morphogenetic proteins 2 and 4 (B*mp 2, 4*), fibroblast growth factor 8 (F*gf8*), sonic hedgehog (S*hh*), wingless (W*nt4*), thyroid transcription factor 1 (T*tf1*; also called N*kx2.1*), and molecules involved in Notch signaling play critical roles in early organogenesis.[55,56,72] A close interaction between oral ectoderm and neural ectoderm is critical for the initial development of the pituitary gland. Formation of the rudimentary Rathke's pouch is dependent upon *Bmp4*, and *Fgf8* activates two key regulatory genes, LIM homeobox 3 (*Lhx3*) and LIM homeobox 4 (*Lhx4*), that are essential for subsequent development of the rudimentary pouch into a definitive pouch. Both *Bmp4* and *Fgf8* are present only in the diencephalon and not in Rathke's pouch. Murine mutations within the gene encoding TTF1/Nkx2-1 (also known as thyroid-specific enhancer-binding protein), which is expressed only in the presumptive ventral diencephalon, can cause severe defects in the development of the diencephalon and AP. Conditional deletion of *RBPJ* that encodes RBPJ (recombination signal binding protein for immunoglobulin kappa J region), the major mediator of the Notch pathway, leads to the conversion of the late pituitary-specific transcription factor 1 (*Pit1*) lineage into the early corticotroph lineage. Notch signaling is required for maintaining the expression of prophet of Pit1 (*PROP1*), which is required for the generation of the *Pit1* lineage. Attenuation of Notch signaling is necessary for terminal differentiation in *Pit1* cells and for maturation and proliferation of the GH-producing somatotrophs.[73]

Generally, mutations in genes involved in early development (*HESX1*, *LHX3*, *LHX4*, *SOX2*, *SOX3*, *GLI2*, and *OTX2*) tend to be part of a syndrome that includes extrapituitary defects and midline abnormalities, such as cleft lip and/or palate, and eye abnormalities, as well as congenital hypopituitarism. Conversely, mutations in genes implicated in later stages (*PROP1* and *POU1F1*) result in variable phenotypes of combined pituitary hormone deficiencies (CPHD) without any extrapituitary defects.[74]

The variety of phenotypes seen in patients with CPHD is a reflection of the close developmental relationships seen during organogenesis of the pituitary gland, eye, optic nerve, ear, nose, and cranial nerve ganglia. Different gene mutations can result in the same phenotype, and different phenotypes can be secondary to the same single genetic mutation. Therefore the clinical phenotype and associated morphological findings are crucial in the investigation of the underlying genetic mutations of cases of CH.

Spontaneous or artificially induced mutations in the mouse have led to significant insights into human pituitary disease, and identification of mutations associated with human pituitary disease has in turn been invaluable in defining the genetic cascade responsible for the development of this embryological tissue.[55,75] No genetic etiology has been identified in the vast majority of cases of CH to date, suggesting a role for other unidentified genes, oligogenic disease, or environmental factors. However, it is also likely that further genes implicated in hypothalamo-pituitary disease will be identified that play a role in hypothalamic development. Mutations involved specifically in human hypothalamo-pituitary disease[74] are listed in Table 130.3 and will be briefly discussed below.

Syndromic Forms of CH. Syndromic forms of CH are mainly due to mutations in transcription factors implicated during early pituitary development.

SOD and Its Variants. SOD (de Morsier syndrome) is a heterogeneous and complex disorder comprising at least two of the following: (1) optic nerve hypoplasia (ONH), (2) midline abnormalities seen in brain and pituitary magnetic resonance imaging (MRI) (mainly agenesis of the corpus callosum (ACC) and absence of the septum pellucidum), or (3) pituitary hypoplasia with hypopituitarism. The prevalence of SOD is 1 in 10,000 live births.[74,76–78] Transcription

factors, such as *HESX1, SOX2, SOX3,* and *OTX2*, are the most common genes to date implicated in the etiology of SOD.

Genetic mutations implicated in Kallmann syndrome (KS; a disorder characterized by hypogonadotropic hypogonadism, anosmia/hyposmia, cleft lip/palate, sensorineural hearing loss, dental anomalies, synkinesia, and renal abnormalities), such as *KAL1, FGFR1, PROKR2,* and *FGF8*, have also been recently identified in patients with SOD.[44,74,79]

HESX1: *HESX1* is a member of the paired-like class of homeodomain proteins, the initial activation of which may be dependent upon *LHX1* and *OTX2*. *Hesx1*, one of the earliest markers of the pituitary primordium, can be detected in the anterior forebrain from E7.5 to E8.5 and in Rathke's pouch from E8.5 to E135.[80] *Hesx1* is rapidly downregulated from E12 and becomes undetectable by E13.5.[81] *Hesx1* is a transcriptional repressor and its downregulation activates other downstream genes such as *Prop1*, suggesting that both function as opposing transcription factors. Targeted disruption of *Hesx1* in mice results in anophthalmia or microphthalmia and midline neurological defects (such as absent septum pellucidum and pituitary hypoplasia), reminiscent of SOD.[82] The first homozygous missense mutation reported in *HESX1* (p.R160C) was described in two siblings with SOD, born to consanguineous parents, who presented with a hypoplastic AP gland and panhypopituitarism, ACC, and ONH.[83] Since then, several homozygous and heterozygous *HESX1*

TABLE 130.3 Genes With Reported Pathogenic Variants Known to Cause Hypothalamo-Pituitary Disease

Gene With Reported Variants	Phenotype	Mode of Inheritance
ARNT2	CPHD, congenital abnormalities of the kidneys and urinary tract	Recessive
CDON	PSIS	Dominant
EIF2S3	GHD, TSHD, glucose dysregulation, MEHMO syndrome	X-linked
FGF8	HH/KS; HPE	Dominant
FGFR1	HH/KS, SOD	Dominant
FOXA2	CPHD, HI, childhood-onset diabetes, choroidal coloboma, biliary atresia (cardiac/endoderm-derived organ abnormalities)	Dominant
GH1	IGHD Type IA	Recessive
	IGHD Type IB	Recessive
	IGHD Type II	Dominant
GHRHR	IGHD Type IB	Recessive or dominant (rare)
GLI2	HPE, IGHD/CPHD, polydactyly, single central incisor	Dominant: haploinsufficiency
GPR161	PSIS	Recessive
HESX1	IGHD, CPHD, SOD	Dominant or recessive
IFT172	GHD, retinopathy, metaphyseal dysplasia, renal failure (ciliopathies)	Compound heterozygous
IGSF1	TSHD, hypoprolactinemia, transient GHD; usually with macroorchidism	X-linked
KAL1	HH/KS	X-linked
KCNQ1	GHD, maternally inherited gingival fibromatosis	Dominant
LHX3	CPHD, short neck with limited rotation	Recessive
LHX4	CPHD, Chiari malformation, cerebellar abnormalities, respiratory distress	Dominant or recessive
MAGEL2	Arthrogryposis with hypopituitarism (anterior and posterior pituitary hormone deficiencies, learning difficulties, scoliosis, dysmorphic features, central sleep apnoea, ONH	Maternally imprinted: paternal or de novo mutation
OTX2	IGHD, CPHD, SOD, anophthalmia/microphthalmia, retinal dystrophy	Dominant: haploinsufficiency or dominant negative
PCSK1	IAD, GHD, TSHD, DI, malabsorption	Dominant, compound heterozygous
PNPLA6	Oliver-McFarlane and Laurence-Moon syndrome; GH and gonadotrophin deficiencies	Recessive
POMC	IAD; early-onset obesity and red hair pigmentation	Recessive
POU1F1	GH, TSH, and ACTH deficiencies	Dominant or recessive
PROKR2	HH/KS	Recessive
PROP1	CPHD, pituitary tumors	Recessive
RAX	Anophthalmia/microphthalmia, CPHD, DI, and cleft palate	Recessive or compound heterozygous
RNPC3	IGHD	Recessive
ROBO1	PSIS	Dominant
SOX2	HH, anophthalmia/microphthalmia, learning difficulties, hypothalamo-pituitary tumors	Dominant
SOX3	GHD, CPHD, absent infundibulum, persistent craniopharyngeal canal	X-linked
TBC1D32	Craniofacial dysmorphism, cleft palate, post-axial polydactyly, hypopituitarism with EPP, Joubert-like findings on MRI	Recessive
TBL1X	TSHD, ASD	X-linked
TBX19	IAD	Recessive
TCF7L1	SOD	Dominant
TRHR	TSHD	Recessive
TSHB	TSHD	Recessive

ASD, Autism spectrum disorder; *CPHD,* combined pituitary hormone deficiency; *DI,* diabetes insipidus; *EPP,* ectopic posterior pituitary; *GHD,* growth hormone deficiency; *HH,* hypogonadotropic hypogonadism; *HI,* congenital hyperinsulinism; *HPE,* holoprosencephaly; *IAD,* isolated adrenocortical deficiency; *IGHD,* isolated growth hormone deficiency; *KS,* Kallmann syndrome; *MEHMO,* mental retardation, epileptic seizures, hypogonadism with hypogenitalism, microcephaly and obesity; *PSIS,* pituitary stalk interruption syndrome; *SOD,* septo-optic dysplasia; *TSHD,* thyroid-stimulating hormone deficiency.

mutations have been described. The majority of cases are sporadic and about 1% of patients with SOD present with genetic mutations in *HESX1*. In some patients, the penetrance is variable, suggesting the impact of additional genetic or environmental factors. There is no clear genotype-phenotype correlation, and clinical features range from isolated GHD to CPHD, associated in some cases with SOD and pituitary malformations.[84–87] MRI findings are variable, including a hypoplastic or aplastic AP and an ectopic PP.

SOX2: *SOX2* is a transcription factor member of the SRY-related HMG box (SOX) family. Expression of *SOX2* occurs at 4.5 to 9 weeks' gestation during human development within Rathke's pouch and is maintained throughout AP development as well as in the diencephalon. *SOX2* is expressed throughout the developing CNS as well as in sensory placodes, inner ear, cochlea, and in the developing lens, retina, and optic nerve.[88,89] *SOX2* plays an important role in the maintenance of pituitary progenitor cells and their differentiation into all hormone-producing lineages.[90] Murine *Sox2* loss-of-function mutations result in a phenotype that includes GH, TSH, and gonadotrophin deficiencies.[91] Heterozygous *de novo* mutations in humans have been observed in patients with hypogonadotropic hypogonadism, anophthalmia/microphthalmia (bilateral, often severe), small corpus callosum, hippocampal abnormalities, and variable learning difficulties.[92] Esophageal atresia has also been reported.[93] The pituitary phenotype occasionally includes GHD. Imaging of the hypothalamo-pituitary region can show hippocampal abnormalities, hypoplasia of the corpus callosum, hypothalamic hamartoma, and pituitary enlargement that is reminiscent of tumors.[94]

SOX3: *SOX3* is also a member of the SOX family. It is located on the X chromosome (Xp27.1) and is expressed along the full length of the CNS including the brain and spinal cord. *SOX3* dosage is critical for normal hypothalamic-pituitary development and both under- and overdosage of the gene can lead to hypopituitarism.[95,96] Male patients present with variable hypopituitarism (CPHD or idiopathic GHD) and infundibular hypoplasia, an ectopic/undescended PP and abnormalities of the corpus callosum. Learning difficulties are also frequently reported in these patients.[95] Patients with duplication of *SOX3* can present with GHD without other pituitary defecits.[97] Loss-of-function polyalanine expansions and gene deletions are associated with hypopituitarism including GH, TSH, ACTH, and gonadotrophin deficiencies. Neuroradiological features including a hypoplastic AP, absent pituitary stalk, and ectopic PP are associated with *SOX3* sequence variants or whole gene deletions/duplications. Persistence of the craniopharyngeal canal has been reported in association with a *SOX3* deletion.[98]

OTX2: Orthodenticle homeobox 2 (*OTX2*) is a transcription factor gene involved in the brain, eye, nose, and ear development.[99] *Otx2* is expressed from E10.5 to E14.5 in the ventral diencephalon, from E10.5 to E12.5 in Rathke's pouch. *Otx2* becomes undetectable at both sites from E16.5. *OTX2* regulates various transcription factors implicated in the human brain, eye, and pituitary development, including *RX1*, *PAX6*, *SIX3*, *LHX2*, *MITF*, *GBX2*, and *HESX1* in order to coordinate cell determination and differentiation. As *OTX2* is essential in retinal development, many patients with *OTX2* mutations also present with a variety of ocular abnormalities. In humans, heterozygous *OTX2* mutations or gene deletions have been implicated in the etiology of 2% to 3% of anophthalmia/microphthalmia syndromes.[100] There is no clear genotype-phenotype correlation, even among patients with the same mutation. The pituitary phenotype ranges from partial to complete GHD and brain imaging reveals a normal or hypoplastic AP, normal or ectopic PP, and Chiari malformation. Mutations in *OTX2* have rarely been reported in patients with no ocular involvement, who have CPHD and a small AP, with or without an undescended PP.[101]

PAX6: Paired box protein-6 (*PAX6*) is an early dorsal marker of early AP gland formation, and its expression is required for somatotrope, lactotrope, and thyrotrope development. It is also an important regulator of eye development, and heterozygous mutations in humans cause congenital eye anomalies.[102] *PAX6* mutations have been reported to be associated with impaired pituitary function (ACTH deficiency, hypogonadotropic hypogonadism, and GHD).[103]

BMP4: Bone morphogenetic protein 4 (Bmp4) is the first secreted molecule detected in the prospective infundibulum at E8.5 and is essential for Rathke's pouch formation and maintenance. It is expressed in the optic vesicle, in the diencephalic floor, and in the medial ganglionic eminence and in developing limbs. A study of over 200 individuals with eye abnormalities identified *BMP4* mutations in a familial case of anophthalmia, retinal dystrophy, brain malformation, and poly/syndactyly.[104] Deletions in *BMP4* were associated with bilateral anophthalmia/microphthalmia, in association with hypothyroidism, deafness, developmental delay, and cerebellar and pituitary abnormalities.

FGFR1: FGF receptor 1 (FGFR1) is a tyrosine kinase receptor that acts as a cell-surface receptor for FGF. It is the main receptor mediating FGF8 signaling. Mutations in *FGFR1* have previously been reported in patients with KS; more recently, *FGFR1* variants have been associated with CPHD, absent corpus callosum, SOD, and midline defects.[105]

ARNT2: Aryl hydrocarbon receptor nuclear translocator 2 (*ARNT2*) belongs to the HLH-PAS (Per-ARNT-Sim homology) subfamily of transcription factors. ARNT2 is a basic helix-loop-helix transcription factor that is critical for normal development of the paraventricular and supraoptic nuclei.

In the mouse, *Arnt2* is expressed in hypothalamus, neural retina, kidney, and urinary tract, and this expression pattern is recapitulated in humans. Mutations in *ARNT2* are associated with severe hypothalamo-pituitary insufficiency, including GH, TSH, and ACTH deficiencies as well as DI, together with progressive microcephaly, seizures, severe visual impairment, and severe learning difficulties and abnormalities of the renal and urinary tracts.[106] Webb et al. reported *ARNT2* mutations in six children from a large, consanguineous Saudi Arabian family, who presented with central DI and ACTH deficiency after birth: four had TSH deficiency, two had GHD, and of these two, the single affected male also had gonadotrophin deficiency with undescended testes. Pituitary and extrapituitary anomalies were found on neuroimaging: hypoplastic AP, thin pituitary stalk, hypoplastic frontal and temporal lobes, thin corpus callosum, and a global delay in brain myelination. Postretinal eye anomalies were also reported. All children had dysmorphic features with microcephaly, prominent forehead, deep-set eyes, a well-grooved philtrum, and retrognathia. Hydronephrosis, vesicoureteral reflux, and neurogenic bladder were also found. All carried a homozygous c.1373_1374dupTC *ARNT2* truncating variant.[106]

Holoprosencephaly (HPE). Mutations of the sonic hedgehog (*SHH*) signaling pathway components (*SHH, TGIF, ZIC2, PTCH1, GLI2*) and the transcription factors sine oculis–related homebox 3 (*SIX3*), teratocarcinoma-derived growth factor 1 (*TDGF1*), and *FOXH1/FAST1*, among several other genes, have been identified in patients with HPE, with and without hypothalamo-pituitary defects.[107–112]

***GLI2*:** This mediator of SHH signaling is expressed in the ventral diencephalon. *GLI2* induces *BMP4* and *FGF8* expression. It is also expressed in the oral ectoderm, inducing pituitary progenitors.[113] *GLI2* mutations are associated with HPE or HPE-like features, with craniofacial anomalies, pituitary abnormalities, and polydactyly.[107,114] Variants are frequently identified in patients with isolated hypopituitarism.

FGF8: Fibroblast growth factor 8 (*FGF8*) is a member of the FGF family of signaling molecules that are involved in pituitary organogenesis. *Fgf8* expression is seen in the infundibulum at E9.5, 1 day after the expression of *Bmp4*, and is important in midbrain development.[115] *FGF8* mutations are associated with KS and have more recently been described in association with recessive HPE, craniofacial defects, and hypothalamo-pituitary dysfunction.[44]

Wolfram Syndrome. ***WFS1:*** Mutations in *WFS1* are associated with autosomal recessive Wolfram syndrome includes DI, diabetes mellitus, optic atrophy, and sensorineural hearing loss.[116]

Hypopituitarism With Spine Abnormalities. ***LHX3:*** Expression of the LIM homeobox 3 (*LhX3*) gene, a member of the LIM class of homeodomain proteins, is detected early during AP development at E9.5 (Rathke's pouch, ventral hindbrain, and spinal cord) and persists in the mature pituitary gland. It is one of the earliest markers implicated in the anterior and intermediate lobes development and its expression plays an important role in the formation of gonadotrophs, thyrotrophs, somatotrophs, and lactotrophs.[117] Mice with homozygous mutations of *Lhx3* die soon after birth as a result of pituitary aplasia, whereas those with heterozygous mutations have no abnormalities. In humans, several homozygous or compound heterozygous *LHX3* mutations and a heterozygous variant have been reported to date. Patients with *LHX3* mutations commonly present with GH, TSH, and FSH/LH deficiencies, while ACTH deficiency is reported in 50% of cases.[118] The phenotype varies depending on which part of the gene is affected.[119] If the mutation affects the entire gene or protein, the LIM domains or the homeodomain, patients will present with syndromes involving the nervous and skeletal systems,[120] whereas if the mutation affects the carboxyl terminus of LHX3 protein alone, isolated pituitary dysfunction will be present. *LHX3* is also required for inner ear development. Extrapituitary phenotypes include a short neck with abnormal head and neck rotation (70% of cases), vertebral abnormalities (50% of cases) including a rigid cervical spine, flattened lumbar vertebrae, thoracic kyphosis and progressive scoliosis, and variable degrees of sensorineural hearing loss (50% of cases).[121,122] Developmental delay and learning difficulties have also been reported in nearly 40% of the patients. Two patients have been reported to have respiratory distress. Heterozygous family members are largely unaffected, although a recent publication has described a mild limitation of neck movement in a heterozygous carrier.[123] MRI findings vary from normal (10%) to aplasia or hypoplasia of the AP, a hypointensity suggestive of microadenoma, and enlargement with a hyperintense signal.

Hypopituitarism With Cerebellar Abnormalities. ***LHX4:*** LIM homeobox 4 (*LHX4*) gene is closely related to *Lhx3* and is expressed in the developing brain and spinal cord.[124] *Lhx4* is also detected during early stages (E9.5 in Rathke's pouch and E12.5 in the anterior part of the pituitary) and is subsequently found in the future anterior lobe, with a decrease in expression by E15.5. The AP in patients with *LHX4* mutations is hypoplastic, containing all the differentiated cell types but in reduced numbers. Other brain abnormalities can also be present such as an ectopic PP and a hypoplastic sella turcica as well as corpus callosum hypoplasia or Chiari syndrome.[125,126] Several sporadic or familial *LHX4* mutations have been reported to date. The phenotype in patients ranges from isolated GHD to complete panhypopituitarism.[127] Of note, four patients also presented with respiratory distress, and one presented with a cardiac defect.[128] Several of the variants are variably penetrant, although the underlying mechanism remains to be established. A lethal neonatal phenotype (severe panhypopituitarism associated with AP aplasia and ectopic PP, mild facial hypoplasia, undescended testes, and severe respiratory distress) has been recently described, secondary to a homozygous mutation.[127]

Pituitary Stalk Interruption Syndrome (PSIS). PSIS is a congenital defect of the pituitary gland characterized by the triad of (1) a thin pituitary stalk, (2) an ectopic PP gland, and (3) hypoplasia or aplasia of the AP gland identified by neuroimaging. Patients with PSIS may present with either isolated GHD or CPHD.[129] Genetic alterations in *HESX1*, *LHX4*, *OTX2*, *SOX3*, and *PROKR2* have been reported in patients with PSIS, and among others.

PROKR2: PROKR2, a G-protein–coupled receptor essential for proper neuronal migration and angiogenesis, is involved in sex development and olfactory bulb development in mice. In humans, patients with mutations in *PROKR2* can present with hypogonadotropic hypogonadism or KS. More recently, mutations have been associated with variably penetrant hypopituitarism, including SOD.[129,130]

OTX2: As described previously, *OTX2* gene defects have also been reported in patients with no ocular abnormalities.[131]

GPR161: This orphan member of the G-protein–coupled receptor family has been recently identified in patients with PSIS. *GPR161* is widely expressed in both mouse and human during the early stages of embryogenesis including the neural folds, the pituitary and the hypothalamus. It is a key negative regulator of the SHH pathway, the pituitary target of which is GLI2. It has been suggested that gain-of-function mutations of *GPR161* could lead to abnormal pituitary development by repressing the SHH pathway. A homozygous missense mutation p.L19Q in *GPR161* has been recently described in two female siblings with short stature due to GHD associated with AP hypoplasia and an empty sella with an ectopic PP. Additional clinical features included fifth finger brachydactyly, congenital alopecia, and ptosis of the left eye.[132]

Robo: Roundabout genes (*Robo*), first identified in Drosophila, encode Robo proteins that belong to the immunoglobulin superfamily of proteins secreted by midline glial cells and play a role in axon guidance. Whole-exome sequencing recently identified *ROBO1* variants in 25 patients with PSIS; however, functional studies were not performed to support causality.[133]

Deficient AP Function With Variable Immune Deficiency (DAVID) Syndrome. ***NFKB2:*** This belongs to the NF-κB family, which consists of a collection of evolutionarily conserved transcription factors involved primarily in development including the AP, immunity, and oncogenesis. Patients with *NFKB2* mutation present with deficit in AP function and common variable immune deficiency, a novel disorder called DAVID syndrome.[134] However, the precise mechanism underlying endocrine deficits remains largely unclear.

Axenfeld-Rieger Syndrome. ***PITX2:*** This homeobox gene is detected in the stomodeum at E8, Rathke's pouch at E10.5, and 2 days later in the anterior and intermediate lobes. Patients affected with *PITX2* mutations present with Axenfeld-Rieger syndrome, which is characterized by eye, craniofacial, dental, cardiac, and umbilical anomalies.[135] *Pitx-2* null mice manifest pituitary hypoplasia and decreased *GHRH receptor, GH, FSH, LH,* and *TSH* gene expression.[136]

Pallister Hall Syndrome. ***GLI3:*** This is a component of the SHH signaling pathway. Haploinsufficiency of *GLI3* results in Pallister Hall syndrome, which is associated with polydactyly, hypothalamic disorganization, hypothalamic hamartoma, and hypopituitarism.[137,138]

CHARGE Syndrome. ***CHD7***: CHARGE syndrome is a rare autosomal-dominant disorder that affects multiple organs. It is characterized by ocular coloboma, cardiac defects, choanal atresia, growth and developmental delay, and ear abnormalities. Ectopic PP and hypopituitarism in patients with CHARGE syndrome have been reported in association with two novel *CHD7* variants.[139]

Other CPHD. ***PCSK1***: In a study of 13 children with proprotein convertase 1/3 (PC1/3) deficiency, an autosomal-recessive disorder caused by rare mutations in the *PCSK1* gene, obesity and severe diarrhea were associated with central DI, GHD, ACTH deficiency, hypothyroidism, and primary male hypogonadism.[140]

IGSF1: *IGSF1* is located at Xq26 and is expressed in Rathke's pouch, pituitary gland (present in GH, prolactin, and TSH-secreting cells), and testis. *IGSF1* mutations (loss-of-function or deletions) cause an X-linked syndrome. Male patients with mutations in *IGSF1* present with a characteristic phenotype, which consists of congenital central hypothyroidism, delayed puberty, and adult macroorchidism. PRL and/or GH deficiencies have also been reported in some cases. Some female patients with heterozygous mutations in *IGFS1* present with central congenital hypothyroidism, PRL deficiency, and delayed puberty.[141,142] Recently, *IGSF1* mutations have been associated with acromegaloid features with elevated concentrations of GH and IGF-1 in humans and mice.[143]

Other: More recently, mutations have been described in *FOXA2* (CPHD, eye abnormalities, and congenital hyperinsulinism [CHI]), *EIF2S3* (CPHD with glucose dysregulation), *TCF7L1* (SOD), *KCNQ1* (CPHD, maternally inherited gingival fibromatosis), and *RAX* (anophthalmia, CPHD, and cleft lip and palate). Mutations in *MAGEL2* have been associated with both anterior and PP hormone deficiencies associated with a range of clinical features, including arthrogryposis within the Schaaf-Yang and Chitayat Hall syndrome phenotypes. Mutations in *TBC1D32* have also been associated with CH within a ciliopathy phenotype.[74] Mutations in *BRAF* have also recently been identified in patients with cardio-facio-cutaneous syndrome and SOD.[144]

Syndromic Forms of Isolated GnRH Deficiency. This includes normosmic isolated GnRH deficiency causing hypogonadotropic hypogonadism, and KS. A number of genes have been reported to date in KS, including *KAL1, CCDC141, FEZF1, IL17RD, SEMA3A, SEMA3E*, and *SOX10*.[145–148] Pathogenic variants in *CHD7, FGF8, FGF17, FGFR1, DUSP6, SPRY4 and FLRT3, HS6ST1, NSMF (NELF), PROK2, PROKR2*, and *WDR11* cause both KS and normosmic hypogonadotropic hypogonadism.[148,149]

Variants in PROKR2 and PROK2, encoding prokineticin receptor-2 and prokineticin-2, respectively, have been identified in approximately 9% of patients with KS.[150] PROK1 and PROK2 act through their G-protein–coupled receptors, PROKR1 and PROKR2, which are expressed in the olfactory bulbs. PROK2 functions as a chemoattractant for neuronal progenitors, which follow a rostral migratory stream. *Prokr2*$^{-/-}$ mice have reduced LH in the pituitary, small gonads, and abnormal olfactory bulb formation but *Prokr2* seems to be dispensable for normal pituitary formation.[130] Variations in *PROKR2* have also been associated with hypopituitarism, PSIS, and SOD, but are unlikely to be causative in isolation and likely only contribute to the phenotype, including KS, in combination with other genetic mutations and/or environmental factors.

Mutations in a number of genes have also been identified in association with normosmic hypogonadotrophic hypogonadism, and these include *GNRH1* and its receptor *GnRHR*, *Kisspeptin* (*KISS1*) and its receptor *KISS1R*, and *Neurokinin B* (encoded by *Tachykinin 3* (*TAC3*)) and its G-protein–coupled receptor encoded by *TACR3*.[151–154]

Recently mutations in genes such as *RNF216, OTUD4, STUB1*, and *PNPLA6* have been found in syndromic forms of GnRH deficiency that have associated features such as ataxia and dementia as part of Gordon Holmes syndrome (*RNF216, OTUD4, STUB1*) and Boucher-Neuhauser syndrome (*PNPLA6*).[155–157]

Nonsyndromic CPHD. Mutations in *PROP1* and *POU1F1* constitute the main genetic cause found in patients with nonsyndromic GHD or CPHD.

PROP1: *PROP1* (prophet of PIT-1) is a member of the paired-like family of homeodomain transcription factors and is the earliest expressed pituitary-specific transcription factor. *Prop1* is detected within Rathke's pouch by E10, peaks at E12, and disappears by E15.5.[158] *Prop1* can act as both a transcriptional repressor (for *Hesx1* expression) or a transcriptional activator (for *Pou1f1*).[158,159] Mice with *Prop1* overexpression present with delayed puberty as a consequence of a delay in the differentiation of gonadotrophs.[160] The most frequent genetic cause of CPHD is recessive mutations in *PROP1*.[161–163] The most common of these is a 2-base pair deletion within exon 2, which results in a frameshift at codon 101 and introduction of a termination codon at position 109.[164] Recessive *PROP1* mutations are associated with GH, TSH, PRL, and gonadotrophin deficiencies, which can vary in onset and severity. It is therefore important to have ongoing clinical surveillance. GHD and growth delay usually present during the first years of life in patients with *PROP1* mutations; however, there is a case report of a patient who had normal growth and achieved a normal adult height without GH treatment.[165] Both TSH and gonadotropin deficiency can appear at birth or later in life.[166,167] Some patients may present with micropenis and undescended testes at birth and some others with delayed puberty. Spontaneous puberty can also be seen.[168,169] The majority of patients do not have ACTH deficiency during the first years of life but this can evolve later and ongoing surveillance is needed.[168,170] Neuroimaging shows variable pituitary morphology. The commonest finding is a normal pituitary stalk and posterior lobe with a small or normal AP gland. An enlarged AP gland has also been described with waxing and waning of size and posterior regression.[171]

POU1F1: *POU1F1* (previously known as *PIT-1*) is a member of the POU family. It is expressed later during pituitary organogenesis (E14.5) and persists during adulthood.[172] *POU1F1* plays a crucial role in the regulation of the genes encoding GH, PRL, and TSH-β. Patients with *POU1F1* mutations tend to present first with GH and prolactin deficiencies during the first years of life, whereas TSH deficiency tends to present later.[173] Gonadotroph and corticotroph axes usually remain functional. *POU1F1* mutations are mainly recessive. However, dominant mutations have been described, the most frequent being p.R271W mutation.[174] MRI reveals a normal or small AP gland; the PP and infundibulum are normal and no midline abnormalities have been reported.[173,175]

Isolated Pituitary Hormone Deficiencies. Rare isolated pituitary hormone deficiencies have been associated with mutations in the respective hypothalamic-releasing hormones or the releasing hormone receptors (e.g., familial GHD due to *GHRH-R* mutations, TSH deficiency due to *TRHR* mutations, and gonadotropin deficiency due to *GNRHR* mutations).[152,176,177]

Heterozygous mutations in *HESX1* have been identified in patients with isolated GHD.[82,178] The phenotype of those patients with heterozygous mutations in *HESX1* tends to be milder presenting with isolated GHD and an ectopic or undescended PP, although midline forebrain abnormalities can also be seen. Patients with duplication of *SOX3* can present with isolated GHD without other pituitary deficiencies.[97]

Congenital isolated ACTH deficiency is mainly due to recessive mutations in *TBX19* (formerly *TPIT*), which are responsible for approximately 65% of the cases of isolated ACTH deficiency diagnosed during the first month of life.[179] Neonates present with severe hypoglycemia that can result in seizures and prolonged cholestatic jaundice. Biochemical findings include low basal ACTH and cortisol concentrations and a poor ACTH response to CRH. It is extremely important to diagnose this as it can be a cause of neonatal death if replacement treatment is not started promptly.[180]

CCH may be more common than previously thought, with up to 1 in 16,000 neonates reported to be affected in the Netherlands. Rare recessive biallelic inactivating mutations in *TRHR* have been reported in three affected individuals from two unrelated pedigrees with CCH.[176,181] More recently, a novel homozygous mutation that decreases TRH affinity has been identified in an overweight patient with CCH and normal stature.[182] The X-linked transducing β-like protein 1 (*TBL1X*) gene is a component of the thyroid receptor-corepressor complex. Like *IGSF1*, *TBL1X* is associated with an X-linked form of TSH deficiency.[183,184]

KEY POINTS

- The pituitary consists of three lobes of dual embryologic origin. Pituitary hormone secretion is evident from 8 weeks' gestation.
- Mutations in genes involved in early development tend to be part of a syndrome that includes extrapituitary defects and midline abnormalities, as well as congenital hypopituitarism. Mutations implicated in later developmental stages result in variable phenotypes of CPHD without any extrapituitary defects.

Fetal Adrenal

The fetal adrenal is a remarkable organ, but its uniqueness was largely overlooked until 1911 when its large fetal zone (FZ) was first described as an immature cortex that undergoes involution postnatally.[185] The fetal adrenal is rapidly emerging as a key component of the fetoplacental unit in pregnancy and understanding its development may help to elucidate the pathophysiology of parturition, as well as furthering insight into many congenital adrenal disorders.

Adrenal Development. The adrenal appears as the bipotential adrenogonadal primordium (AGP) at 28 to 30 days post conception (dpc) in humans[186] due to expression of the transcription factor, steroidogenic factor 1 (SF1, NR5A1). The adrenal cortex is derived from a thickening of the intermediate mesoderm, in contrast to the adrenal medulla, which derives from the ectoderm. This region, known as the "gonadal ridge," contains AGP cells that give rise to the steroidogenic cells of the adrenal gland as well as those of the gonad. Cells expressing the highest levels of *NR5A1* are destined to become adrenal tissue and migrate retroperitoneally to the upper pole of the mesonephros to form the adrenal primordium at 33 dpc. At about 48 dpc, sympathetic cells derived from the neural crest infiltrate this area. These cells coalesce and differentiate after birth into the catecholamine-producing chromaffin cells of the adrenal medulla. Following the neural crest invasion, the adrenal primordium becomes encapsulated. The cells of the developing adrenal cortex segregate into two distinct zones by 50 to 52 dpc. The large, inner eosinophilic cells of the FZ have high levels of expression of steroidogenic enzymes, whereas the outer definitive zone (DZ) cells have lower levels of expression. A third transitional zone (TZ) becomes identifiable from about 12 weeks' gestation. The TZ lies between the DZ and FZ and has histological appearances of both.[187]

As pregnancy progresses the fetal adrenal grows tremendously, due largely to an increase in the FZ, which accounts for 80% to 90% of adrenal mass by midgestation,[188,189] with a relative size 10- to 20-fold that of the adult adrenal.[18,190,191] Growth is paralleled by increasing functional development. The fetal adrenal produces C_{19} androgens such as DHEA and DHEA sulfate (DHEAS) for the majority of pregnancy, with brief periods of cortisol production. These steroids maintain intrauterine homeostasis and prepare the fetus for adaptation to extrauterine life. FZ cells robustly express cytochrome P450 17 alpha (P450c17α), a bifunctional enzyme with both 17-hydroxylase and 17,20 lyase activities, that converts pregnenolone to DHEA. DHEA is sulfated to DHEAS, which is subsequently aromatized by the placenta in order to produce estrogens.[187] The FZ is identified in humans and a few higher primates only and the adrenal gland undergoes rapid involution postnatally, largely due to regression of the FZ. Immediately after birth, the FZ involutes and remodels by a process involving apoptosis of cells with a concomitant decrease in androgen secretion.[186] The weight of the adrenal drops by 50% within 2 weeks after birth,[192] and the FZ is absent by 6 months in the majority of cases. Whether the timing of FZ involution is determined by birth or gestational age remains controversial.[187,193] Postnatally, the DZ and TZ give rise to the zona glomerulosa and zona fasciculate, respectively, of the definitive adrenal cortex. Cells with zona reticularis morphology are detectable from around 3 years of age until a continuous ZR forms at around 6 years of age and androgen synthesis recommences, a stage referred to as adrenarche.[194]

Genetic Regulation of Adrenal Development. Fetal adrenal cortical development is programmed by a cascade of genetic transcription factors (Fig. 130.3) (e.g., ODD1, SALL1, FOXD1/FOXD2, WT1, NR5A1, NR0B1), coregulators (e.g., CITED2), signaling molecules (e.g., SHH/GLI3, WNT3/WNT4/WNT11), matrix proteins (e.g., SPARC), and regulators of telomerase activity (e.g., ACD). *Wt1* knockout mice have renal and gonadal abnormalities and lack adrenal glands.[195] Several other transcription factors, notably Pbx1, Lim1, and Wnt4, are involved earlier in the complex genetic cascade programming adrenal gland organogenesis from the coelomic epithelium and urogenital ridge.[195,196] *Pbx1* knockout mice die *in utero* with multiple organ defects that include adrenal agenesis and impaired testis development while *Wnt4* gene disruption leads to abnormal adrenal development, masculinization of XX females, and Müllerian-duct agenesis.

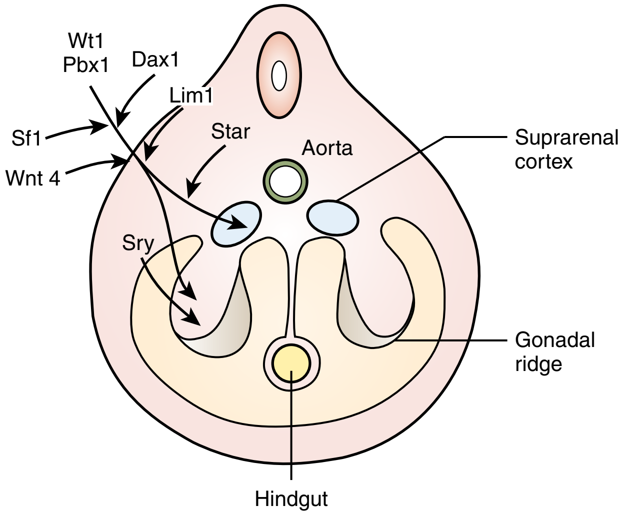

Figure 130.3 Cartoon showing a cross section of a 5-week human embryo, with location of the adrenal primordia (suprarenal cortices) and gonadal ridges. The most important genes known to be implicated in adrenal development and function are indicated. SF1 is required for adrenal and gonadal development, while SRY is the single critical regulator of testicular embryogenesis. DAX1 gene inactivation leads to adrenal hypoplasia. The steroidogenic acute regulatory protein *(StAR)* is the rate-limiting factor for adrenal steroidogenesis.

The most significant transcription factors for early AFP development are NR5A1 and NR0B1.[195,197,198] As well as expression in the adrenal cortex, these genes are expressed in the gonads, hypothalamus, and pituitary. *Nr5a1* gene knockout mice manifest adrenal and gonadal agenesis, gonadotropin deficiency, and absence of the hypothalamic ventromedial nucleus.[195] In the absence of *NR5A1* expression, the adrenal does not form.[186] Severe disruption of *NR5A1* in humans can cause adrenal dysfunction, although most pathogenic variants cause impaired testicular development and Leydig cell function. Heterozygous loss-of-function mutations in *NR5A1* in humans result in 46,XY and 46,XX DSD, complete gonadal dysgenesis and primary adrenal failure.[195]

NR5A1 upregulates *NR0B1*, which is itself a negative regulator of *NR5A1* transcriptional activity, and therefore steroidogenesis. Inactivating *Nr0b1/NR0B1* mutations in mice and humans are associated with gonadotropin deficiency and adrenal hypoplasia.[195] Pathogenic variants or deletions of *NR0B1* are well established as the cause of X-lined AHC.

Signaling Pathways in Adrenal Development. SHH, a member of the vertebrate hedgehog (Hh) family of secreted ligands, performs a number of crucial roles in embryogenesis. *SHH* is expressed in AP subcapsular cells at a later stage than *NR5A1* and *NR0B1*.[199–201] *Shh* expression marks cortical progenitors and Shh-expressing cells are thought to give rise to all steroidogenic cells in cortical zones,[199,200] and *Shh* mutant mice have a thin capsule and a small cortex.

FGF signaling controls early developmental processes[202] such as anterior/posterior patterning and organogenesis and interacts with NR5A1 and SHH signaling. FGFs bind to four receptors, FGFR1 to 4. *Fgfr2* and *Fgfr4* are expressed in the developing adrenal cortex, and deletion of *Fgfr2-IIIb* leads to reduced adrenal growth and impaired expression of NR5A1 and steroidogenic enzymes.[203]

Epidermal growth factor (EGF) stimulates proliferation of both the FZ and DZ. The fetal adrenal expresses high levels of IGF-2 mRNA and protein, which are responsive to ACTH.[204] IGF-2 augments ACTH-stimulated expression of steroidogenic enzymes and stimulates steroid hormone production in fetal adrenal cortical cells.

CDKN1C (Cyclin-dependent kinase inhibitor 1 C, *P57KIP2*) is a paternally imprinted gene, located on chromosome 11p.15 and encoding for the CDKN1C protein, an inhibitor of cell cycle progression. Variations in *CDKN1C* or its genomic imprinting can lead to adrenal pathology. Loss-of-function of CDKN1C results in Beckwith-Wiedemann syndrome (BWS), an overgrowth syndrome with increased susceptibility to adrenal carcinoma. IMAGe (intrauterine growth restriction, metaphyseal dysplasia, AHC, and genital anomalies) syndrome is a rare multisystem disorder that mirrors the features of BWS and is caused by gain-of-function mutations in *CDKN1C*. The resultant adrenal insufficiency can be life threatening shortly after birth secondary to salt loss, hypoglycemia, and shock due to loss of mineralocorticoid and glucocorticoid synthesis.[205]

Fetal Adrenal Steroidogenesis. The maintenance of intrauterine homeostasis and fetal maturation depends on fetal adrenal steroidogenesis. Cholesterol, the major substrate for fetal adrenal steroidogenesis, is derived from circulating low-density lipoprotein (LDL) and from *de novo* adrenal synthesis. LDL cholesterol, largely of fetal liver and testicular origin, contributes 70% of the total. The FZ contains more LDL binding sites and manifests a greater rate of *de novo* cholesterol synthesis than does the DZ, in keeping with its greater steroidogenic activity. Cholesterol availability is tightly controlled by the expression of steroidogenic acute regulatory protein (StAR), which regulates the transport of cholesterol to the inner mitochondrial membrane. StAR expression therefore is a rate-limiting factor in adrenal steroidogenesis.[206] *StAR* knockout mice manifest glucocorticoid and mineralocorticoid deficiency and female genitalia in XY animals. In humans, inactivating *StAR* mutations cause adrenal hypoplasia and adrenal insufficiency.[206] Recently, 46,XY males with normal male genitalia have also been described in association with *StAR* mutations.[206,207]

Sphingosine-1-phosphate lyase (SGPL1) is an endoplasmic reticulum enzyme, ubiquitously expressed in tissues, which mediates cleavage of the lipid-signaling molecule sphingosine-1-phosphate. Several recent studies report mutations in *SGPL1* resulting in primary adrenal insufficiency and steroid-resistant nephrotic syndrome.[208,209]

The fetal adrenal expresses the same five steroidogenic apoenzymes as the adult gland: two microsomal enzymes with 17-hydroxylase and 17,20-desmolase (CYP17 or P450c17) and 21-hydroxylase (CYP21A2 or P450c21) activities, plus two mitochondrial cytochrome P450 enzymes providing cholesterol side-chain cleavage (CYP11A1 or P450scc) and C11/C18 hydroxylation of the parent steroid structure (CYP11B1/CYP11B2 or P450c11/aldosterone synthase).[190,210] A fifth enzyme, expressed by the smooth endoplasmic reticulum, exhibits both 3βHSD and Δ4,Δ5-isomerase activities.[190,210] Quantitative differences in the relative activities of these enzymes are found, however, between cells derived from the FZ versus the DZ, and these differences are largely due to regulated steroidogenic gene transcription.[190] The FZ has relatively high steroid sulfotransferase (*SULT2A1*) activity, and because of the low 3βHSD and high sulfotransferase activities, the major steroid products of the fetal adrenal are DHEA, DHEAS, pregnenolone sulfate, several Δ5 3β-hydroxysteroids, and limited amounts of Δ5 3-ketosteroids, including cortisol and aldosterone.[190,210]

The paradox of human fetal adrenal function is that steroidogenesis is programmed largely to the production of inactive products.[190] The gland is maximally stimulated to maintain fetal cortisol levels and ACTH feedback homeostasis but is programmed by the steroidogenic enzyme expression pattern (e.g., relative 3βHSD deficiency) to produce inactive DHEA and pregnenolone and their sulfate conjugates. Much of the DHEA is converted to 16-hydroxy-DHEAS by fetal adrenal and liver. This programming is designed to provide DHEA substrate for placental estrone and estradiol production; 16-hydroxy-DHEA undergoes metabolism to estriol in the placenta. Fetal DHEAS production and maternal estriol concentrations increase progressively to term; DHEAS production approximates 200 mg/day near term.[204] In the anencephalic fetus, placental estrogen production is reduced to about 10% of normal, and estrogen is known to suppress FZ growth during the second half of primate pregnancy. It is proposed that estrogen feedback regulates the secretion of fetal adrenal DHEA to maintain normal fetal-placental function and development.[211]

Glucocorticoids are synthesized in the TZ in the first trimester (6 to 7 weeks' gestation) due to transient expression of 3βHSD2, and this is maximal between 8 and 9 months of gestation.[212] The hypothalamic-pituitary-adrenal (HPA) axis is sensitive to glucocorticoid-mediated feedback at this time; 46XX fetuses with steroidogenic defects such as CYP21A2 or CYP11B1 lack cortisol and have an elevated ACTH drive that results in excess production of fetal androgens at a time when the genital and scrotal folds are sensitive to androgen exposure, resulting in virilization of female genitalia.[212] Cortisol can retard fetal growth and is converted to inactive cortisone by the enzyme 11βHSD2. In this way, the fetus is protected from the high concentrations of cortisol *in utero*. The concentration of circulating cortisone in the fetus at midgestation is 4- to 5-fold higher than cortisol concentration (Fig. 130.4). In the third trimester, expression and activity of 11βHSD2 decreases and selected fetal tissues, including lung and liver, express 11βHSD1 so that glucocorticoids become available to promote maturation of organs in preparation for

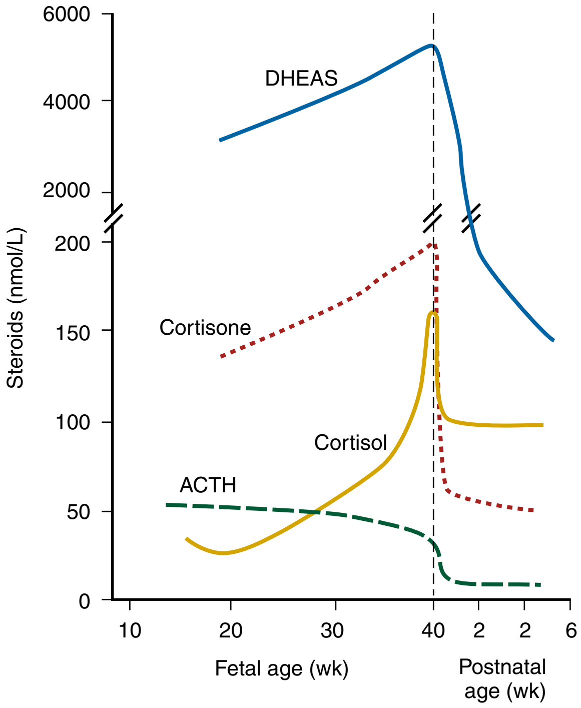

Figure 130.4 The pattern of maturation of serum cortisol, cortisone, and dehydroepiandrosterone *(DHEA)* in the human fetus during midgestation and the perinatal period. *ACTH,* Adrenocorticotropic hormone.

transition to extrauterine life.[190,213] Near-term fetal cortisol production per unit body weight is similar to that in the adult.[190] About two-thirds of fetal cortisol is derived from the fetal adrenal glands and one-third from placental transfer.[190] The metabolic clearance of cortisol in the fetus is rapid; 80% is oxidized in fetal tissues or placenta to cortisone or further metabolites.[190] Glucocorticoid receptors (GRs) are present at birth and are probably present at midgestation in most tissues, including placenta, lung, brain, liver, and gut.[190,210,214,215] Mice lacking GR function manifest enlarged and disorganized adrenal cortices, adrenal medullary atrophy, lung hypoplasia, and defective gluconeogenesis.[214]

In developing mammalian fetal models, all components of the renin-angiotensin system (RAS), including renin, angiotensinogen, angiotensin, angiotensin-converting enzyme, and angiotensin II receptor, are present. The genes are generally expressed at higher levels in fetal than in postnatal life.[190] Both ACTH and angiotensin II receptors (AT_1 and AT_2) are present on fetal adrenal cells early in gestation to stimulate adrenal steroid production.[190] AT_1 receptor mRNA expression in the fetal sheep kidney is low, early in gestation, increases in the latter third of pregnancy, and decreases postnatally; AT_2 mRNA levels, in contrast, are high at midgestation and decrease during the third trimester.[216] These changes reflect growth factor–mediated changes in AT-containing cells in various tissues. Hormonal factors modulate fetal renal AT gene expression in sheep; angiotensin II suppresses both AT_1 and AT_2; cortisol increases AT1 gene expression in kidneys and lungs.[216] The human fetal adrenal is able to produce aldosterone near term. Mineralocorticoid receptors (MRs) are present in fetal tissues (including fetal kidney, skin, hair follicles, trachea, and bronchioles) from 12 to 16 weeks' gestation.[217] The role of these MRs is unclear. MR knockout mice appear normal at birth but demonstrate defects in mineralocorticoid and RAS functions postnatally.[218] The role of the fetal RAS is not clear; rather than modulating renal sodium excretion through aldosterone, it may maintain renal excretion of salt and water into amniotic fluid to prevent oligohydramnios.[219]

Hormonal Regulation of Adrenal Development. A major stimulus to fetal adrenal functional development is fetal pituitary ACTH.[190,204] ACTH is a 39-amino acid peptide secreted from the AP under the control of CRH. ACTH binds to the melanocortin 2 receptor, MC2R, and exerts downstream effects via the cAMP and Ras/MEK/ERK signaling pathways. Although placental hCG may support early adrenal growth, the involution of the adrenal gland that occurs after 15 weeks in the anencephalic fetus suggests a role for pituitary-derived factors.[198] At midgestation, fetal plasma ACTH concentrations average 250 pg/mL, and although concentrations decline toward term, fetal ACTH concentrations exceed those later in life.[204] It does appear that ACTH-dependent and ACTH-independent mechanisms regulate fetal adrenal steroidogenesis.

CRH protein has been demonstrated in fetal baboon pituitary, adrenal, liver, kidney, and lung tissues during the last third of gestation. Concentration is highest in the pituitary (300 to 500 pg/mg protein); concentrations in adrenal, lung, liver, and kidney tissues average 20 to 30 and 5 to 10 pg/mg protein.[220] Circulating CRH concentration is high in the fetus and probably results largely from placental production.[220,221] Maternal concentration of CRH is elevated during the last trimester of gestation and reaches values of 0.5 to 1 nmol/L at term; normal values in nonpregnant women are <0.01 nmol/L.[222] At the end of pregnancy, there is increased bioavailability of CRH due to a fall in its binding protein, and this results in an exponential increase in maternal CRH from 35 weeks' gestation to term.[40,223] This placental CRH is bioactive, and concentrations correlate with maternal cortisol concentrations, suggesting that this circulating placental CRH plays a role in stimulating maternal corticotropin release. Fetal plasma CRH concentration at term, however, is approximately 0.03 nmol/L and, relative to the presumably high concentration in pituitary portal blood, probably has little role in modulating fetal corticotropin release. Midgestation fetal plasma ACTH concentration averages about 55 pmol/L (250 pg/mL), a concentration that maximally stimulates fetal adrenal steroidogenesis. Concentration is higher throughout gestation than in postnatal life, although it falls near term.[190,204] AVP and catecholamines are also significant stimuli for fetal ACTH secretion.[224]

The corticotropin feedback control system matures progressively during the second half of gestation and the early neonatal period. Dexamethasone can suppress the human fetal pituitary-adrenal axis at term but not at 18 to 20 weeks of gestation.[190] In the fetal sheep, hypothalamic and pituitary GRs are present at midgestation and corticotropin suppressibility can be demonstrated by the midpoint of the third trimester of gestation.[215] The number of GRs in the sheep fetal hypothalamus increases at term at the time of increasing glucocorticoid concentrations, suggesting that some process in the fetus allows the normal autoregulation of GRs to be overridden at term.[225]

Neonatal Adrenal Insufficiency. Adrenal insufficiency may be secondary to ACTH deficiency or primary due to abnormal adrenal development or resistance to ACTH.

The mature ACTH peptide is cleaved from the larger precursor molecule, POMC, together with other small peptides such as β-endorphin and α- and β-melanocyte–stimulating hormone (MSH). Given that mineralocorticoid secretion is largely independent of ACTH secretion, it is preserved and salt loss is therefore unusual. Nevertheless, mineralocorticoid deficiency can be an issue in some patients with ACTH insensitivity. ACTH deficiency can be part of MPHD or may be due to isolated ACTH deficiency. A number of single gene defects have now been associated with MPHD that include ACTH deficiency (e.g., mutations in *HESX1*, *SOX3*, *LHX3*, *LHX4*, *PROP1*, *ARNT2*).[178] Occasionally, ACTH insufficiency may not be present at the time of diagnosis but may develop progressively with time.

Isolated ACTH deficiency can be due to recessive mutations in the T-box factor *TPIT* (*TBX19*). TPIT is required for the specification, maturation, and maintenance of both precorticotrope and premelanotrope populations. It is also required to activate the expression of POMC in conjunction with the transcription factor PTX1. *TPIT* deficiency in humans leads to severe, early-onset isolated ACTH deficiency with profound hypoglycemia and prolonged jaundice and may result in sudden neonatal death.[226]

POMC/PC1 mutations lead to ACTH deficiency combined with pale skin, red hair, diarrhea, and obesity. Recently, *POMC* mutations have been found that result in immunoreactive but bioinactive ACTH and MSH; patients manifest cortisol deficiency, obesity, and red hair.[227]

ACTH resistance leads to isolated glucocorticoid deficiency (although salt loss can occasionally occur), hyperpigmentation and markedly elevated concentrations of ACTH.[228,229] ACTH resistance can occur in a number of well-defined entities such as defects in the ACTH receptor (*MC2R*, familial glucocorticoid deficiency [FGD] type 1), MC2R accessory protein (*MRAP*, FGD type 2), or as part of the Triple A syndrome (Alacrimia, Achalasia, Addison; also known as Allgrove syndrome, due to defects in ALADIN/AAAS).[230] Mutations in NNT (nicotinamide nucleotide transhydrogenase), GPX1 (glutathione peroxidase 1), and MCM4 (mini-chromosome maintenance-deficient-4 homolog) have also been found as a cause of FGD.[231–233] Mutations in MCM4 were found in an Irish traveler community, and result in late onset, less severe glucocorticoid deficiency, short stature and NK cell deficiency, due to increased chromosomal breakage. Mutations in GPX1and NNT, involved in detoxification of reactive oxygen species (ROS), can also result in FGD.[234]

Primary adrenal failure may be due to AHC or various forms of CAH. AHC results in severe salt-losing primary adrenal failure in early infancy or childhood, although milder, delayed onset forms of the condition exist.[235] The commonest form of AHC is X-linked and due to mutations in the nuclear receptor encoded by *NR0B1*. In addition to adrenal failure, the males also suffer from hypogonadotropic hypogonadism.[236,237] Heterozygous and homozygous mutations in *NR5A1* can lead to adrenal failure and 46,XY disorders of sexual development (DSD), or isolated adrenal insufficiency[235] or isolated gonadal dysgenesis in 46,XY DSD.[238] Additionally, *NR5A1* mutations have been associated with male infertility[239] and primary ovarian failure and infertility in 46,XX females.[240]

Syndromic adrenal insufficiency due to adrenal hypoplasia includes IMAGe syndrome, Triple A syndrome, Irish Travelers syndrome, and recently MIRAGE syndrome. MIRAGE syndrome comprises a striking phenotype of a multisystem disorder including myeloproliferative dysplasia, infection, growth restriction, adrenal hypoplasia, genital anomalies, and enteropathy, and mutations in *SAMD9* have been identified by whole-exome sequencing.[241,242] Up to 30% of cases of syndromic adrenal hypoplasia have no cause identified.

CAH can lead to a variable degree glucocorticoid and mineralocorticoid deficiency and varying degrees of genital ambiguity and may be due to mutations in *CYP11A1*, *StAR*, *3βHSD2*, *CYP17*, *CYP21A2*, *CYP11B1*. Isolated mineralocorticoid deficiency is due to deficiency of the enzyme P450c11AS, which has 11β hydroxylase, 18-hydroxylase, and 18 methyl-oxidase activities, and catalyzes all the reactions needed to convert deoxycortisol to aldosterone.[243] Functional mineralocorticoid deficiency with severe salt loss resulting in hyponatremia and hyperkalemia may also arise as a result of mutations in the *MR* or in the genes encoding the three subunits of the epithelial sodium channel, ENac (*SCNN1A*, *SCNN1B*, *SCNN1G*).[244]

Manifestations of mineralocorticoid deficiency in the newborn term infant can occur because of aldosterone deficiency or competition for binding to renal MRs by other steroids. Relatively reduced glomerular filtration in the newborn limits sodium loss initially but by 1 week of age, aldosterone deficiency produces the characteristic manifestations of hyponatremia, hyperkalemia, and volume depletion.

KEY POINTS

- Paradoxically fetal adrenal steroidogenesis is programmed largely to produce inactive products.
- The fetal adrenal is a key component of the fetoplacental unit, producing androgens that are aromatized to estrogens by the placenta.

Fetal Gonads

A series of molecular events result in sex determination, directing the bipotential gonad to become a testis or ovary. Factors produced by the gonad then drive sex differentiation and the development of phenotypic sex.

Gonadal Embryology. The mammalian gonad is derived from two tissue anlagen: the primordial germ cells that have migrated from the yolk sac wall and somatic stromal cells that migrate from the primitive mesonephros.[245,246] The germ cells are incorporated into the developing gonadal ridge during the sixth week, Until 6 weeks, the fetal gonads are bipotential.

SRY is the critical regulator of gonadal differentiation; its presence results in differentiation of the gonad into a testis and its absence leads to ovarian differentiation. *WT1*, the Wilms tumor suppressor gene located at 11p13, *SOX9*, and *NR5A1* are expressed in the bipotential gonadal ridge and are critical for normal male sexual differentiation.[247,248] WT1 is expressed in both the primitive kidney and genital ridge and plays a role in mesenchymal-epithelial transition[249] WT1 is a zinc finger DNA-binding protein that acts as a transcriptional activator or repressor depending on the cellular or chromosomal context. Alternative splicing results in several WT1 isoforms that have separate functions. WT1 isoforms associate and synergize with *NR5A1* to promote the expression of AMH. *WT1* missense mutations, associated with 46XY DSD in Denys-Drash syndrome, fail to synergize with *NR5A1*.[250] In addition, *WT1* binds to and activates the *SRY* promoter. NR5A1 is required for both testicular and ovarian development and mediates *AMH* gene expression and gonadotropin production.

NR5A1 and NR0B1 are orphan receptors of the steroid-thyroid hormone family of nuclear receptors and interact as heterodimers in the regulation of target genes in the ventromedial hypothalamic nucleus, the hypothalamic gonadotroph cells, and the adrenal glands.[247,248] *NR5A1* also regulates the expression of *SRY*. *Sry* binds to multiple elements within a *Sox9* gonad-specific enhancer in mice, along with *Nr5a1*. *NR5A1* and *SRY* cooperatively upregulate *SOX9* and then, together with *NR5A1*, *SOX9* also binds to the enhancer to help maintain its own expression after that of *SRY* has declined.[251]

The expression of *SRY* is transcriptionally regulated by *WT1*, *NR5A1*, *GATA4* and its cofactor zinc finger protein *FOG-2* (also called *ZFPM2*), and chromobox protein homolog 2 (*CBX2*).[252] SRY is thought to have evolved from SOX3. Loss-of-function mutations of *SOX3* do not effect sex determination, but *Sox3* overexpression in murine XX gonads leads to testis differentiation, and in humans, *SOX3* duplication or rearrangements of the *SOX3* regulatory region have been found in 46,XX individuals with dysgenetic testes.[253]

INSL3 and its G-protein–coupled receptor relaxin family peptide receptor 2 (RXFP2) play a role in testicular descent. INSL3 is produced in Leydig cells, is secreted in the circulation, and may prove to be a biomarker of Leydig cell function. Rare mutations have been described in cryptorchidism.[254,255]

A menu of genes identified so far in gonadal development is shown in Fig. 130.5. Fetal pituitary gonadotropins are not required for gonadal development or sexual differentiation; lh or fsh receptor knockout mice are born phenotypically normal.[256] Human mutations in several of the genes programming gonadal differentiation have been described.[246] Loss-of-function mutations of *SRY* or *SOX9* lead to 46,XY DSD and sex reversal, while gain-of-function mutations lead to 46, XX DSD and sex reversal. *SOX9* mutations are also associated with campomelic dysplasia. *NR5A1* mutations have been associated with 46,XY DSD with gonadal dysgenesis with or without adrenal failure. More recently, the phenotypic spectrum of *NR5A1* mutations has widened to encompass gonadal dysgenesis, premature ovarian failure, male infertility, and the vanishing testis syndrome.[238,240,257] Mutations may be heterozygous or recessive, the latter being likely to be associated with a more severe loss of function.

WT1 mutations are found in several syndromes associated with abnormal testicular embryogenesis and renal abnormalities such as Wilms tumor or glomerulosclerosis (WAGR, Denys-Drash, and Frasier syndromes). *WNT4* gain-of-function mutations result in 46,XX DSD with sex reversal, and *DAX1* duplication results in 46,XY DSD with sex reversal.53 Mutations in *CBX2* are also associated with 46XY DSD with gonadal dysgenesis and ovarian development.[258]

Testicular Development. In the presence of SRY, male gonadal differentiation begins at 7 weeks' gestation with organization of the gonadal blastema into interstitium and germ cell–containing testicular cords.[259] The primitive cords lose their connections with the epithelium, primitive Sertoli cells and spermatogonia become visible

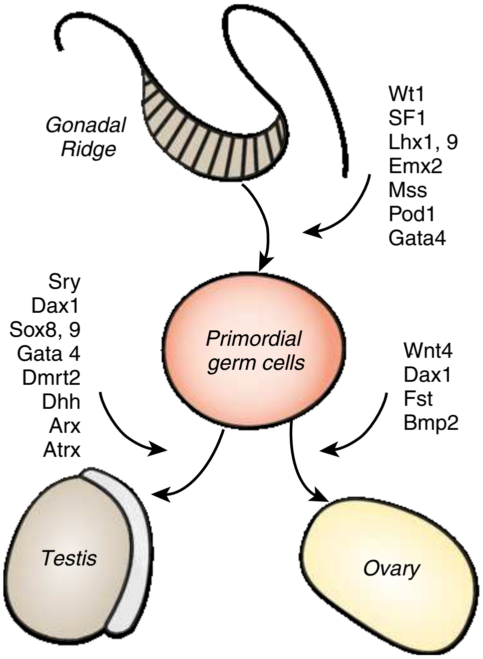

Figure 130.5 Summary of the molecular and cellular events of gonadal differentiation.

within the cords, and the epithelium differentiates to form the tunica albuginea. Leydig cells, derived from the undifferentiated interstitium, are visible by the end of the eighth week of gestation and are capable of androgen synthesis at this time. By 14 weeks, these cells make up as much as 50% of the cell mass, but as the tubules develop, they account for a smaller percentage of the tissue.

The fetal testes grow from approximately 20 mg at 14 weeks of gestation to 800 mg at birth; at 5 to 6 months, they descend into the inguinal canal in association with the epididymis and the ductus deferens.[259] The gonad, adrenal, and kidney all initially develop in close proximity, and as the testes descend, they may carry rests of adrenocortical cells with them. Testicular descent is regulated by Insl3, which is a member of the Insulin-like family and is secreted by Leydig cells.[254,255] Targeted disruption of the *Insl3* gene is associated with maldevelopment of the gubernaculum with bilateral cryptorchidism[151]. *Insl3* is also secreted by theca cells of the postnatal ovary, and females homozygous for *Insl3* mutations are subfertile with deregulation of the estrous cycle. Sertoli cells in the male gonad produce AMH, also called Müllerian-inhibiting substance (MIS), which dedifferentiates the primitive Müllerian system.[260] AMH, a 12-kD glycoprotein, is a member of the TGF-β family. *AMH* gene expression, stimulated by SRY and NR5A1, continues throughout gestation at the time of Müllerian-duct regression and then decreases after birth.68 In the female fetus, Müllerian-duct differentiation proceeds in the absence of AMH, and the primitive mesonephric duct system dedifferentiates in the absence of testosterone. In the absence of dihydrotestosterone (DHT), the urogenital sinus and external genitalia differentiate to the female phenotype. Mutation of the *AMH* gene results in a persistent Müllerian-duct syndrome in the 46,XY fetus.[260] Changes in AMH concentrations throughout the lifespan in males and females, as well as patients with Turner syndrome, have been documented.[261,262]

In the male Leydig cells, there is an increase in testicular testosterone production stimulated by the high levels of circulating placental hCG between 10 and 20 weeks.[263,264] Fetal pituitary LH contributes to fetal Leydig cell stimulation, but the predominant gonadotropic effect at this time is hCG. Fetal testosterone stimulates male sexual differentiation of the primitive mesonephric ducts (to form the ductus deferens, epididymis, seminal vesicles, and ejaculatory ducts) and masculinizes the urogenital sinus and external genitalia (to form the prostate gland, phallus, and penile urethra).

Ovarian Development. In females, differentiation of ovaries begins during the seventh week of gestation, in the absence of SRY.[265] The gonadal blastema differentiates into interstitium and medullary cords containing the primitive germ cells now referred to as *oogonia*. The cords degenerate, and cortical layers of surface epithelium containing individual small oogonia appear. By 11 to 12 weeks, clusters of dividing oogonia are surrounded by cord cells within the cortex.[265] The medulla at this time consists largely of connective tissue.[265] At 12 weeks of gestation, primitive granulosa cells begin to replicate and many of the large oogonia in the deepest layers of the cortex enter their first meiotic division. Primordial follicles appear at about 18 weeks, and the number increases rapidly thereafter.[266] The number of oocytes progressively declines from a peak of 3 to 6 million at 5 months to some 2 million at term.[204,266] Germ cell proliferation and apoptosis are ongoing simultaneously; only those oocytes enfolded by developing granulosa cells (as primordial follicles) survive.[204,266] By 5 to 7 months, stroma-derived thecal cells develop around the primordial follicles as they mature to primary follicles. The number of surviving primary follicles at birth correlates with the duration of postpubertal ovulation.

Each fetal ovary weighs about 15 mg at 14 weeks of gestation and 300 to 350 mg at birth.[265] Interstitial steroid-producing cells are present after 12 weeks, and during the third trimester, theca cells with steroidogenic capacity surround the developing follicles.[204] Significant aromatase activity is also present, but few, if any, steroids are produced by the ovary during development.[204,265]

In the 46,XX female, the absence of androgens leads to development of female genitalia; the Wolffian duct regresses and the Müllerian is maintained and forms the oviduct, uterus, cervix, and upper part of the vagina.[267]

The specific genetic mechanisms dictating ovarian development are being unraveled and some of the most powerful regulators include the WNT/FZD/β-catenin, FOXO/FOXL2, and TGFβ/SMAD, pathways.[252,268] *FOXL2*, encoding a forkhead transcription factor, is required for ovarian development.[269] *DMRT1*, expressed in testis, prevents expression of *FOXL2*, and hence female programming, in the postnatal testis.[270] In the XX gonad, the absence of SRY results in the inability of SOX9 expression to reach a critical threshold, and together with the expression of *RSPO1*, *WNT4*, *CTNNB1*, *FOXL2*, and *FST* lead to formation of the ovary. In humans and mice, R-spondin-1 (encoded by *RSPO1*) augments β-catenin signaling, possibly via WNT4.[271] Homozygous mutations in *RSPO1* result in a syndrome with palmoplantar hyperkeratosis and 46,XX DSD with sex reversal and dysgenetic testes or ovotestes.[272,273] Aberrations of the *WNT4* gene cause Mayer-Rokitanski syndrome or SERKAL syndrome (SEx Reversal, dysgenetic Kidneys, Adrenals and Lung).[274,275]

Gonadal Steroid Action. Androgen receptors appear in the mesenchyme of urogenital structures at 8 weeks of gestation, followed by the appearance of the receptors in the epithelium at 9 to 12 weeks.[276] There is no difference in receptor expression in male and female fetuses. DHT stimulates male differentiation of the urogenital sinus and external genitalia, including differentiation of the prostate, growth of the genital tubercle to form a phallus, and fusion of the urogenital folds to form the penile urethra. DHT is formed from testosterone by the 5α-reductase enzyme within the urogenital sinus and urogenital tubercle and acts through the same androgen receptor that mediates the action of testosterone in the Wolffian ducts.

Both androgens and estrogens are involved in the structural development of the rodent brain.[277,278] Gonadal hormones control gonadotropin production in the hypothalamus, programming cyclic ovarian function, and function of the testes.[278,279] Testosterone administration to neonatal female rats produces permanent inhibition of cyclic hypothalamic control through local aromatization to estradiol. In primates and humans, estrogens seem to be more effective in this regard. However, there is no evidence for permanent programming in the primate, and there appear to be no major tissue biochemical differences between the sexes *in utero* to account for sexual dimorphic behavioral or gonadotropic programming.[280]

Estrogen effects are mediated by cognate receptors, members of the large family of steroid and thyroid hormone, vitamin D, and retinoid receptors.[281,282] Two receptors, estrogen receptors α and β (ERα and ERβ).3,60,61 have been identified with 96% and 58% homology in the DNA-binding and ligand-binding domains, respectively. Expression profiles for mRNAs for both receptors have been characterized in the 16- to 23-week human fetus. One or both receptor mRNAs are present in most tissues. *ERβ* message is predominant, particularly in testis, ovary, spleen, thymus, adrenal, brain, kidney, and skin. *ERα* message is prominent in the uterus, with relatively low levels in most other tissues.[281,282] The significance of ERs in fetal development remains unclear. Knockout of the *ERα* gene in mice does not impair fetal development of any tissue, but adult females are infertile, with hypoplastic uteri and polycystic ovaries; adult males manifest decreased fertility.[282] *ERβ* knockout mice develop normally, and female adults are fertile with normal sexual behavior; adult males reproduce normally but have prostate and bladder hyperplasia.[281] Knockout of both *ERα* and *ERβ* genes also has little impact on fetal development, but after birth, the uterus, fallopian tubes, vagina, and cervix in females are hypoplastic and unresponsive to estrogen.[282] In humans, ERα mutations in males are associated with tall stature and insulin insensitivity.[283]

Disorders of Sex Development. Elucidating the mechanisms underlying sex determination and differentiation, together with society's evolving fluidity regarding gender and sexual identities, has led to rapid changes in the approach to the management of infants with disorders of sex development (DSD) (see Chapter 101). Optimal care requires an experienced multidisciplinary team, which transitions into adolescence and adulthood.[284] There is a need for data sharing and research, as highlighted by the Chicago Consensus in 2005.[285]

KEY POINTS

- In the presence of SRY, male gonadal differentiation begins at 7 weeks' gestation. Ovarian development is not a "default" or passive outcome of the bipotential gonad.

Fetal Thyroid

Thyroid Embryology. The thyroid gland, one of the first endocrine organs to develop, is a derivative of the primitive buccopharyngeal cavity and is composed of two sets of anlagen, which fuse together during development. A median anlage is derived from a midline thickening of the pharyngeal floor in the region of the first pharyngobranchial pouch, consisting of foregut endoderm cells, which give rise to precursors of the T_3- and T_4-producing follicular cells. Paired lateral anlagen (or ultimobranchial bodies), originating from caudal extensions of the fourth pharyngobranchial pouches, give rise to the parafollicular calcitonin (C)–secreting cells. Recent lineage-tracing studies in mice have shown that both medial and lateral anlagen are of endodermal origin rather than the earlier theory of a neural crest origin of thyroid C cells.[286,287]

In humans, the thyroid anlagen are discernible by 20 to 22 dpc, and between 24 and 48 dpc thyroid precursor cells undergo caudal migration, proliferation, and lateral expansion. This whole process is known as lobulation. At 24 dpc, the median anlage develops a thin, flask-like diverticulum extending from the floor of the buccal cavity at a point that is later known as the foramen caecum on the developing tongue to the fourth branchial arch. A persisting epithelial stalk, the thyroglossal duct, connects the thyroid primordium to the pharynx during descent through the anterior midline of the neck to its definitive location in the anterior neck. During normal development, the thyroglossal duct has usually disappeared by 37 dpc leaving behind only the foramen caecum remnant. If the thyroid descent is abnormal, this may result in an ectopic thyroid gland or a persistent thyroglossal duct.[288] Fusion of the lateral and median anlagen occurs at about 44 dpc. By 51 dpc, the gland has formed into two lateral lobes with a connecting isthmus and has descended below the thyroid cartilage, its final position, by 7 to 9 weeks. At the same time, connection of the median anlage with the ultimobranchial body, developed from the endoderm of the fourth pharyngeal pouch, occurs, resulting in the incorporation of the C cells into the thyroid.

The terminal differentiation of thyroid follicular cells and the formation of follicles occur only once migration is complete, at around 60 dpc. By 10 weeks, colloid is visible histologically and thyroglobulin synthesis and iodide accumulation/uptake can be demonstrated within the gland. During the final follicular phase of development, colloid spaces increase in size and there is progressive cell growth and accumulation of thyroid hormones. Terminal differentiation of the human thyroid is characterized by the onset of follicle formation and thyroid hormone synthesis at 11 weeks and is marked by expression of the TSH receptor (TSHR), the sodium-iodide symporter (NIS), thyroglobulin (Tg), and thyroperoxidase (TPO). Thyroid hormones can be detected in the thyroid from 9 weeks post conception (wpc) and in fetal blood from 10 wpc.[289–292] At 12 weeks of gestation, the fetal thyroid gland weighs about 80 mg, and at term, it weighs 1 to 1.5 g. The parathyroid glands develop between 5 and 12 weeks of gestation from the third and fourth pharyngeal pouches.

Genetic Regulation of Thyroid Development. Several developmental genes are involved in programming thyroid and parathyroid gland development. Genes encoding the transcription factors Hhex, Nkx2-1 (Titf1/ Ttf1), Foxe1 (Titf2/ Ttf2), and Pax8 (Fig. 130.6) are coexpressed in the thyroid anlage and are involved in a transcriptional network of interactions of mutual dependence.[293] Deletion of any one of the genes encoding Hhex, Nkx2-1, Pax8, or Foxe1 inevitably results in thyroid agenesis or severe thyroid hypoplasia despite the fact that the other factors are still being expressed in the thyroid placode.[293] In addition to mediating the formation of the thyroid bud, these transcription factors drive functional differentiation, regulate the expression of genes involved in thyroid hormone biosynthesis, and play a role in the maintenance of the mature thyroid gland. Nkx2-1 and Pax8 also play a role in the survival of thyroid cell precursors and regulate thyroid-specific gene expression, while Foxe1 is critical for cellular migration.[290] It is not known if Hhex directly influences specific steps in thyroid morphogenesis, although it might play a role acting indirectly through Pax8 in thyroid progenitor cell survival.[293]

Evidence from mouse and zebrafish studies suggests that thyroid morphogenesis is guided by cues from extrinsic factors such as permissive signals from cardiac mesoderm and blood vessels.[294] Genes known to contribute to thyroid morphogenesis in animal models include the Notch ligand *Jag1*, the thyroid and cardiac transcription factor *Nkx2*–5, and *Ntn1*, which is implicated in zebrafish aortic arch artery formation and thyroid morphogenesis.[295–298]

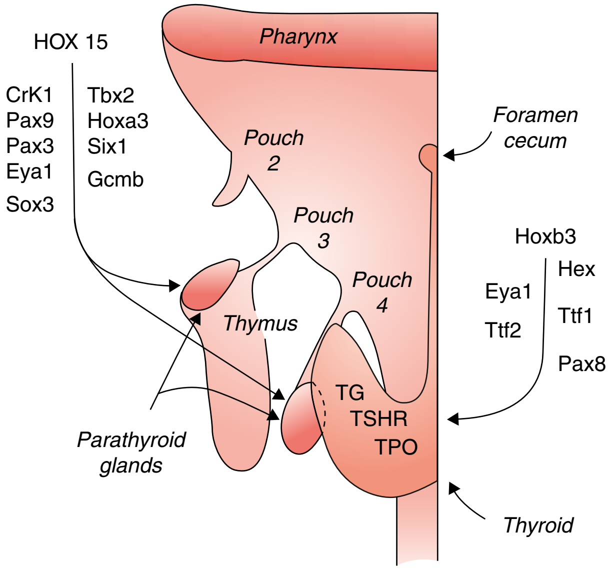

Figure 130.6 Cartoon showing genes implicated in programming the development of the thyroid and parathyroid glands. Most of this information was derived from genetic studies in mice.

Other autonomous factors that may play a role in thyroid morphogenesis include *Tbx1*, a transcriptional regulator of the Fgf signaling pathway.[299] *TBX1* is the prime candidate gene missing in 22q11.2 deletion or DiGeorge syndrome. In mice, Tbx1 is expressed in both the pharyngeal endoderm and subpharyngeal mesoderm but only its mesodermal activity promotes the generation of Nkx2-1$^+$ progenitors in the thyroid placode. In *Tbx1*$^{-/-}$ mice, the downward translocation of *Nkx2.1* expressing thyroid progenitor cells is much delayed. In late mutant embryos, the thyroid gland fails to form symmetric lobes but persists as a single mass that is approximately a quarter of the normal size. The hypoplastic gland mostly attains a unilateral position resembling thyroid hemiagenesis. The effect of *Tbx1* on the embryonic thyroid is mediated by *Fgf8*, which is also produced in the mesoderm. Conditional ablation of *Fgf8* in *Tbx1*-expressing cells caused an early thyroid phenotype similar to that of *Tbx1*-mutant mice. In addition, the expression of an *Fgf8* cDNA in the *Tbx1* domain rescued the early-size defect of the thyroid primordium in *Tbx1* mutants.[300,301] The Shh signaling pathway has also been implicated in murine thyroid development.[302] Shh appears to have an important role in the patterning and process of symmetrical bilobulation late in organogenesis, as well as suppressing ectopic expression of thyroid follicular cells.[303]

Mutations in *NKX2-1*, *PAX8*, and *FOXE1* are all associated with thyroid dysgenesis in humans.[290,292,304–306] *Hhex* gene knockout in mice is associated with thyroid agenesis or severe hypoplasia; however, no mutations have been identified in *HHEX* in humans as yet. Gene expression studies in thyroid tissues from human embryos showed that *NKX2-1*, *FOXE1*, *PAX8*, *TSHR*, and *DUOX2* were stably expressed from 7 to 33 gestational weeks. Genes encoding Tg, TPO, and pendrin (PDS) were expressed as early as 7 weeks but increased significantly before 11 weeks. *NIS* is the last gene to appear, and it shows the strongest upregulation at 10 weeks. Its expression is the most strongly correlated with the sudden onset of thyroid hormone synthesis at 11 weeks.[307]

Fetal Thyroid Hormone Biosynthesis. Although the onset of fetal thyroid hormone synthesis starts at the end of the first trimester, concentrations are low and necessitate a high dependency on maternal thyroid hormones during the first half of pregnancy. Overt maternal hypothyroidism has been shown to be associated with significant complications including miscarriage, premature delivery, and placental abruption, as well as adverse effects on fetal brain development and neurocognitive outcomes in offspring.[308] The effects of subclinical maternal hypothyroidism are less clear. Using a zebrafish model, the ontogeny of the hypothalamic-pituitary-thyroid axis and its negative feedback regulation by thyroid hormones has been characterized. Embryonic exposure to excess thyroid hormone during a developmental time window resulted in long-term dysregulation of pituitary function by apoptosis of developing thyrotrope cells.[309] These findings are relevant in the context of maternal hyperthyroidism due to maternal Graves disease or over-replacement of pregnant hypothyroid women in the first trimester with levothyroxine.

The fetal hypothalamus secretes TRH from 8 weeks' gestations, resulting in fetal pituitary TSH secretion. Despite the high TRH concentration, the TSH concentration in the fetal circulation remains low until 18 to 20 weeks' gestation when the gland functionally matures.[310] Pituitary and plasma TSH concentrations increase during the second trimester in the human fetus, coincident with the development of the pituitary-portal circulation.[311] In the rat, expression of the *TSHR* gene is significantly upregulated on fetal day 17 and this is accompanied by significant growth and rapid development in terms of structure and function. The activation of the TSH/TSHR signaling pathway is concurrent with the expression of genes needed for thyroid hormone synthesis and secretion. The expression of *Tg* and *TPO* increases and thyroid follicles are seen with thyroid hormonogenesis, suggesting that the TSHR must play an important role in these events. Murine mutation of the *TSHR* gene is associated with the *hyt/hyt* phenotype, which exhibits severe hypothyroidism and a hypoplastic but normally located thyroid gland with a poorly developed follicular structure.[312,313] In humans, a similar phenotype is observed in babies of mothers with potent TSHR-blocking antibodies and in babies with severe loss-of-function mutations in *TSHR*.[313]

Plasma concentrations of thyroxine-binding globulin (TBG) and total T_4 increase progressively, from low concentrations at 16 to 18 weeks of gestation to maximal concentrations at 35 to 40 weeks. Free T_4 concentrations increase with the rise in T_4 production. The increases in plasma TSH and T_4 concentrations during the third trimester reflect progressive maturation of hypothalamic pituitary control and of thyroid gland responsiveness to TSH, respectively. A peak T_4 of 6 to 8 μU/mL (6 to 8 mU/L) occurs by term.[310] Pituitary TSH secretion is responsive to hypothyroxinemia and to TRH early in the third trimester. Hypothyroxinemia results in an elevated fetal serum TSH, whereas hyperthyroidism due to maternal Graves disease is associated with a suppressed fetal TSH concentration.[290]

Premature infants born at 26 to 28 weeks of gestation respond to exogenous TRH with an increase in plasma TSH concentration comparable to that in adults.[314] However, their TSH response to extrauterine exposure is reduced, indicating hypothalamic immaturity, and their T_4 and T_3 increments are reduced relative to term infants. Compared to infants born at term, neonatal free T_4 increments are reduced in premature infants born at 31 to 34 weeks' gestation, attenuated at 28 to 30 weeks and absent in 23 to 27-week infants.[315] This reflects hypothalamic-pituitary-thyroid system immaturity inversely related to gestational age.[316]

Hypothalamic-pituitary-thyroid control matures during an interval corresponding to the late third trimester and early neonatal period of human development.[311,317] The period of concomitant increases in fetal TSH and free T_4 concentrations during the latter half of gestation is followed by sequential surges of TSH, free T_4, and T_3 in the early neonatal period and a final slow equilibration of the TSH/free T_4 ratio to adult values during infancy and childhood.[311,316,318,319] This sequence requires coordinated maturation of hypothalamic TRH secretion, pituitary TRH sensitivity, thyrotropin negative-feedback control, and thyroid follicular cell responsiveness to TSH. Fetal serum TRH concentrations are higher than in maternal blood and are a consequence of extrahypothalamic (placenta and pancreas) TRH production and decreased TRH degradation in fetal serum. Functionally, the fetus progresses from a state of both primary (thyroidal) and tertiary (hypothalamic) hypothyroidism at midgestation, through a state of mild tertiary hypothyroidism during the final weeks *in utero*, to a fully mature hypothalamic-pituitary-thyroid axis by 2 months after birth.[317] At birth, several changes occur to stimulate neonatal thyroid hormone production (see "Adaptations to Extrauterine Life"). In response to a cool extrauterine environment, the neonatal hypothalamus secretes TRH, which stimulates a pituitary TSH surge. The TSH concentrations reach a peak of 60 to 80 μU/mL (60 to 80 mU/L) by 30 minutes after delivery and fall to normal-term infant concentrations by 3 to 5 days of life.[310]

The adult thyroid follicular cell can modify iodine transport or uptake with changes in dietary iodine intake, independent of variations in serum TSH concentrations.[320] Before 36 to 40 weeks of gestation, the thyroid gland lacks this autoregulatory mechanism and is susceptible to iodine-induced inhibition of thyroid hormone synthesis.[314,321] The fetal thyroid follicular cell, when exposed to high circulating levels of iodide, is unable to reduce iodide trapping and prevent the high intracellular iodide concentrations that produce the blockade of hormone synthesis referred to as the *Wolff-Chaikoff effect*. Failure of the immature thyroid to exhibit autoregulation is probably due to failure of downregulation of thyroid cell membrane NIS units, which may be related to the absence or reduced iodination of an 8- to 10-kDa protein in the thyroid follicular cell.[320,321] In addition to maturation of autoregulation, thyroidal responsiveness to TSH increases during the last trimester.[322]

Thyroid hormones are metabolized by different pathways: glucuronidation, sulfation, and deiodination, the latter being the most important. The metabolism of thyroid hormones occurs through a progressive series of monodeiodinations.[311,323] Three deiodinase enzymes act to remove an iodine atom from the outer (phenolic) ring or the inner (tyrosyl) ring of the tetraiodothyronine (T_4) molecule, thus, respectively, activating or inactivating the hormone. The deiodinases are encoded by separate genes and share sequence homology. Most of the circulating biologically active T_3 in adults is derived by outer-ring monodeiodination of T_4 in the liver and other nonthyroidal tissues; biologically inactive rT_3 derives from inner-ring deiodination of T_4 in peripheral tissues. The type I enzyme (D1), an outer-ring monodeiodinase, is a high Michaelis constant (K_m) enzyme inhibited by propylthiouracil and stimulated by thyroid hormone. It deiodinates T_4 to T_3 and rT_3 to T_2. D1 also has inner-ring deiodinase activity, converting T_3 to T_2. The activity of D1 is low throughout gestation. The type 2 outer-ring monodeiodinase (D2) is a low-K_m enzyme that is insensitive to propylthiouracil and inhibited by thyroid hormone. It deiodinates T_4 to T_3 and rT_3 to T_2, and it is highly expressed in the brain and pituitary. Type 3 monodeiodinase (D3) inactivates T_4 and T_3 via inner-ring deiodination of T_4 to rT_3 and of T_3 to T_2; it is highly expressed in fetal tissues and placenta. D1 is largely responsible for the production of T_3 that escapes from the cells, especially liver and kidney, into the circulation, whereas D2 is responsible for the production of local tissue T_3. Inactive rT_3 also diffuses out of most tissues to appear in plasma.

Iodothyronine deiodinases belong to a family of selenoproteins. Selenium is an essential trace element required for the biosynthesis of selenoproteins. Selenocysteine insertion sequence (SECIS)–binding protein 2 (SBP2) represents a key factor for the insertion of selenocysteine into selenoproteins. Recently, mutations in the *SBP2* gene have been described that lead to a multisystem disorder with deficiencies of multiple selenoproteins, resulting in growth retardation, myopathy and skin photosensitivity, nonketotic hypoglycemia, colitis, and infertility.[324,325] Due to abnormal D2 activity, T_3 is low, T_4 and rT_3 are increased, and TSH is slightly elevated. As selenoproteins also serve as antioxidants, tissue damage may be related to increased concentrations of ROS.[325,326]

The distribution of the deiodinases has been characterized in rodent and human tissues (Table 130.4).[327] D2 is detectable by midgestation and plays an important role in supplying T_3 to developing brain tissue, regulating thermogenesis in brown adipose tissue (BAT) in the neonatal period, and regulating pituitary TSH secretion. D3 activity is present in the placenta, liver, and perhaps fetal skin, accounting for the higher concentrations of rT_3 in the fetus and limiting the metabolic effects of thyroid hormones during much of fetal life. There is little conversion of T_4 to circulating T_3 via D1 deiodination until midgestation in the human fetus; plasma T_3 concentrations are low (<0.2 nmol/L or <15 ng/dL) until 30 weeks of gestation, after which the mean value increases to 0.7 nmol/L (50 ng/dL) at term (Fig. 130.7).[328] On the other hand, fetal brain T_3 concentrations are 60% to 80% of those in the adult by fetal age 20 to 26 weeks owing to D2 activity. In the presence of fetal hypothyroidism, D2 increases while D3 decreases in an effort to maintain near-normal brain T_3 concentrations.

TABLE 130.4 Deiodinase Expression in Human and Rodent Tissues

From Miller WL. Steroid hormone biosynthesis and actions in the materno-feto-placental unit. *Clin Perinatal* 1988;25:799–817.

Sulfation is active in fetal tissues, and the predominant thyroid hormone metabolites in the fetus are iodothyronine sulfates.[311,329,330] High levels of phenolsulfotransferases (SULT) have been characterized in the fetal liver, lung, and brain by midgestation. SULT activities decrease rapidly in the neonatal period.[330] In the last third of gestation in fetal sheep, the mean plasma production rates for T_4 and metabolites (in micrograms per kilogram of body weight per day) are as follows: T_4, 40; T_4 sulfate (T_4S), 10; rT_3, 5; rT_3S, 12; T_3, 2; and T_3S, 2. All metabolites are biologically inactive except T_3 and perhaps T_3S, so 90% of the T_4 metabolites in the fetus are biologically inactive.[329] The sulfated metabolites accumulate in fetal serum as a result of the low D1 activity in fetal tissues and because the sulfated iodothyronines are not substrates for D3.[320,331] The production rate of T_3 increases progressively between 30 weeks of gestation and term because of maturation of D1 activity in the liver and other tissues and because of decreasing D3 activity in the placenta.[322,330] In fetal sheep, hepatic D1 activity increases progressively during the last trimester.[332]

It has long been assumed that thyroid hormones passively diffuse into cells. However, several classes of cell membrane iodothyronine transporters have been described, questioning this hypothesis.[333–335] These transporters belong to different families of organic anion, amino acid, and monocarboxylate solute carriers, including the organic anion transporting polypeptide (OATP) family and the solute carrier family 21 (SLC21).[333–335] The significance of these transporters is not yet clear, but mutations of the human monocarboxylate transporter 8 (MCT8), a member of the SLC21 family shown to be a specific thyroid hormone transporter present in developing brain, leads to X-linked Allan-Herndon-Dudley syndrome (AHDS), which is characterized by thyroid hormone deprivation in the brain resulting in severe psychomotor retardation and elevated T_3 concentration in peripheral tissues.[336–338] A

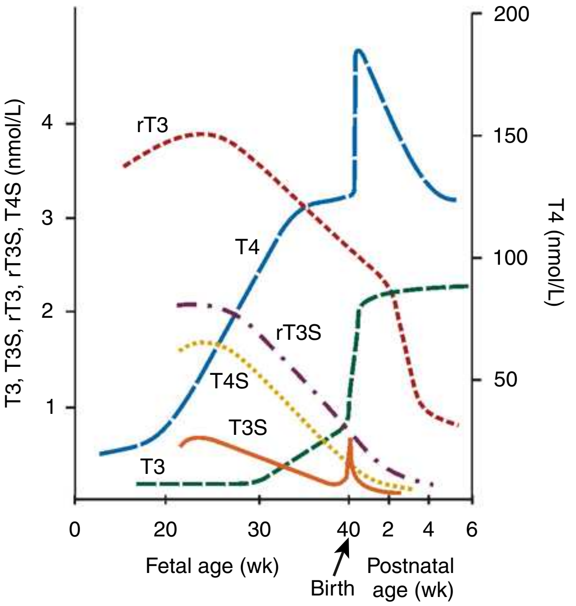

Figure 130.7 The pattern of maturation of thyroid hormone levels in the human fetus from midgestation through the perinatal period. The thyroid-stimulating hormone surge *(not shown)* at birth and the prenatal increase in fetal hepatic monodeiodinase type 1 activity stimulate marked increases in T_3 and T_4, facilitating the transition to postnatal life. The concentrations of bioinactive sulfated iodothyronine analogues T_3S, T_4S, reverse T_3 (rT_3)S, and T2S *(not shown)* peak during midgestation and fall progressively to term.

recent study has shown that brain damage in human fetuses is already induced *in utero*.[339] *Mct8* expression in neonatal mice has been localized to neurons in the olfactory bulb, cerebral cortex, hippocampus, and amygdala. Presumably, all thyroid hormone–sensitive cell populations express iodothyronine membrane transporters. A cell surface T_4 receptor has been characterized as an $\alpha_V\beta_3$ integrin that serves as the initiation site for T_4-induced activation of the mitogen-activated protein kinase (MAPK) pathway for angiogenesis and perhaps actin polymerization and neuronal migration.[340] The ontogenesis and significance of these cell surface receptors and membrane transporters in fetal development remain to be further defined. Recent studies have suggested that MCT8 is also required for normal thyroid hormone secretion, in addition to its role as a thyroid hormone transporter.[341] Treatment options for patients with MCT8 deficiency are limited. PTU blocks thyroid hormone production and inhibits the conversion of T_4 to T_3. PTU in combination with levothyroxine has shown limited metabolic benefits but no effect on neurological features. To date, two thyromimetics, DITPA (diiodothyropropionic acid) and Triac (triiodothyroacetic acid), are under investigation.[342,343] DITPA has been used in a small number of patients from age 9 months, and it has been shown that DITPA crosses the placenta and reaches neuronal target cells in mice inducing a T_3-like effect.[342,343] DITPA may therefore be a future candidate for *in utero* treatment of MCT8 deficiency. Triac has been used in a phase I clinical trial evaluating its effectiveness and safety for treatment of peripheral thyrotoxicosis in MCT8-deficient patients (both pediatric and adult).[337] This study is currently in phase II to evaluate the action of Triac in young boys <30 months with AHDS, in particular its effect on neurological symptoms and neurodevelopment.

The role of maternal thyroid hormone during fetal development remains controversial. The high placental concentration of D3 inactivates most of the thyroid hormone presented from the maternal circulation. The iodide released in this manner is used for fetal thyroid hormone synthesis. Despite the limited maternal-fetal placental transfer of T_4 and the predominant production of inactive thyroid hormone metabolites in the human fetus, significant concentrations of free T_4 are present in fetal fluids, from placental transfer early in gestation and from fetal thyroid production during later gestation.[322,344] Early in gestation, placental transfer is the only source of T_4 in fetal fluids and is essential for normal fetal neurodevelopment. T_4 is detectable in human coelomic fluid at concentrations of 0.5 to 2 nmol/L between 6 and 11 weeks of gestation, before the onset of fetal thyroid function.[345] Low concentrations of T_4 are detectable in the fetal brain at about 10 weeks of gestation. Significant placental transfer continues to term, when serum T_4 concentrations in the athyroid fetus range from 30 to 70 nmol/L (2.3 to 5.4 μg/dL).[346] Isotopic equilibrium studies with pregnant rats at term suggest that 15% to 20% of the T_4 in fetal tissues is of maternal origin.[347] As indicated, thyroid hormones cross the placenta early in gestation, supplying the low concentrations of free T_4 that are essential for brain development between 12 and 20 weeks, before the onset of fetal thyroid hormone production.[344] Most thyroid hormone in the fetal compartment is inactivated to sulfated and deiodinated analogues until the perinatal period.[311,329] This neutralization of active circulating thyroid hormone maintains the low T_3 metabolic state, facilitating fetal growth and programmed tissue maturation.

Thyroid Hormone Action. Classic thyroid hormone actions are mediated via functional thyroid hormone nuclear receptors (TRs), members of the steroid/retinoid/vitamin D family of nuclear transcription factors. Two genes code for the receptors: *THRA* on chromosome 17 encodes TRα and *THRB* on chromosome 3 encodes TRβ.[348] These genes code for four classic receptor isoforms (TRα1, TRα2, TRβ1, and TRβ2), three of which bind thyroid hormones (T_3/T_4 affinity 10 : 1) and bind to DNA to effect gene transcription. The TRα2 isoform does not bind thyroid hormone but binds to DNA and can inhibit binding of other TRs. The TRs exist as monomers, homodimers, and heterodimers with other nuclear receptor family members such as retinoid X (RXR). Other TR transcripts, including TRΔα1 and TRΔα2, have been characterized; they do not bind DNA or T_3 but can inhibit TR and retinoid receptor activities.[349]

The TRs are expressed developmentally and differentially in various fetal and adult tissues (Table 130.5). TRα proteins are present in most tissues. TRβ1 is expressed in the liver, kidney, and lung and in developing brain, cochlea, and pituitary. TRβ2 expression is restricted largely to the pituitary gland, retina, and cochlea.[322,348] The receptors function redundantly, as indicated by knockout studies in mice, but predominant effects of one or other TR have been characterized. Knockout of both the *TRα* and *TRβ* genes in mice is not lethal but results in elevated TSH concentrations, deafness, bradycardia, and decreased postnatal growth with delayed bone maturation.[322,348] Lethality occurs because of improper intestinal development associated with persistent TRΔα isoforms in TRα or combined TRα and TRβ knockout mice.[349] In the fetal rat brain, TRα1 mRNA and receptor binding are detectable by 12 to 14 days of gestation (term is 21 days), increasing to maximal levels at birth. The TRβ1 isoform is detected at birth and increases approximately 40-fold in the early postnatal period.[322,350] In the human fetal brain, TRα1 and TRβ1 isoforms and receptor binding are present by 8 to 10 weeks of gestation; TRα1 transcripts and receptor occupancy increase 8- to 10-fold by 16 to 18 weeks.[322,351,352] Liver, heart, and lung receptor binding can be identified by 13 to 18 weeks.[322,352,353]

Heterozygous missense mutations in *THRA,* coding for the TRα1, have recently been described in association with short stature, developmental delay, and chronic constipation. The mutations act in a dominant-negative fashion. The clinical phenotype is in line with the TRα1 being the predominant subtype receptor in bone, the gastrointestinal tract, cardiac and skeletal muscle, and the CNS.[354,355]

Thyroid hormone–programmed development of selective fetal tissues requires the interaction of local tissue D1, D2, thyroid receptors, receptor coactivators, and thyroid-responsive genes.

TABLE 130.5 Predominant Thyroid Hormone Receptor Subtype Functions in Developing Mice

Brain	Thermogenesis
TRα1, TRβ1	TRα1, TRβ1, TRβ2
Pituitary TSH secretion	Inner ear
TRβ2, TRα1	TRα1, TRβ2
Pituitary GH secretion	Retina

TRβ1	TRα1

GH, Growth hormone; *TR,* thyroid hormone receptor; *TSH,* thyroid-stimulating hormone.
From Rivier C, Vale W: Neuroendocrine interactions between corticotrophin releasing factor and vasopressin on adrenocortical hormone secretion in the rat. In: Schrier RW, ed. *Vasopressin.* New York: Raven Press; 1985:181-188 and Rose JC, Turner CS, Ray DeW, et al. Evidence that cortisol inhibits basal adrenocorticotropin secretion in the sheep fetus by 0.70 gestation. *Endocrinology* 1988;123:1307–1313.

There is growing evidence that thyroid hormones act on embryological and fetal tissues early in development. Thyroid hormones regulate gene transcription mostly through the T_3 form, which binds to nuclear receptors, encoded by the *TRα* and *TRβ* genes. TRs are transcription factors with ligand-regulated activity. In most responsive tissues, the timing of maturation events is controlled by the state of the thyroid receptors acting as a molecular switch.[349,356] In the absence of T_3, the unliganded receptor (aporeceptor) recruits corepressors, repressing gene transcription. Non–T_3-binding receptors also can repress transcription by inhibiting receptor DNA binding. Local tissue maturation events are initiated by the coincident availability of T_3, liganded T_3 receptor, T_3-mediated receptor exchange of co-repressor with coactivators for creation of an active holoreceptor, and activation of responsive gene transcription. The iodothyronine deiodinases initiate or terminate thyroid hormone action and are therefore critical for the biological effects mediated by thyroid hormone. The activating deiodinase (D2) and the inactivating deiodinase (D3) can locally increase or decrease thyroid hormone signaling in a tissue- and temporal-specific fashion independently of changes in thyroid hormone serum concentrations.

These programming events have been investigated in studies of transgenic mice, including brain, liver, heart, intestine, and bone tissues, thermogenesis, and spleen erythropoiesis.[356–362] The timing of these events in the mouse ranges from early midbrain neuronal development at gestational day 15, through perinatal activation of hepatic enzymes, cardiac ion channels, and spleen erythropoiesis, to postnatal brain, intestinal, and bone maturation and thermogenesis. Parturition occurs at a gestational age equivalent to human midgestation. In hypothyroid mice, repressive effects of aporeceptors have been shown to delay tissue maturation in the brain, bone, intestine, spleen, and heart.[360] The increase in circulating T_3 levels associated with parturition in mice and humans normally triggers the development of tissue functions essential to postnatal metabolism and homeostasis (e.g., hepatic, intestinal, and cardiac functions and brown fat thermogenesis). Thyroid hormone–stimulated maturation of vision and hearing appears to be triggered by the local expression of D2, mediating local T_3 production, postnatally in the mouse and probably toward the end of the second midtrimester in the human fetus.[363]

In humans, T_3-mediated maturation of fetal tissues, including liver, heart, BAT, and bone, allows them to become thyroid hormone responsive during late gestation and in the perinatal period. Paracrine actions of thyroid hormone are critical for normal fetal development—for example, in the cochlea, where D2 is expressed in connective tissue immediately adjacent to the sensory epithelium and spiral ganglion, where thyroid hormone receptors are located. This implies that D2-containing cells in the connective tissue take up T_4 from the circulation, convert it to T_3, and then release D3 to adjacent responsive cells. Similarly, in the brain, D2 is expressed predominantly in glial cells, whereas TRs are expressed in adjacent neurons and oligodendrocytes. In other areas of the brain, such as the pituitary gland, hippocampus, and caudate nucleus, there is coexpression of D2 and TRs. On the other hand, D3 is coexpressed with TRs in neurons, thereby protecting sensitive tissues from the effects of excess thyroid hormone.

The actions of thyroid hormones and their developmental regulation in the brain are complex. Functionally, thyroid hormones are critical for the establishment of neural circuits during a critical window of brain development. They provide inductive cues for the differentiation and maturation of a number of processes such as neurogenesis and neural cell migration (occurring between 5 and 24 weeks of gestation), neuronal differentiation, dendritic and axonal growth, synaptogenesis, gliogenesis (late fetal period to 6 months postpartum), myelination (second trimester to 24 months postpartum), and neurotransmitter enzyme synthesis. TRs are found in highest concentration in developing neurons and in multiple areas of the fetal brain, including the cerebrum, the cerebellum, and the auditory and visual cortices. The hormones bind to receptors and stimulate a number of genes such as myelin, neurotrophins and their receptors, cytoskeletal components, transcription factors, extracellular matrix proteins and adhesion molecules, intracellular signaling molecules, and mitochondrial and cerebellar genes.

Thyroid hormone is also important for normal bone growth. T_3 regulates endochondral ossification and controls chondrocyte differentiation in the growth plate both *in vivo* and *in vitro*. TRs are expressed on osteoblasts and growth plate chondrocytes, and T_3 target genes have been identified in bone. T_3 stimulates skull suture closure *in vivo*.[364]

In the perinatal period, thyroid hormone stimulates the transcription of thermogenin, also known as uncoupling protein 1 (UCP1), a protein that uncouples nucleotide phosphorylation and the storage of energy as adenosine triphosphate (ATP), actions that are important for nonshivering thermogenesis by BAT.

Congenital Hypothyroidism. Congenital hypothyroidism (CH) is a common endocrine disorder with an incidence of 1:3000 to 4000 at birth. It is typically reported to be sporadic. Pathogenic variations in candidate genes have been found in <10% of the cases; however, genetic studies targeting specific phenotypes or particular ethnic groups yielded higher mutation detection rates suggesting that CH can be considered as a disease with a strong genetic component, but with a largely missing explanation for its heritability.[365]

Thyroid dysgenesis is causal in the majority (85%) of children with permanent primary CH; however, mutations in known genes account for less than 5% of patients. The defects in thyroid morphogenesis can be classified as athyreosis (lack of thyroid tissue), ectopy, hemiagenesis (hypoplasia of one thyroid lobe), or hypoplasia. Genes associated with thyroid hormone dysgenesis and/or syndromic congenital primary hypothyroidism account for less than 5% of patients and include *NKX2-1, FOXE1, PAX8, NKX2-5, GLIS3, JAG1, TBX1, NTN1,* and *CDCA8.*[365] Carré et al. also recently described the impact of *BOREALIN* mutations as a genetic cause of thyroid dysgenesis in humans. *BOREALIN* expression in human embryonic thyrocytes was shown before and after the onset of thyroid hormone synthesis and *BOREALIN* is involved in the adhesion and migration of the thyrocytes, in keeping with a phenotype of thyroid ectopy.[366] Known causative genes in congenital hypothyroidism associated with dyshormonogenesis and/or with gland *in situ* include *TSHR, GNAS, TG, TPO, DUOX1/DUOX2, DUOXA2, SLC5A5, SLC26A4/PDS, IYD,* and the molecular spectrum is increasing. Table 130.6 shows mechanisms resulting in congenital hypothyroidism due to abnormal thyroid

TABLE 130.6 Mechanisms Involved in Congenital Hypothyroidism

Thyroid Dysgenesis (1 in 4500)

- Isolated thyroid aplasia, hemiagenesis, hypoplasia, or ectopy
  - Transcription factor defect (PAX-8)
  - Unknown[a]
- Associated with other developmental abnormalities
  - Transcription factor defect (TTF-1, FOXE1 [TTF-2], NKX2-5, SHH, Tbx1)

Inborn Errors of Thyroid Hormonogenesis (1 in 35,000)

- Abnormal iodide uptake (NIS, SLC5A5)
- Failure to concentrate iodide
- Abnormal organification of iodine
- Abnormal TPO enzyme
- Abnormal H_2O_2 generation (THOX, DUOX2)
- Pendred syndrome (SLC26A4)
- Defective Tg synthesis or transport
- Abnormal iodotyrosine deiodinase (DEHAL1)
- Abnormal thyroid hormone transport in the brain (MCT8)
- Abnormal selenium incorporation (SECISBP2)

Secondary and/or Tertiary Hypothyroidism (1 in 50,000 to 100,000)

- Hypothalamic abnormality
  - Isolated TSH deficiency
    - TRH deficiency
  - Multiple hypothalamic hormone deficiencies
    - Isolated hypothalamic defect
    - Associated with other midline facial/brain dysmorphic features (e.g., SOD, cleft lip/palate)
- Pituitary abnormality
  - Isolated TSH deficiency (IGSF1)
    - TRH resistance
    - Abnormal TSHβ molecule
  - Multiple pituitary hormone deficiencies
    - Ectopic posterior pituitary gland (transcription factor defect, e.g., POU1F-1, PROP1, LHX3)
    - Ectopic posterior pituitary gland (idiopathic, transcription factor defect, e.g., HESX1, SOX3, LHX4, OTX2)

TSH Resistance

- TSH receptor gene mutation
- Post-receptor defect?
- Gsα gene mutation

Thyroid Hormone Resistance (1 in 100,000)

SOD, Septo-optic dysplasia; *TRH,* thyrotropin-releasing hormone; *TSH,* thyroid-stimulating hormone

[a] Most common.

development, dyshormonogenesis, abnormal thyroid hormone transport or action, and the genes involved in these mechanisms.[367] Lower neonatal screening thresholds have increased the incidence of congenital hypothyroidism with a normally located gland *in situ*, and recent studies reveal that a significant proportion of patients have multiple gene mutations in more than one thyroid-specific gene, supporting the hypothesis of an oligogenic etiology of congenital hypothyroidism.[368]

Classical signs of CH (jaundice, lethargy, feeding difficulties, macroglossia, myxedema, hypothermia, growth restriction, progressive developmental delay, and IQ deterioration) appear during the early weeks and months of extrauterine life as maternal T_4 becomes unavailable and the non-CNS tissues become responsive to thyroid hormone.[369] The period of brain dependency for thyroid hormone extends postnatally to 2 to 3 years of age, but the early weeks and months of life are most critical. Untreated thyroid agenesis is associated with a loss of 5 to 7 IQ points monthly during the first months of postnatal life and over 6 to 8 months can amount to a 30- to 40-point IQ deficit.[370,371] Most countries therefore have a neonatal screening program to ensure early diagnosis and treatment and international guidelines for the management of CH are available.[372,373]

In congenital hypothyroidism, there is increasing evidence of maternal-fetal T_4 transfer in the first half of pregnancy, resulting in cord T_4 concentrations that are 25% to 50% of normal.[374] The transplacental passage of thyroid hormone, in conjunction with adjustments in brain deiodinase activity, has a critical role in minimizing the adverse effects of fetal hypothyroidism and helps explain the normal or near-normal outcome of hypothyroid fetuses (provided that prompt and adequate treatment of hypothyroidism ensues postnatally) as well as the relatively normal clinical appearance of the majority of babies with congenital hypothyroidism at birth. On the other hand, in the presence of both maternal and fetal hypothyroidism (such as that observed in the presence of potent TSHR-blocking antibodies, maternal and fetal *POU1F1* deficiency, and severe iodine deficiency), there is severe neurocognitive impairment despite early and adequate commencement of thyroid replacement. Importantly, the presence of inadequately controlled maternal hypothyroidism is also associated with significant neurocognitive deficit in the offspring that is not reversible by early postnatal therapy.[375]

KEY POINTS

- Thyroid hormone synthesis begins at 11 weeks' gestation. Maturation of the hypothalamo-pituitary control of the fetal thyroid develops in the third trimester.

THE FETAL AUTONOMIC NERVOUS SYSTEM

The ANS controls many physiological functions including heart rate, blood pressure, perspiration, and salivation and is composed in part of sympathetic neurons, parasympathetic neurons, and chromaffin cells of the adrenal medulla. The ability of the ANS to regulate the fetal CNS) and adapt to perturbations in homeostasis is a key necessity during human fetal maturation. The interplay between the sympathetic and parasympathetic nervous systems is achieved via the cerebral cortex, the medulla oblongata, the sympathetic ganglia, and the vagus nerve.

There is an increasing realization that the process of fetal autonomic regulation *in utero* serves specialized needs particular to development and that the onset of maturity represents the loss of these unique patterns of neural activity. Nowhere is this more evident than in the sympathetic nervous system and its endocrine counterpart, the adrenal medulla.

Embryology. The primordia of the sympathetic trunk ganglia are visible in the human fetus from as early as 4 to 5 wpc. The sympathoadrenal (SA) cell lineage is a derivative of the neuroectodermal crest (NC), which gives rise to sympathetic neurons, neuroendocrine chromaffin cells of the adrenal medulla, and extra-adrenal chromaffin cells. Signals that are important for the differentiation of SA cells into sympathetic neurons and chromaffin cells are largely unknown. In mice, the SA progenitor cells delaminate from the dorsal neural tube and migrate ventrally through the sclerotome toward the dorsal aorta to form numerous extramedullary sympathetic paraganglia,[376] which are scattered throughout the abdominal and pelvic sympathetic plexuses.[377] Each of the sympathetic paraganglia may reach a maximal diameter of 2 to 3 mm by 28 wpc and the largest of these, the organs of Zuckerkandl near the origin of the inferior mesenteric arteries, may reach 10 to 15 mm in length at term. After birth, the paraganglia gradually atrophy and disappear by 3 years of age.

The SA cells that migrate ventrally to reach the dorsal aorta[378] give rise to tyrosine hydroxylase-expressing, catecholaminergic neuronal progenitor cells, in response to bone morphogenetic protein cues from cells of the wall of the dorsal aorta and the surrounding mesenchyme.[379] Some cells migrate further ventrally around the dorsal aorta along nerves and blood vessels to enter the adrenal primordium at the cranial end and acquire a chromaffin cell phenotype.[380,381] This occurs from 6 wpc. It was thought that these were SA cells that lost expression of neuronal genes; however, more recently, it has been shown that at least some of the presumptive chromaffin cell population enters the adrenal primordium still expressing neural crest markers and then gains tyrosine hydroxylase and dopamine β-hydroxylase expression but not neuronal markers.[382] A recent study has shown that preganglionic axons and chromaffin cell precursors require class 3 semaphorin (SEMA3) signaling through neuropilins (NRP) to target the adrenal medulla.[383]

A variety of transcription factors have been identified in the development of the SA cell lineage including PHOX2B (paired-like homeobox 2b), MASH1 (mammalian achaete-scute homolog-1), PHOX2A (paired-like homeobox 2a), and HAND2 (heart- and neural crest derivatives-expressed protein 2).[376]. The *PHOX2B* gene is pivotal in the development of the ANS. *Phox2b* null mice die *in utero* because ANS neurons either fail to develop or degenerate. Mutations in human *PHOX2B* cause a rare syndrome of dysautonomia (congenital central hypoventilation syndrome), Hirschsprung disease, and a predisposition to neuroblastoma.[384]

Nerve growth factor (NGF) is required for the survival of developing sympathetic neurons. In the rodent, NGF antiserum injected into neonatal rats resulted in degeneration of immature chromaffin cells, sympathetic cells, and phaeochromoblasts.[385] It is unclear whether NGF and other growth factors are involved in the maturation of the human fetal ANS.

Functional Development of the SA System. Chromaffin cells are located in adrenal and extra-adrenal sites during fetal development, although the function of the extra-adrenal tissue is unknown and these chromaffin cells regress postnatally. Chromaffin cells are initially scattered within the adrenal cortex and are mostly noradrenergic. At around 10 wpc, small islets of chromaffin cells express PNMT (phenylethanolamine *N*-methyltransferase), the enzyme required to catalyze the methylation of noradrenaline (NA) into adrenaline, to become adrenergic.[386] With increasing gestational age, there is progressive growth of the adrenal medullae, increasing catecholamine content, and progressive maturation of medullary functional capacity. Histologically, the adrenal medullae are somewhat immature at birth but by 1 year they resemble the adult glands.

Catecholamines are present in the para-aortic chromaffin tissue by 8 to 13 wpc and concentrations increase until term. The predominant catecholamine is NA, presumably because of low activity of PNMT in para-aortic chromaffin tissue. In contrast, the adrenal medulla has high levels of PNMT activity. Adrenal PNMT is activated by the high levels of glucocorticoids that diffuse into the adrenal medulla from the adrenal cortex.[377,387] In contrast, cortisol concentrations in extramedullary chromaffin tissue are low. Cortisol and catecholamine concentrations in the fetus increase significantly in the third trimester, playing a critical role during transition of the fetus to an *ex utero* environment by priming the fetal nervous system.

How the fetus withstands an *in utero* environment of relative hypoxia has been a vibrant area of research for over a century. The ovine model provides a comparative system for physiological and developmental research in the fetus that is applicable to humans. This model has been used to study fetal adaptive responses to chronic oxygen and nutrient deprivation during placental insufficiency. Basal plasma adrenaline, NA, and dopamine concentrations decrease during the last trimester in sheep due to the maturation of clearance mechanisms.[388] The fetal sheep responds to hypoxia with increased catecholamine concentrations.[389] This response is also present in human fetuses during the third trimester of gestation.[390] There is evidence that during the basal state, circulating catecholamines are predominantly derived from sympathetic neurons, whereas the fetal adrenal is the major source of catecholamines during acute hypoxia.[391,392]

Catecholamines are critical for fetal cardiovascular function and fetal survival. Gene knockout studies in mice, targeting either tyrosine hydroxylase or dopamine β-hydroxylase, produced fetal catecholamine deficiency and midgestation fetal death in 90% of the mutant embryos.[393,394] In addition, fetal catecholamines are the major stress hormones in the fetus.[387,390,395,396] The cells of the adrenal medulla and para-aortic tissue can respond directly to fetal hypoxia by secreting large amounts of catecholamines directly into the circulation.[387] Moreover, the defense against fetal hypoxia involves catecholamine actions mediated through cardiac α-receptors that are unique to immature animals. α-Adrenergic receptors predominate in immature cardiac tissue and gradually decline in number as β-adrenergic receptors increase with maturation. Chromaffin tissue in the fetus is also innervated by opiate receptors and contains relatively large amounts of opiate peptides or enkephalins that appear to be cosecreted with the catecholamines. Pretreatment with naloxone potentiates and methadone inhibits the catecholamine response to hypoxia.[397] The extent to which these peptides or pituitary endorphins are involved in modulating fetal catecholamine secretion remains unclear.

The human neonate responds to parturition with an increase in plasma adrenaline and NA concentrations, and these responses are augmented by hypoxia and acidosis.[389,393,394] In the newborn infant, catecholamine secretion also increases after cold exposure and hypoglycemia.[387,390] Labor-induced catecholamine release may provide an important mechanism underlying the neonate's process of adapting to extrauterine conditions and the recruitment of vital postnatal adaptations.

KEY POINTS

- Fetal autonomic regulation *in utero* serves specialized needs particular to development, and this is clearly evident in the interplay between the sympathetic nervous system and its endocrine counterpart, the adrenal medulla.

FETAL PANCREAS AND GLUCOSE HOMEOSTASIS

Pancreas Development. Pancreatic development is a complex, multistep process, in which morphologically and functionally distinct exocrine and endocrine tissue types are derived from common endodermal progenitor cells. The exocrine tissue consists of acinar cells that secrete digestive fluid, centroacinar cells, and a branched ductal network that drains the fluid into the gastrointestinal tract. The endocrine cells are located in clusters called the islets of Langerhans, scattered throughout pancreatic parenchyma. They include insulin-secreting β cells (50% to 60%), glucagon-secreting α cells (30% to 45%), somatostatin-secreting δ cells (5%), pancreatic polypeptide (PP)–secreting γ cells (<5%), and ghrelin-secreting ε cells (<1%). Unlike in mice, where there is clear segregation of cell types in different regions of the islet, for example, β cells are central, surrounded by α, δ, and γ cells, in humans, β cells are intermingled with α and δ cells, throughout the islet.[398]

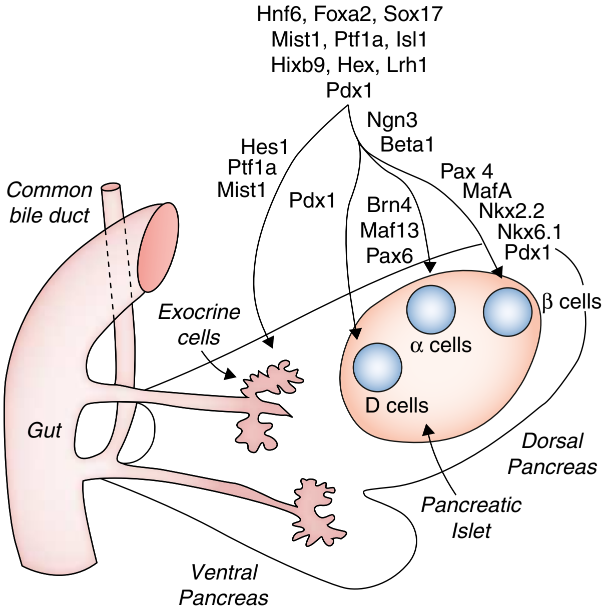

Figure 130.8 Genes implicated in programming development of the pancreas and pancreatic islets. Knockout of *Pdx1* or *Isl1* is associated with early arrest of pancreatic development. *Hes1*, *Ptf1A*, or neurogenin 3 (*Ngn3*) disruption leads to aplasia or hypoplasia of the islets of Langerhans. Disruption of the downstream transcription factors impacts formation of the beta cells or alpha cells. *Sox9* and *Hnf3b* (not shown) are required for early foregut formation and pancreas specification. (Data from Habener JF, Kemp DM, Thomas MK. Minireview: transcriptional regulation in pancreatic development. *Endocrinology*. 2005; 146: 1025–1034.)

Our understanding of human pancreas development has been extrapolated from data obtained in other species, particularly the mouse (Fig. 130.8). Specification of the mouse pancreas is initiated from the distal part of the endodermal foregut and proximal part of the midgut beginning at E8.5 and is first indicated by expression of the transcription factor Pdx1.[399,400] The pancreas arises from distinct dorsal and ventral buds, which are induced by different mesodermal structures and signaling pathways. The pancreas can only develop in an area free of Shh. Coincident with the start of pancreas development, Shh expression is repressed in the dorsal and ventral pancreatic buds, dependent on signals from the notochord that include FGF2 and the TGFβ signaling molecule, activin.[401,402]

In addition to *Pdx1*, which is necessary for normal pancreas development, there are several other transcription factor genes involved in foregut patterning and early pancreas development, including *Hnf4a*, *Hnf6 (Onecut1)*, *Hnf1b*, *Mnx1* (also known as *Hlxb9*), and *Ptf1a*.[403] Both the dorsal and ventral bud, pancreatic progenitors express the essential transcription factor *Pdx1* and *Ptf1a*, but only the dorsal bud expresses *Hoxb9*.[404] Genetic lineage-tracing in mice indicates that essentially all mature pancreatic cells, including acinar, ductal, and endocrine cells, arise from *Pdx1*$^+$/*Ptf1a*$^+$ progenitor cells.[399,405–407]

After pancreatic specification and the onset of bud formation, there are continued signaling processes that regulate the proliferation and differentiation of progenitor cells for the endocrine, ductal, and exocrine lineages. Multipotent progenitor cells initially go through a period of rapid proliferation under the influence of *Fgf10*, forming a branching epithelial network of the pancreas.[408] At around E13, the epithelium becomes segregated into distinct "tip" and "trunk" domains, while the tip domains contain multipotent pancreatic progenitor cells, which are capable of differentiating into proacinar cells, the adjacent trunk epithelial region consists of a duct/endocrine bipotential progenitor pool.[407] *Ptf1a* appears to be the key player in acinar formation and its loss results in acinar agenesis.[409] The β-catenin/Wnt signaling pathway is required for the maintenance of Ptf1a exocrine progenitor cells.[410,411]

Loss-of-function experiments in mice have identified several transcription factors that play a role in specifying the multiple endocrine lineages in the developing pancreas. *Ptf1a* and *Nkx6-1* have an antagonistic relationship, and the segregation of *Nkx6-1* and *Ptf1a* expression into exclusive trunk and tip compartments, respectively, appears to correlate with the progressive restriction of trunk and tip cells toward the future duct/endocrine or acinar lineages.[412] In the mouse, endocrine specification, via the generation of Neurog3 endocrine precursors, occurs in two major waves termed the primary and secondary transition. The primary transition takes place during the bud stages of early pancreas development, where *Neurog3*$^+$ transcripts can be detected in the presumptive pancreatic anlage as early as E8.5 to E9.5. The majority of endocrine precursors are however generated from the trunk plexus during the secondary transition, peaking in absolute numbers at around E15.5.[413]

The level of Notch signaling has been demonstrated to exert antagonistic effects on *Neurog3* transcription. Low levels of Notch signaling induce expression of *Sox9*, which positively regulates *Neurog3* expression, whereas high levels of Notch signaling induce both *Sox9* and *Hes1* leading to repression of *Neurog3* expression.[413] The remaining nondelaminating *Hnf1b*$^+$/*Sox9*$^+$/*Nkx6-1*$^+$ trunk cells are fated to become duct cells. Precocious endocrine differentiation, for example, from deficiency in Notch pathway components, such as *Rbpj*, *Dll1*, and *Hes1*, results in pancreatic hypoplasia due to *Ptf1a*$^+$ progenitor pool depletion.[414–416] *NeuroD1*, *Insm1*, and *Isl1* are all required for the development of multiple endocrine cell lineages and are thought to act downstream of *Neurog3*.[417–419]

Neurog3 expression defines the development of a progenitor population for all endocrine lineages, including α cells, β cells, δ cells, γ cells, and ε cells.[405] Endocrine progenitor cells delaminate from the trunk epithelium and coalesce to form islets. With further maturation, complex networks of factors function to establish the different endocrine lineages. Expression of transcription factor genes in a combinatorial manner further restricts cells into distinct monohormonal endocrine lineages; α cells express *Pax6*, *Nkx2.2*, *Foxa2*, *Arx*, *MafB*; β cells express *Pax4*, *Pax6*, *Nkx2.2*, *Nkx6-1*, *Pdx1*, *Mnx1*, and *MafA*; δ cells express *Pax4* and *Pax6*.[420,421]

Most of our understanding of the molecular mechanisms involved in human pancreas development is derived from studies initiated at 7 to 8 weeks of fetal development, by which time the two pancreatic buds have coalesced as a single organ, and endocrine commitment has already started and later gestational-aged human pancreatic tissue (>22 weeks' gestation).[422] More recent studies, examining specimens obtained from human embryos from as early as human embryonic stage Carnegie Stage 9 (CS9) or 22 to 26 days post conception (dpc), have provided important insights into earlier development and pancreas specification.

In humans, as in mice, the pancreas develops from dorsal and ventral pancreatic buds, which emerge as distinct outgrowths from the posterior foregut endoderm. Foregut endoderm lying adjacent to the notochord can be observed at 25 to 27 dpc (CS9). *SHH*, which must be excluded for pancreatic buds to develop, can be detected at CS10 and *PDX1* expression is first seen at CS12 (29 to 31 dpc).[423–425] It appears that human foregut and pancreatic patterning is similar to those of mice. In mice, a "primary transition" stage occurs between E9.5 and E12.5. The first differentiated endocrine cells, mainly glucagon-producing α cells, begin to appear in the dorsal bud at this phase of development, in a cluster-budding process, rather than by individual delamination of epithelial cells. By contrast, there has been no evidence of early pancreatic endocrine differentiation in human embryos possibly due to a lack of proximity between the paired dorsal aortae and the early pancreatic endoderm.[424]

The ventral and dorsal pancreatic buds at CS13 (30 to 33 dpc) are marked by *SOX9*, *PDX1,* and *GATA4*, all of which are required for human pancreas development based on the phenotype of patients with loss-of-function mutations in these genes.[426–428] Significant growth of the pancreas and proliferation of MPCs occur between CS13 and CS19. Unlike mice, *NKX2.2* is not detected in these cells. Further differences in pancreatic progenitor cells are seen from CS19 (45-47 dpc), equivalent to E14 to E14.5 in mice. *SOX9*$^+$/*NKX6-1*$^+$ "trunk" cells show low expression of *GATA4*, whereas peripheral "tip" cells are *SOX9*$^+$/*NKX6-1*$^+$/*GATA4*$^+$. By 10 wpc, proacinar "tip" cells no longer express *NKX6-1*, similar to mice. Loss of *SOX9* expression in acinar cells is delayed in humans (at 10-14 wpc) compared with mice, in which *Sox9* is lost from peripheral tip cells shortly following their formation, at around E14.5 to E15.[425]

Detection of *NEUROG3* (or *NGN3*) first occurs at CS21 (49-52 dpc) closely followed by detection of insulin-positive cells, which is the first islet cell type to appear.[423,424] *SOX9* expression persists in pancreatic duct cells but is absent in *NEUROG3*-positive endocrine progenitors. Transient expression of *NEUROG3* is also seen in humans as in mice.[425] The ventral pancreatic bud migrates toward the dorsal bud and both buds fuse together resulting in a single pancreatic organ by the end of embryonic development (CS23, eighth week). Between 10 and 12 weeks, the proliferation of branched tubules into primitive acini, islets, and ducts occurs with limited differentiation.[420,424,429]

Functional Development of the Endocrine Pancreas. Insulin, glucagon, somatostatin, and pancreatic polypeptide are measurable by 8 to 10 weeks of gestation.[430] Endocrine cell clusters, in which β cells form a core with a periphery of α cells and δ cells, similar to mouse islets are observed by 12 to 14 weeks. By 18 weeks, the peripheral α cells and δ cells dissociate from the β-cell core to form juxtaposed homogenous islets and these homogenous islets reintegrate after week 22 to form the configuration seen in adult islets, with a heterogeneous distribution of β, α, and δ cells.[431] Early in gestation, α cells predominate, whereas β-cell proliferation is programmed during the latter half of gestation. At term, the ratio of α and β cells is approximately 1:1.[423,432] α and β cells have opposing roles in glucose homeostasis, although they derive from a common progenitor and share many proteins important for glucose sensing and hormone secretion. Mouse models have underlined the similarities between the two cell types by showing that β-to-α as well as α-to-β transdifferentiation can take place under certain experimental circumstances, revealing a remarkable degree of plasticity among the different pancreatic endocrine cells.[433]

In rodents, a period of a rapid increase in β-cell mass around and shortly after birth has been noted and this rapid change is attenuated by a period of apoptosis before adult mass is arrived at. β-cell mass is more difficult to determine from a developmental standpoint in humans. At birth in the human, there are approximately 200 to 300 × 10^6 β cells, which is approximately one-third of the population present in adulthood. However, most of the actual mass change takes place in the newborn period and is associated with changes in β-cell size rather than number.[434] Thereafter there is rapid further expansion in terms of cell numbers, but the fluctuations in β-cell mass particularly with pregnancy is poorly understood. Progression to type 2 diabetes mellitus may depend on the number and functionality of β cells at birth and how these are affected by interaction with environmental factors throughout life.

The β cell is functional by 14 weeks of human gestation, and fetal pancreatic insulin content exceeds that of the adult throughout most of gestation. Fetal glucose metabolism is largely independent of the glucoregulatory hormones insulin and glucagon,[435–437] and acute hypoglycemia or hyperglycemia is not associated with significant alterations in either insulin or glucagon levels. Insulin release from the fetal rat pancreas *in vitro* in response to glucose or pyruvate is minimal but can be stimulated by leucine, arginine, tolbutamide, or potassium chloride, indicating that parts of the secretory mechanism are functional in the fetus.[435,438] Insulin secretion in adult islets is mediated by two or more mechanisms, including stimulation of the adenylate cyclase system with production of cAMP and inhibition of potassium efflux, which leads to depolarization of the cell membrane and opening of voltage-dependent calcium channels. The former mechanism, although suppressed in the fetal islets, can be augmented by theophylline, but calcium channel activation does not occur in fetal islets in response to initiators of insulin release that cause depolarization of adult islet cells.[438]

Infusion of glucose or arginine in pregnant women before hysterotomy fails to provoke fetal insulin secretion at midgestation or near term, and plasma insulin levels in the late human fetus are relatively unresponsive to high glucose concentrations before the onset of labor.[439] Similar observations have been made in the monkey: neither glucose nor arginine stimulated fetal insulin release near term but glucagon evoked prompt insulin production.[439] Late in gestation in the ovine fetus, epinephrine inhibits insulin release through a receptor pathway.[439]

In the anencephalic human fetus, the endocrine pancreas develops normally if maternal carbohydrate metabolism is not impaired; β-cell hypertrophy and hyperplasia do not occur in the anencephalic fetus nor in decapitated fetal rabbits exposed to chronic hyperglycemia. This lack of β-cell response to hyperglycemia may be the result of deficiency of GH and/or IGF-1. GH stimulates insulin gene expression and may play a permissive role in β-cell hyperplasia and hypertrophy.[440] In contrast to acute changes in glucose concentration, chronic fetal hyperglycemia does evoke hyperinsulinemia and glucagon suppression, and chronic hypoglycemia may inhibit fetal insulin and promote fetal glucagon release.[435,439]

Pancreatic glucagon concentrations are relatively high in fetal plasma and increase progressively with fetal age.[435,439] As is true for insulin, the capacity for glucagon secretion is blunted in the fetus. Hyperglycemia does not suppress fetal plasma glucagon concentrations in rats, monkeys, or sheep, and acute hypoglycemia does not evoke glucagon secretion in the rat fetus. Amino acids, which are important secretagogues for insulin and glucagon in the adult, probably have little role in modulating insulin and glucagon secretion in the preterm fetus but infusion of alanine into women at term increases both maternal and cord blood glucagon concentrations, indicating a fetal glucagon response to amino acids in the term fetus. Catecholamines also evoke glucagon release in the near-term ovine fetus.[439]

Thus the fetal pancreatic islet cells, although histologically mature and capable of hormone synthesis and hyperplasia, are relatively immature functionally at birth with regard to the capacity to secrete both insulin and glucagon. The rapid maturation of responsiveness to glucose in the neonatal period in both premature and mature infants suggests that this blunted state may be a secondary result of the relatively stable fetal serum glucose concentrations maintained by placental transfer of maternal glucose rather than a primary, temporally fixed maturation process. Alternatively, the lack of any enteric signal to the pancreas from feeding via the release of incretins may also account for this stability. The blunted capacity for insulin and glucagon secretion has been related to a deficient capacity of the fetal pancreatic islet cells to generate cAMP or a rapid destruction of cAMP by phosphodiesterase, or both.[439]

Insulin and glucagon are normally not necessary for substrate metabolism in the fetus.[435] Fetal energy needs are met by a continuous intravenous supply of glucose across the placenta, fetal glucose uptake being directly related to both the maternal blood glucose concentration and the transplacental gradient. There is little endogenous glucose production. The fetal respiratory quotient is approximately 1, which suggests that glucose is the primary energy substrate for the fetus. Other substrates such as amino acids and lactate may also be utilized in the human, as in the sheep fetus. However, at least early in gestation, hepatic metabolism and substrate utilization appear to be independent of insulin and to be modulated in an autoregulatory fashion by glucose.[439] In addition, the constant supply of glucose normally precludes the necessity for endogenous gluconeogenesis, and gluconeogenic enzyme activities are low in the fetal liver.

Glycogen storage in the fetus is modulated by fetal glucocorticoids and probably by hPL. Fetal insulin plays a role near term, when insulin also has the capacity to increase fetal glucose uptake and lipogenesis.[435,439] Insulin receptors are present in a variety of fetal tissues at levels generally exceeding those of the adult. However, downregulation of insulin receptor binding does not occur during fetal hyperinsulinemia, in contrast with observations in adult animals.[439] Fetal hepatic glucagon receptors, in contrast, are reduced in number, and the fetal liver is therefore relatively resistant to the glycemic effect of glucagon.[439] These conditions tend to potentiate the fetal anabolic milieu during the period of rapid growth in the last trimester of gestation.

Congenital Hyperinsulinism. CHI represents a group of clinically, genetically, and morphologically heterogeneous disorders and is the most frequent cause of persistent and recurrent hypoglycemia in neonates and infants. It is due to inappropriate and unregulated secretion of insulin and can be transient or permanent. Transient forms associated with maternal diabetes mellitus, rhesus isoimmunization, IUGR, perinatal asphyxia, and BWS can last for days to months and may require diazoxide treatment.

Genetic forms of hyperinsulinism (HI) can histologically be divided into focal and diffuse forms that are inherited in a sporadic or autosomal manner, respectively. The estimated incidence is 1 in 30,000 births and a genetic diagnosis is possible for 40% to 50% of individuals. At present, mutations have been described in 14 genes, which include genes encoding the following: ion channels: *ABCC8, KCNJ11, CACNA1D*; enzymes: *GLUD1, GCK, HADH, PGM1, HK1 PMM2*; transporters: *SLC16A1, UCP2*, and transcription factors: *HNF1A, HNF4A, FOXA2*.[441–443]

ABCC8 and *KCNJ11* encode for the subunits (Kir6.2 and SUR1) of the pancreatic β-cell ATP-sensitive K^+ channel. Due to its sensitivity to ATP, K^+ channels convert intracellular metabolic signals into membrane excitability in the following cascade: glucose is transported into the cell by glucose transporters; intracellular glucokinase catalyzes an essential irreversible step for glycolysis; intracellular glucose metabolism raises the cytosol ATP/ADP ratio, which inhibits the SUR1 component of the K^+ channel, resulting in K^+ channel closure, which subsequently results in membrane depolarization, opening of voltage-gated Ca^{2+} channels, and Ca^{2+} influx, which triggers the release of insulin from stored granules. Mutations in *ABCC8* and *KCNJ11* can thus result in oversecretion of insulin.[444]

The HI/hyperammonemia syndrome (HI/HA) is due to heterozygous gain-of-function mutations in *GLUD*, which encodes the glutamate dehydrogenase (GDH) enzyme, and is characterized by both fasting hypoglycemia and hyperinsulinemic hypoglycemia due to protein ingestion. Mutations in the enzyme hydroxyacyl coenzyme A dehydrogenase (*HADH*) also cause protein-sensitive HI and are relatively common in consanguineous populations after *ABCC8/KCNJ11* mutations have been excluded.[445]

Certain syndromes have been associated with CHI with varying mechanisms underlying the HI. These include overgrowth syndromes (BWS, Sotos, Simpson-Golabi-Behmel, Perlman), chromosomal abnormalities (Trisomy 13, mosaic Turner syndrome), growth failure syndromes (Kabuki, Costello, Rubenstein-Taybi), syndromes with abnormal calcium homeostasis (Timothy syndrome), congenital disorders of glycosylation, insulin resistance/Donohue syndrome (*INSR*), congenital hypoventilation syndrome (*PHOX2B*), and a contiguous gene deletion including *ABCC8* (Usher syndrome).[443,446]

At the time of hypoglycemia, a hypoglycemia screen including glucose, insulin, C-peptide, acetoacetate, and β-hydroxybutyrate will easily identify CHI. Diagnostic criteria are a glucose infusion rate of >8 mg/kg/minute, a laboratory blood glucose <3 mmol/L with detectable serum insulin or C-peptide, low serum ketone bodies, and low serum fatty acids.[447] First-line treatment is diazoxide and chlorothiazide, and second-line treatment is octreotide or glucagon. Patients who are diazoxide insensitive will need further investigation with a combined computed tomography (CT)/18F-DOPA positron emission tomography (PET) scan to assess for focal or diffuse lesions. Focal lesions can be cured with surgery, whereas diffuse lesions require near-total pancreatectomy, which often does not result in a cure and may lead to diabetes mellitus.[448]

Neonatal Diabetes. Neonatal diabetes mellitus (NDM) is defined as diabetes with onset before 6 months of age and has an approximate incidence of 1:100,000 live births. There are many different subtypes of neonatal diabetes defined by different genetic causes. We now know of 30 different genetic subtypes of NDM and a genetic diagnosis can be found for 82% of patients.[449–452]

Neonatal diabetes may be transient (TNDM) or permanent (PNDM) or part of a syndrome, with extrapancreatic features. TNDM accounts for 60% of NDM and normally spontaneously remits before 18 months of age or is so mild as not to require treatment. After remission, diabetes mellitus often recurs, usually during adolescence.[453] The majority of cases are due to overexpression of an imprinted gene on chromosome 6q24 (*PLAGL1/HYMAI* genes). Activating mutations of *KCNJ11* and *ABCC8*, encoding for the two subunits (Kir6.2 and sulfonylurea receptor 1 [SUR1]) of the pancreatic β-cell ATP-sensitive inward rectifier potassium (K-ATP) channel, account for 25% of cases.[454] Other rarer causes include mutations in the *HNF1B* gene (renal cyst and diabetes syndrome), encoding a transcription factor, *INS* gene, encoding preproinsulin and *ZPF57*, which regulates gene methylation.

PNDM is most often due to activating mutations in *KCNJ11* or *ABCC8*, resulting in overactivation of potassium channels and thus impaired insulin secretion. These patients are responsive to sulfonylurea therapy and do not require insulin treatment. Other nonsyndromic causes of PNDM include *INS* and *GCK* mutations. In approximately 50% of PNDM cases, the diabetes-causing gene encodes a transcription factor, and the mutation leads to defects in pancreas development and a decreased number of β cells with or without extrapancreatic features. To date, mutations in 12 different genes encoding transcription factors important for pancreatic development have been identified in patients with neonatal diabetes including *PDX1*, *PTF1A* (coding and distal enhancer regions), *GLIS3*, *PAX6, RFX6, NEUROD1, NEUROG3, GATA4, GATA6, NKX2-2, MNX1,* and *CNOT1*.[449,455,456]

Impaired cellular stress response is a known β-cell dysfunction mechanism and cause of early-onset diabetes. The most common PNDM syndromic subtype is Wolcott-Rallison syndrome, which is caused by autosomal recessive mutations in the EIF2AK3 gene (eukaryotic translation initiation factor 2 alpha kinase 3), encoding the pancreatic eIF2-alpha kinase (PERK). Wolcott-Rallison syndrome is characterized by neonatal/early-onset diabetes, skeletal dysplasia, liver dysfunction, cardiac and renal abnormalities, developmental delay, epilepsy, and neutropenia. More recently heterozygous *de novo* variants in EIF2B have been found to cause PNDM and transient liver dysfunction. These mutations disrupt the ability of the eIF2B complex to sense eIF2 phosphorylation, likely resulting in severe cellular/ER stress.[457]

Other recessively inherited syndromes with neonatal-onset diabetes as a component include Wolfram syndrome or DIDMOAD (DI, diabetes mellitus, optic atrophy, and deafness) caused by *WFS1* mutations, thiamine–responsive megaloblastic anemia syndrome (PNDM, thiamine–responsive megaloblastic anemia, sensorineural deafness) caused by mutations in a thiamine transport gene (*SLC19A2*), Roger syndrome and Fanconi-Bickel syndrome (PNDM, hypergalactosemia, liver dysfunction) caused by mutations in *SLC2A2* encoding GLUT2 transporter, and microcephaly with simplified gyration, epilepsy, and PNDM (MEDS) caused by *IER3IP1* mutations.[449]

A growing list of genes causing monogenic autoimmune syndromes, in which diabetes due to β-cell destruction is a common feature, have been identified: *FOXP3* mutations result in IPEX (immune dysregulation, polyendocrinopathy, enteropathy, on X chromosome) syndrome; biallelic LRBA mutations cause common variable immunodeficiency-8, characterized by early-onset severe autoimmune manifestations, enteropathy, lymphoproliferation, hypogammaglobulinemia, and recurrent respiratory tract infections; *IL2RA* mutations cause immunodeficiency 41 with lymphoproliferation and autoimmunity; heterozygous activating *STAT3* mutations result in early-onset polyautoimmunity; T1D, autoimmune hypothyroidism and celiac disease, and mutations in the nucleoside transporter *SLC29A3* cause histiocytosis-lymphadenopathy plus syndrome.[458]

Neonatal diabetes associated with monogenic severe insulin resistance and or lipodystrophy is far less common than monogenic β-cell failure and is caused by genetic defects affecting insulin receptor signaling (*INSR*; Donahue syndrome) or adipocyte function, for example, congenital lipodystrophy syndrome due to AGPAT2, BSCL2, CAV1, and PTRF mutations.[459]

Next-generation sequencing (NGS), using targeted gene panels, enables simultaneous analysis of multiple genes, vastly reducing costs and leading to even higher rates of mutation detection.[451,460] Whole-exome or whole-genome sequencing is subsequently being performed in cases when a pathogenic variant is not identified using the targeted NGS approach. Identifying the genetic causes of neonatal diabetes is not only relevant for patients but also provides great insights into the human pancreas and β-cell development and function, and the clinical heterogeneity of diabetes. Neonatal diabetes that does not respond to sulfonylurea therapy is best treated with continuous subcutaneous insulin infusion via a pump using rapid-acting insulin analogues rather than multiple daily injections as insulin doses are so small, and feeding is so frequent.[461,462]

KEY POINTS

- Pancreatic development is a complex process, in which morphologically and functionally distinct exocrine and endocrine tissue types are derived from common endodermal progenitor cells
- Insulin, glucagon, somatostatin, and pancreatic polypeptide are measurable by 8 to 10 weeks' gestation. Fetal energy needs are met by a continuous intravenous supply of glucose across the placenta
- Insulin, glucagon, somatostatin, and pancreatic polypeptide are measurable by 8 to 10 weeks of gestation

FETAL PARATHRYOID AND BONE METABOLISM

Parathyroid Development

During the fourth to fifth week of intrauterine development, the embryonic pharynx is marked externally by four branchial clefts of ectoderm origin and internally by five branchial pouches of endoderm origin. The branchial arches of mesoderm origin are in between them. Together these structures comprise the branchial apparatus, which normally undergoes involution leaving behind derivatives including the thyroid gland, parathyroid glands, thymus, ultimobranchial body, Eustachian tube, middle ear, and external auditory canal.[463]

The parathyroid glands develop as epithelial thickenings of the dorsal endoderm of the third and fourth branchial pouches. The superior parathyroid glands are derived from the fourth branchial pouch, which also gives rise to the thyroid gland. The third branchial pouch gives rise to the inferior parathyroid glands and the thymus. The parathyroid glands remain intimately connected with their respective branchial pouch derivatives and parathyroid gland development from the third and fourth pharyngeal pouches proceeds in synchrony with thyroid embryogenesis.[322,464]

The parathyroid glands develop between 5 and 15 weeks of gestation. The third pouches encounter the migrating thyroid anlage and the parathyroid anlagen are carried caudally with the thyroid gland, finally coming to rest at the lower poles of the thyroid lobes as the inferior parathyroid glands.[322,464] The fourth pouches encounter the thyroid anlage later and come to rest at the upper poles of the thyroid lobes as the superior parathyroid glands.[322,464] The fifth pouches contribute paired ultimobranchial bodies that are incorporated into the developing thyroid gland as the parafollicular or C cells that secrete calcitonin. The individual parathyroid glands increase in diameter from less than 0.1 mm at 14 weeks of gestation to 1 to 2 mm at birth and adult glands measure 2 to 5 mm in width and 3 to 8 mm in length.

Most of the parathyroid gland parenchyma is composed of chief cells (also known as the parathyroid gland principal cells). These play a critical role in calcium homeostasis by sensing changes in extracellular calcium concentration and releasing the appropriate amount of PTH to correct or maintain normal blood calcium concentrations. The chief cells spend most of their time inactive due to normal calcium homeostasis. Near term, fetal parathyroid cells are largely composed of inactive chief cells, with only a few intermediate chief cells containing occasional secretory granules. The calcitonin content of C cells in the neonatal thyroid gland is as high as 540 to 2100 mU/g of tissue, values as much as 10 times those observed in the normal adult gland.[465] Both endocrine systems are functional during the second and third trimesters.

Transcription Factors Involved in the Development of Parathyroid Glands

The molecular signaling pathways and transcription factors that are involved in determining the differentiation of the pharyngeal pouch endoderm into parathyroid cells are being elucidated by studies of appropriate mouse models and patients with hypoparathyroidism. Fig. 130.6 shows the gene cascade programming normal thyroid-parathyroid development. Deletions of genes encoding several transcription factors in mice result in developmental anomalies that include parathyroid defects, although such abnormalities have not yet been reported in men. The transcription factors include members of the Hox (Hoxa3 and Hox15, which result in parathyroid agenesis) and Pax (Pax1, Pax3 and Pax9) families, Pbx1 (a protein that acts as a cofactor of Hox transcription factors), Eya1, Six1, Gcm2, Crk1, and Tbx1 and Tbx2.[466,467]

In humans, the most common cause of isolated parathyroid aplasia and severe hypoparathyroidism is loss-of-function mutations in the *GCM2* (previously *GCMB*) gene, which is expressed exclusively in the parathyroid glands.[468,469] A study of 20 patients who had childhood-onset, permanent hypoparathyroidism, which was not due to a chromosome 22q11 deletion, showed that 35% had a mutation in one of three genes (*GATA3*, *GCM2*, or *CASR*). Among the 13 patients with syndromic hypoparathyroidism, which was associated with deafness and/or renal dysplasia, six (>45%) had a mutation involving *GATA3*, *GCM2*, or *CASR*, and among seven patients with nonsyndromic hypoparathyroidism, two (>25%) had a mutation involving *GCM2*.[470] These studies indicate that the likelihood of a genetic etiology in hypoparathyroidism is likely to be high. Gain-of-function mutations of *GCM2* are a cause of parathyroid hyperplasia and familial isolated hyperparathyroidism.[471,472] X-linked recessive hypoparathyroidism with complete agenesis of the parathyroid glands has been reported in two multigenerational, related kindreds with a deletion-insertion downstream of *SOX3* likely to exert a position effect on *SOX3* expression.[473] These findings point to a potential role for the *SOX3* gene in the embryologic development of the parathyroid glands from the pharyngeal pouches. Isolated hypoparathyroidism due to disorders of PTH synthesis or secretion can be found in association with mutations in genes expressing PTH, calcium-sensing receptor (CaSR), and GNA11 (α subunit of the G protein, Gα11 that couples the CSR to activation of intracellular signaling pathways in the parathyroid cell).[467,468]

Human disorders with congenital hypoparathyroidism as a component have been found in association with mutations and deletions in *GATA3* (hypoparathyroidism, deafness, renal dysplasia [HDR] syndrome), *AIRE1* (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy [APECED] syndrome or autoimmune polyglandular syndrome type 1 [APS1]), *CHD7* and *SEMA3E* (CHARGE syndrome), *TBCE* (Kenny Caffey syndrome), *PTH/PTHrP* (Blomstrand chondrodysplasia), and *GNAS1* (pseudohypoparathyroidism). *TBX1* (a DNA-binding transcription factor of the T-box family that is known to have an important role in vertebrate and invertebrate organogenesis and pattern formation) and *CRKL* mutations have been associated with 22q11 deletion syndrome.[474,475]

Fetal Calcium and Phosphate Metabolism

The endochondral skeleton begins forming in the embryo, but it is not until the third trimester that substantial bone is formed and mineralized. Studies in fetal sheep and monkeys and measurements in human preterm and term infants indicate that the majority (~80%) of calcium is transported/accreted during the third trimester.[476] The kidneys, intestines, and skeleton (through bone turnover) are not dominant sources of mineral supply for the fetus as they are for children and adults. Instead, the placenta meets the fetal mineral need by actively transporting calcium, phosphorus, and magnesium from the maternal circulation.[476]

Calcium and phosphate are maintained at a higher set point in the fetus than in the pregnant mother, especially in the third trimester, to meet the demands of fetal bone mineralization.[477] In late gestation, fetal serum concentrations of calcium and phosphate are maintained above the maternal concentrations by approximately 1.2 to 2.0 mg/dL (0.30 to 0.50 mmol/L) and 1.5 mg/dL (0.5 mmol/L), respectively.[478] Although the fetal concentration of Mg is also increased compared with the maternal value, the gradient is less (~0.12 mg/dL, 0.05 mmol/L) than those of calcium and phosphate.

Active transport of calcium across the placenta occurs against a concentration gradient and involves an ATP-dependent calcium pump.[479,480] Calcium enters the placental trophoblast at the brush-border membrane primarily via the TRPV6 channel. Transport is facilitated by calbindin D9K and calcium is released to the fetal circulation through the calcium pump PMCA3. Radiolabeled P^{32} transport studies utilizing rat placenta have revealed increasing inorganic phosphate (Pi) transfer across the placenta until term gestation. The placenta expresses phosphate-regulating genes, including sodium-phosphate channels (NaPi2a, NaPi2b, and NaPi2c) and FGF-23 co-receptor Klotho. Little is known of the mechanism of placental magnesium transport, although an *in vitro* perfusion study of isolated human placental lobules has suggested active transport as the major mechanism.[481]

The calcium concentration in the fetus appears to be largely independent of maternal calcium concentration. In animal models, despite maternal hypocalcemia induced by a calcium-restricted diet, vitamin D deficiency, parathyroidectomy, or a vitamin D receptor deletion model, fetuses were reported to be normocalcemic.

Regulation of Calcium Homeostasis by PTH/PTHrP

PTH is an 84-amino acid protein, produced by chief cells within the parathyroid glands in response to hypocalcemia. It stimulates bone resorption, increases renal tubular absorption, and promotes the synthesis of calcitriol (active 1,25$(OH)_2$D) in the kidneys, which in turn stimulates calcium uptake from the gut. A negative feedback loop occurs with rising ionized calcium and calcitriol concentrations regulating the release of PTH. The fetal sheep has low circulating concentrations of PTH but can increase serum PTH concentrations in response to a fall in serum calcium concentration induced by ethylenediaminetetraacetic acid (EDTA) and can respond promptly to infused calcium with increased serum calcitonin concentrations.[482] In this model, fetal parathyroidectomy decreases placental calcium transport and lowers fetal serum calcium.

The parathyroid glands are active in the human fetus and produce PTH from about 10 to 12 weeks of gestation. Maternal PTH concentrations are suppressed during pregnancy compared with those in the nonpregnant adult and fetal PTH concentrations appear to be strongly suppressed. This is due to the high fetal ionized calcium, which acts through the CaSR to suppress PTH. Despite this suppression, the release of fetal PTH can be stimulated by acute or chronic (e.g., from hypoparathyroidism) maternal hypocalcemia.[483] The placenta is impermeable to PTH, PTHrP, and calcitonin, but 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D (calcitriol) are transported across the placenta.[479] It is unknown whether the human placenta produces PTH.

PTHrP has PTH-like activity and has a major role in fetal bone development and metabolism as well as fetal calcium homeostasis. It is expressed in the uterus, placenta, amnion, umbilical cord, lactating breast, and fetal parathyroid glands. In the human fetus, the effect of PTH on placental calcium transport is uncertain; however, PTHrP is produced by many tissues, including the placenta and parathyroid, and acts on PTH receptors

The principal PTH receptor is PTHR1, which has an equal affinity for PTH and PTHrP. A second receptor PTHR2 is present in the CNS and binds PTH but not PTHrP, whereas PTHrP action in the placenta occurs likely through a distinct receptor that binds PTHrP but not PTH.[484,485]

The PTH concentration in the human fetus near the end of gestation is lower (<4.72 pg/mL) than maternal or nonpregnant adult concentrations. In cord blood, the concentration of PTHrP is 15-fold higher than that of PTH at term and plays a critical role in perinatal calcium homeostasis and maintenance of the higher fetal calcium set point.[480,486] Little PTH is detectable in fetal plasma using immunoassays, whereas bioassays showed significant bioactivity.[487] The principal factor responsible for this bioactivity, however, appears to be PTHrP rather than PTH. Although the fetal PTH concentrations are very low, fetal PTH is thought to be important because studies in fetal mice, rats, and sheep indicate that the absence of PTH causes hypocalcemia, hyperphosphatemia, low amniotic fluid mineral content, and reduced skeletal mineral content.

PTHrP knockout mice display increased ossification of the basal portion of the skull, long bones, vertebral bodies, pelvic bones, and mineralization of the normally cartilaginous portions of the ribs and sternum;

as a result of the cartilaginous mineralization, the animals die of asphyxiation in the early neonatal period.[480,486,488,489] They also display hypocalcemia, hypophosphatemia, reduced fetal-placental calcium transfer, normal amniotic fluid calcium content, and increased PTH.[486,490,491] The increase in PTH partly compensates for lack of PTHrP because the absence of both hormones leads to more marked hypocalcemia and a more substantial reduction in skeletal mineral content.[490] The placental calcium pump is stimulated by a mid-molecule portion of the PTHrP secreted by the fetal parathyroid gland and by other fetal tissues and the placenta, where it may exert a paracrine effect.[486,492] In mice, knockout of the gene for PTHrP abolishes the maternal-fetal calcium gradient, and placental transport of calcium is reduced. Placental calcium transport in these models is restored by the mid-molecule fragment of PTHrP (amino acids 67 to 86) but not by PTH or PTHrP fragment (1 to 34), which activate the PTH/ PTHrP receptor.[486,492]

Overall, it is clear that PTH and PTHrP both play roles in fetal bone and mineral homeostasis because the absence of either hormone leads to adverse effects. Fetal mice lacking parathyroid glands, PTH, or the PTH/PTHrP receptor are hypocalcemic and have undermineralized skeletons.[477,490,493] *Hoxa3* null mice, which lack the parathyroids and thymus, and are thus completely devoid of PTH,[303] had more profound hypocalcemia than in *Pthrp* null fetuses such that the blood calcium level was reduced well below the ambient maternal calcium concentration.[490,491] *Hoxa3* nulls also had hypomagnesemia, hyperphosphatemia, a normal rate of placental calcium transfer, low amniotic fluid mineral content, and reduced skeletal calcium and magnesium content. Animals with combined *PTH* plus *PTHrP* (*Hoxa3/ Pthrp* double mutants) or *PTH/PTHrP receptor* gene ablation have much lower blood calcium concentrations and a more severe skeletal chondrodysplasia than the single mutants.[493,494]

To determine the specific role of PTH in fetal calcium regulation, two different genetic models of PTH deficiency were studied. *Pth*-null mice have enlarged parathyroids that are incapable of making PTH, whereas *Gcm2*-null mice lack parathyroids but have PTH that arises from the thymus. *Pth*-nulls served as a model of complete absence of PTH, whereas *Gcm2*-nulls are a model of severe hypoparathyroidism. The *Pth*–null model demonstrates that PTH contributes to fetal mineral homeostasis because a fetal hypoparathyroid phenotype results, with hypocalcemia, hypomagnesemia, hyperphosphataemia, low amniotic fluid mineral content, and reduced skeletal mineral content in its absence.[477] PTH was found to regulate the placental expression of genes involved in calcium and other solute transfer and may contribute to the regulation of placental calcium transfer. These actions may be through both endocrine/systemic (parathyroid-derived) and paracrine (placental-derived) pathways.

Although hypocalcemia occurs when PTH is absent (*Pth, Gcm2,* and *Hoxa3* null mice), there is no compensatory increase in PTHrP and no alteration in placental calcium transfer.[477] These findings indicate that PTHrP must be regulated differently from PTH during fetal life. The only situation in which PTHrP has been found to be increased is in Pthr1 null fetuses, which lack the PTH/PTHrP receptor.[490] PTHrP may be produced autonomously by the placenta or regulated by other factors, such as the sensing of the calcium content exchanged across the trophoblasts and intraplacental yolk sac.[495]

Knockout of the mouse gene for PTH/PTHrP also results in hypocalcemia in the presence of normal or increased placental calcium transport,[479,492] suggesting that other factors are also involved in the maintenance of fetal serum calcium concentrations. PTH and PTHrP, through the PTH/PTHrP receptor, presumably modulate fetal skeletal calcium flux, calcium excretion through the fetal kidney, and perhaps reabsorption of calcium from amniotic fluid.

The fetal parathyroid-placental axis promotes maternal-fetal transfer of bone mineral and accretion of fetal bone mineral. It seems likely that fetal PTH and presumably PTHrP act on the fetal kidney to stimulate 1α-hydroxylation of 25-hydroxyvitamin D (25OHD) and that 1,25-dihydroxyvitamin D (1,25(OH)$_2$D) participates in modulating placental calcium transport. 1,25(OH)$_2$D or 24,25(OH)$_2$D also play a role in fetal cartilage growth and bone mineral accretion.[496] Thus PTHrP and to a lesser extent PTH in the ovine fetus appear to augment maternal-to-fetal calcium transport across the placenta and thus provide for the high rate of bone mineral accretion in the latter half of pregnancy.

1,25-Dihydroxyvitamin D. During pregnancy, maternal 25OHD crosses the placenta, so the fetal concentrations of 25OHD reach 75% to 100% of the maternal concentration at term.[497] Fetal 1,25(OH)$_2$D concentrations, however, are lower than that in the mother (<50%).[498] The maternal concentration of 1,25(OH)$_2$D during pregnancy is 2- to 3-fold higher than that in the nonpregnant adult. It is suggested that the maternal kidneys contribute to the abundance of 1,25(OH)$_2$D in the pregnant mother.[499] Nephrectomy in the fetal sheep reduces fetal serum calcium concentrations, and this can be prevented by prior administration of 1,25-dihydroxyvitamin D. Moreover, infusion into the sheep fetus of antibody to 1,25(OH)$_2$D reduced the placental calcium gradient.[479] The fetal kidney can produce 1,25(OH)$_2$D and the placenta contains 1,25(OH)$_2$D receptors, as well as a vitamin D–dependent calcium-binding protein.[489] It is thought that the synthesis of 1,25(OH)$_2$D in the fetus is suppressed by the high concentrations of calcium and phosphate and low concentrations of PTH.

Calcitonin. The high blood concentrations of calcitonin in the fetus, probably resulting from the chronic stimulation by fetal hypercalcemia, are thought to contribute to the fetal bone mineral accretion.[479,493] The predominant effect of calcitonin is to inhibit bone resorption and the high fetal serum calcium concentrations coupled with high circulating calcitonin promote bone mineral anabolism.[493] Placental calcitonin production may contribute to the calcitonin in fetal plasma, but the persistence of high plasma concentrations in neonatal plasma argues for predominant fetal production. Thyroid C cells begin to differentiate at around the 12th week of gestation,[500] and calcitonin is detectable at around the 15th week of gestation. Fetal circulating calcitonin concentrations are ~2-fold higher than those in the mother.[478,501,502] The trophoblasts of the placenta also produce calcitonin and supply it to the fetus.[503] Because calcitonin does not cross the placenta in the mouse or rat,[504] fetal circulating calcitonin is derived from fetal sources. The major source of fetal circulating calcitonin has not been determined. In the mouse, knockout of the calcitonin gene or the vitamin D receptor gene leads to postnatal osteosclerosis or osteomalacia, respectively; the pups appear normal at birth.[505]

Calcium-Sensing Receptor and FGF23. The CaSR plays a pivotal role in systemic calcium metabolism by modulating the production and secretion of calcium-regulating hormones such as PTH, calcitonin, FGF23, vitamin D, and urinary calcium excretion.[506,507] It responds to the high fetal serum calcium concentration to keep PTH suppressed. The CaSR is present in parathyroid glands, renal tubules, bone and cartilage, and many other tissues. Magnesium binds to the CaSR and influences PTH secretion. Mutations within the *CaSR* result in either inactivation or overactivation of the receptor resulting in hypercalcemia or hypocalcemia, respectively.[508]

FGF23 is the principal hormone that regulates phosphate transport. It is primarily produced and secreted into the circulation by osteocytes and, after its activation through glycosylation by GALNT3, acts through FGFR1c and FGFR4 on renal tubules to increase phosphate excretion through the sodium-phosphate exchanger (NaPi-IIC, SLC34A3).[509]

Alpha-Klotho acts as a cofactor for FGF23 to bind to FGFR1c, increasing the specificity of FGFR1c for FGF23. FGF23 is inactivated by cleavage by subtilisin/furin-like enzyme. PHEX (phosphate regulating gene with homologies to endopeptidases on the X chromosome) regulates cleavage of FGF23, and *PHEX* mutations therefore render FGF23 constitutively active. Besides increasing renal tubular phosphate excretion, FGF23 inhibits 1α-hydroxylase, thus reducing 1,25 vitamin D activity. Although FGF23 is present in the fetal circulation at concentrations that may equal adult values and there is robust expression of FGF23 target genes in the placenta and fetal kidneys, FGF23 itself may not be an important regulator of fetal phosphorous metabolism. In a study by Ma et al., FGF23 deficiency (*Fgf23*-null) and FGF23 excess (*Phex*-null) did not alter fetal phosphorus or skeletal parameters.[510]

Neonatal Disorders of Calcium and Phosphate Homeostasis

Some conditions affecting calcium homeostasis are particularly important in the neonatal period. When a neonate presents with abnormal calcium concentrations, assessment of calcium, albumin, phosphate, creatinine, alkaline phosphatase, vitamin D, and urine Ca-creatinine ratio and phosphate reabsorption in both the child and parents will help formulate the underlying diagnosis.

Maternal hypocalcemia can result in increased PTH secretion from the fetal parathyroids. This will maintain a normal serum calcium in the fetus but can lead to hyperplasia of the parathyroids, skeletal resorption, loss of mineral content, and fractures occurring *in utero* or during delivery. In contrast, maternal hypercalcemia results in increased placental calcium transport and suppression of the fetal parathyroids. This may have negative impacts after birth, with hypoparathyroidism of the neonate that can be prolonged or permanent.[476]

Hypocalcemia resulting from fetal and maternal vitamin D deficiency is relatively common. Occasionally, severe neonatal vitamin D deficiency can be associated with a dilated cardiomyopathy, which is reversible.[511,512] Vitamin D–dependent rickets type I (VDDR-I) is an autosomal recessive disease characterized by low or undetectable levels of $1,25(OH)_2D_3$ resulting in hypocalcemia, rickets, osteomalacia, growth retardation, and failure to thrive. The disease is caused by mutations in the *1α-OHase* gene.[513] In clinical practice, patients are treated with vitamin D analogues and/or an enriched Ca^{2+} diet to prevent rickets, which correct the major perturbations in Ca^{2+} homeostasis.

Heterozygous activating mutations of the *CASR* gene lead to autosomal-dominant hypocalcemia (ADH) type 1. In this condition, the sensitivity of the CASR to extracellular ionized calcium is increased. Consequently, PTH synthesis and secretion are suppressed at normal ionized calcium concentrations. Patients present with hypocalcemia, hyperphosphatemia, low magnesium levels, and low or low-normal levels of PTH increased urinary calcium excretion and sometimes with pseudo-Bartter syndrome. The differential diagnosis consists of the hypercalciuric hypocalcemia syndrome type 2, involving *GNA11* and other hypoparathyroidism etiologies.

Hypercalcemia disorders related to inactivating mutations of the *CASR* gene are either heterozygous (autosomal-dominant familial hypocalciuric hypercalcemia [FHH] type 1) or homozygous (severe neonatal hyperparathyroidism). FHH can present in neonates with mild to moderately elevated calcium concentrations, high normal (nonsuppressed) PTH, and a low urine calcium/creatinine ratio.[514] FHH may also present as neonatal hyperparathyroidism leading to bone disease and variable symptoms of hypercalcemia. This occurs especially if an affected infant has inherited the inactivating *CaSR* mutation from the father while their mother is normal. The fetus will consider the mother as hypocalcemic and therefore overproduce PTH. Cinacalcet therapy may help bind calcium and settle the hyperparathyroidism but parathyroidectomy is occasionally necessary. The differential diagnosis consists of the hypocalciuric hypercalcemia syndrome, types 2 (involving *GNA11*) and 3 (involving *AP2S1*), other hyperparathyroidism etiologies and abnormalities of vitamin D metabolism involving *CYP24A1* and *SLC34A1* genes.[515,516] Recently, mutations in the gene encoding the calcium channel TRPV6 were identified as a cause of transient neonatal hyperparathyroidism (TNHP).[517]

Neonatal subcutaneous fat necrosis is a rare granulomatous condition that occurs following perinatal asphyxia. It can result in extrarenal synthesis and release of $1,25(OH)_2D$ from macrophages, leading to hypercalcemia.[518] Hyperhydration, steroid therapy, low calcium milk, and occasionally bisphosphonate treatment may be needed to reduce calcium concentrations.

Metabolic bone disease (MBD) of prematurity remains a significant comorbidity in preterm and low birth weight neonates. It most commonly occurs as a result of inadequate calcium and phosphorus stores exacerbated by inadequate intake and the high degree of skeletal growth occurring in the weeks following birth. Biochemical changes commonly include hypophosphatemia, hyperphosphatasia, and secondary hyperparathyroidism, which may be accompanied by rachitic changes and/or fractures.

Loss of FGF23 or components of the FGF23 network (GALNT3, FGF23, alpha-Klotho) cause hyperphosphataemia, extraskeletal calcifications, and early mortality; excess FGF23 or pathway components (FGF23, PHEX, SLC34A3, subtilisins [PCSKs], phosphate transporters NPT2a and NPT2c) cause hypophosphatemia with rickets or osteomalacia.[519]

KEY POINTS

- Active calcium transport across the placenta occurs in the third trimester to maintain fetal calcium concentrations and is dependent on PTHrP.

FETAL GROWTH

The hormones most important for postnatal growth, including T_4, GH, and gonadal steroids, have a limited role in fetal growth even though TR and GHR are expressed in many embryonic tissues including the growth plates.[520–522] Placental hormones including the human GH variant and hPL play a limited role; hPL may promote early embryonic growth and may stimulate IGF and insulin production.[522] IGF-1 and IGF-2 are produced by the placenta and may exert autocrine-paracrine actions on placental growth. IGF-1, IGF-2, and the IGF-1 and IGF-2 receptors are widely expressed in fetal tissues of mesenchymal, ectodermal, and endodermal origin and play a critical role in modulating normal fetal growth, including the nervous system.[521,523]

Insulin-Like Growth Factors

The IGFs are involved in regulation of uterine and placental growth during pregnancy; in early embryonic and fetal development, IGF-1, EGF, and estrogens are mitogens for endometrial stromal cells, and the endometrial contents of IGF-1 and *IGF1* mRNA are high at implantation and during early embryogenesis in the sow.[524] Uterine IGF-1 and *IGF1* mRNA levels decrease progressively with advancing gestation.[524] Placental tissue also contains *IGF1* and *IGF2* mRNAs, significant concentrations of the respective proteins, and IGF-1 receptors.[204] Autocrine and paracrine roles for the IGFs in uterine and placental tissues are postulated. IGF-1 and insulin are produced by embryonic tissues during the prepancreatic stage of mouse development, and both factors stimulate the growth of embryonic mouse cells.[525]

IGF2 is genomically imprinted and paternally expressed in the fetus and placenta. The mature IGF-2 protein is generated from the biologically inactive pro–IGF-2 peptide by the action of proprotein convertase 4. Recent studies have shown the role of IGF-2 in determining placental nutrient supply and hence fetal growth.[526] In mutant mice lacking the imprinted placental-specific *IGF2* transcript, growth of the placenta is altered from early gestation but fetal growth is normal until late gestation, suggesting functional adaptation of the placenta to meet the fetal demands. It is believed that this adaptation may be mediated by the altered expression of placental transporters GLUT3 and Slc38a4.[527]

Studies of transgenic mice with null mutations of the genes encoding IGF-1, IGF-2, or the IGF-1 receptor have defined the role of the somatomedins; the birth weight of the embryos lacking IGF-1 or IGF-2 was 65% of that of the control mice. When both genes were inactive, birth weight was reduced another 35%, and mice lacking IGF-1 receptor had birth weights averaging 55% of control values.[528] IGF-2–deficient mice also manifest intrauterine growth retardation in association with a small placenta. They have near-normal postnatal growth but delayed bone development.[528] IGF-2 receptor knockout fetal mice are 30% overweight, suggesting a negative growth modulating effect of this receptor.[523]

The normal growth in fetuses with both IGF-1 and IGF-2 receptor knockout is due to IGF-1 signaling via the insulin receptor; combined IGF-1, IGF-2, and insulin receptor knockout results in severe intrauterine growth retardation and fetal death. Knockout of individual IGF binding proteins has little effect on fetal or placental growth. In humans, mutations in *IGFI* or *IGF1R* are associated with intrauterine growth retardation, suggesting that IGF-1 signaling also contributes significantly to fetal growth in humans.[529,530] Apart from growth retardation, these children also suffer from developmental delay, microcephaly, hypoglycemia, and sensorineural hearing loss.[529,530] Indeed, there is a relation between umbilical IGF-1 concentration and birth weight in humans; maternal smoking reduces both umbilical IGF-1 and birth weight.[531,532] Studies in mice suggest that IGF-1 and IGF1R are required for late gestational lung maturation.[533]

Hypomethylation of the *11p15* imprinted region is associated with the phenotype of Silver-Russell syndrome (SRS).[534] This results in the relaxation of imprinting and biallelic expression of *H19* and downregulation of *IGF2*. Additionally, abnormal processing of IGF-2 by proprotein convertase 4 in the placenta has been implicated in the etiology of fetal growth restriction.[535] Pregnant women carrying IUGR fetuses had higher concentrations of pro–IGF-2 compared with controls. Severe intrauterine growth retardation and atypical diabetes mellitus secondary to insulin resistance were indeed associated with disruption of the regulation of the *IGF2* gene due to a human translocation.[536] On the other hand, overexpression of *IGF2* as a result of loss of imprinting associated with paternal uniparental disomy, *CDKN1C* loss of function, alteration in the *KvLQT1* DMR or microdeletions in the human *H19* DMR are associated with overgrowth in BWS.[537]

IGF-binding proteins are present as early as 5 weeks of gestation, and prenatally as well as postnatally, the IGFs circulate associated with binding proteins.[538] High concentrations of circulating IGFBP-1 are associated with fetal growth restriction in the mouse, as is overexpression of fetal human IGFBP-1.[539,540] High concentrations of IGFBP-4 have been shown to be related to fetal growth restriction.[541] IGFBP-4 is expressed exclusively in the maternal decidua and inhibits IGF action. Thus during fetal and postnatal life, plasma concentrations of IGFs are relatively high compared with tissue concentrations. In the fetus, IGF-2 concentrations are five to six times higher than those of IGF-1, in contrast to these concentrations in children and adults, and concentrations of both increase progressively throughout gestation.[542] Fetal concentrations of both peptides at term are 30% to 50% of adult concentrations. In most studies, cord blood IGF-1 concentrations correlate with birth size.[523]

Despite the fetal growth-enhancing effects of IGF-2, blood concentrations are only weakly related to size at birth, largely because of the inhibiting effect of soluble IGF-2 receptor (IGF2R) but also because IGF-2 appears to exert most of its growth effects in the earlier part of gestation.[523] Soluble IGF2R is derived through proteolytic cleavage of the transmembrane region of the receptor in many tissues. IGF receptors have been identified as early as 5 weeks of gestation and are widespread in fetal tissues.[541] IGF-1 stimulates glycogenesis in cultured fetal rat hepatocytes and induces the formation of myotubes in cultured myoblasts. IGF-2 is active in cultured muscle and neonatal rat astroglial cells. Insulin receptors are increased in fetal cells and are resistant to downregulation; no similar data are available for the IGF-1 receptor.

The control of IGF production differs in fetal and postnatal life (Fig. 130.10). GH, which stimulates IGF-1 production after birth, has a limited role in fetal IGF production.[520] GH does play a minor role in fetal growth as reflected in the low IGF concentrations and slight reduction in birth weight in infants with GH resistance (Laron dwarfism) and GHD.[543]

Receptors for hPL are abundant in fetal tissues.[522,544] hPL stimulates IGF-1 production and augments amino acid transport and DNA synthesis in human fetal fibroblasts and muscle cells.[522,544] IGF-1 and IGF-2 concentrations are reduced in fetuses of protein-starved pregnant rats and the low IGF-2 concentrations are reversed by hPL.[545] Thyroidectomy of the third-trimester sheep fetus impairs skeletal muscle growth in association with a decrease in muscle *GH receptor* mRNA and *IGF1* mRNA without an effect on *IGF2* concentrations.[546] Glucocorticoids can inhibit fetal growth, presumably by inhibiting *IGF* gene transcription.[546] Evidence also indicates that insulin may play a

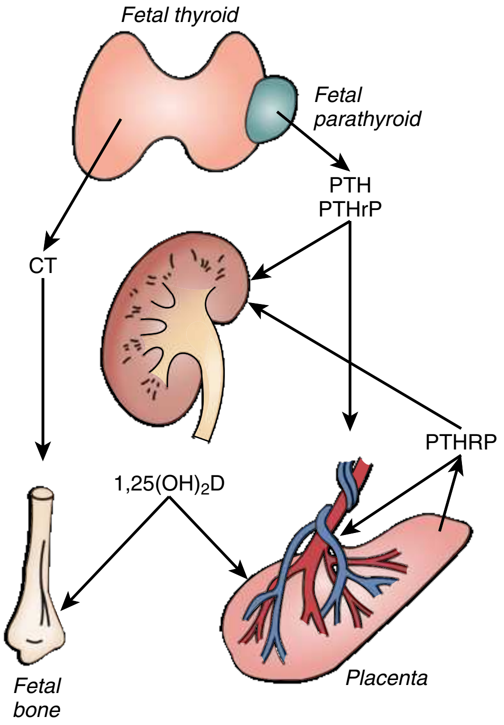

Figure 130.9 Hormonal modulation of fetal calcium homeostasis. Parathyroid hormone *(PTH)* and PTH-related peptide *(PTHrP)* are derived from both fetal parathyroid and placental tissues and stimulate maternal-to-fetal calcium transport. PTHrP also may stimulate renal 1-hydroxylation of 25(OH) vitamin D, which also acts to promote placental calcium transport. *CT,* Calcitonin.

role in modulating IGF synthesis in the fetus.[522,547] Nutrition is the major factor modulating IGF production in the fetus. IGF concentrations fall in suckling rats deprived of milk, and IGF-1 and IGF-2 concentrations are reduced in fetuses of protein-starved pregnant rats and placentally restricted sheep.[522,548] Light stimuli may alter circulating and brain IGF-1 concentration and control neuronal migration through increased IGF-1 signaling.[549] These data support the view that the IGFs are important in embryonic and fetal growth and that in the fetus they are regulated, at least in part, by hPL and by nutritional substrate derived transplacentally. The high concentrations of IGF-2 in fetal rat serum, the high levels of *IGF2* mRNA in fetal tissues, and the presence of a truncated form of IGF-1 in human fetal brain tissue suggest unique developmental actions of these peptides.

Insulin

Insulin has a growth-promoting effect, particularly late in gestation.[521,550] The hyperinsulinemia commonly observed in the fetus of a diabetic mother is associated with augmented body weight and increased body fat deposition. A fetus with pancreatic agenesis and hypoinsulinemia is small and relatively devoid of body fat.[521,547] Insulin infusion to fetal monkeys near term increases body weight, with prominent anabolic effects on the heart, liver, and spleen.[550] Interestingly, homozygosity for a null mutation of the insulin receptor gene in fetal mice leads to early neonatal death with hyperglycemia and ketonemia; birth weight, however, is normal.[551] A homozygous insulin receptor mutation in the human fetus results in severe insulin resistance in association with intrauterine growth retardation, lack of subcutaneous fat, decreased muscle mass, hirsutism, and early death.[459,552] Presumably the difference in growth effect relates to the relatively longer pregnancy in the human species. Treatment with IGF-1 improves the clinical condition to some extent.[459]

Fibroblast Growth Factor

The FGF family has been characterized and includes at least 18 different mammalian FGFs and 4 receptor species.[553] Knockout of Fgf4 and Fgfr1 is lethal. Knockout of Ffg10 leads to pulmonary agenesis and neonatal death. *Fgf2* or *Fgf3* gene knockout in mice produces limb abnormalities, but fetal growth is not impaired. In mice, Fgfr3 knockout leads to chondrocyte hypertrophy and increased bone length.[554] Infusion of FGF into the renal arteries of rats containing a renal subcapsular transplant of a 10-day rat embryo has been shown to stimulate the growth of the embryo.[555,556] The major effects were on tissues of endodermal and mesodermal origin; FGF antiserum inhibited the growth of endodermal tissue in the transplanted embryos, as well as in some of the mesodermal-derived tissues. Thus the FGFs appear to have autocrine-paracrine roles in localized organ growth and differentiation, including an essential role in bone growth and maturation.[553,557]

In humans, a variety of gain-of-function *FGFR* mutations are associated with achondroplasia (*FGFR3*) and craniosynostosis (*FGFR2*).[521] Loss-of-function mutations in *FGFR1* and *FGF8* are associated with KS or hypogonadotropic hypogonadism, and FGF8 mutations are also associated with HPE.[44,558,559]

During calorie restriction in mice, increased FGF21 causes growth attenuation and GH insensitivity. High concentrations of FGF21 may directly suppress growth plate chondrocyte proliferation and differentiation. A negative correlation between FGF21 concentration and linear growth has been reported, and high concentrations of FGF21 were described in association with growth failure in preterm infants.[560]

Other Growth Factors and Signaling Pathways

Additional growth factors involved in fetal growth and organ maturation include the TGF-β superfamily, the vascular endothelial growth factor (VEGF) family, and the platelet-derived growth factor (PDGF) family.[561–564]

The TGF-β superfamily of extracellular growth factors comprises more than 35 members, including TGF-β, the bone morphogenic proteins (BMPs), growth and differentiation factors, activins, inhibins, MIS, nodal, and leftys.[561,562] These ligands activate some 12 transmembrane serine/threonine kinase receptors expressed in a variety of tissues. The family is critical for early embryonic development, left-right asymmetry, heart and vascular system development, craniofacial development, nervous system development, and skeletal morphogenesis and plays an important role in body composition and growth.[561,562] Receptor knockouts in mice generally are lethal *in utero* or during the perinatal period.

The PDGF family is composed of homo- and heterodimers of PDGF A and B chains encoded by two genes. The ligands activate two receptors, α and β, distributed in fibroblasts and in smooth muscle, glial, and endothelial cells.[564] *PDGFα* and/or *β* knockout in mice usually is lethal or results in postnatal death associated with facial anomalies, spina bifida, skeletal anomalies, lack of pulmonary alveolar septa, and epidermal blistering.[563]

During development, VEGF is expressed in almost all tissues.204 The family includes five isoforms from a single gene and two receptor tyrosine kinases widely distributed in vascular endothelium. Receptor gene knockout of either receptor in mice is lethal.[563]

It is of interest that a growing number of these factors have been shown to be produced by the placenta. Thus as is the case for the IGFs, both endocrine and autocrine-paracrine routes of production and action of a variety of growth factors may prove to be important in individual fetal organ development and in overall fetal growth and differentiation.

Lastly, Wnt signaling, Notch signaling, BMP signaling, and hedgehog signaling play major roles in embryogenesis and fetal organ growth and development. These signaling pathways are also involved in bone development and growth and thus have a major effect on fetal size.[565]

KEY POINTS

- Fetal growth involves complex interactions between environmental, genetic, and epigenetic factors. IGFs are important for fetal growth and are regulated by transplacentally derived nutritional substrate. Hormones (T_4, GH, sex steroids), which are so important postnatally for growth, have a limited role in fetal growth.

ADAPTATIONS TO EXTRAUTERINE LIFE

Successful transition to extrauterine life requires that the fetus, previously poikilothermic, with the placenta subserving most of its metabolic needs, becomes homeothermic and self-sustaining. Crucial integration of a variety of neural and endocrine events is a prerequisite for this transition. The coordinated actions of adrenal cortical, adrenal medullary, and thyroid hormones facilitate lung function, cardiovascular adaptation, glucose homeostasis, and thermogenesis (Fig. 130.10). A longer-term extrauterine transition requires adaptation to an intermittent substrate supply, which requires activation of the hormonal control systems for maintenance of serum glucose and calcium homeostasis.

Cortisol-Mediated Adaptations

A modest increase in prenatal near-term circulating cortisol concentrations occurs in a variety of primates and other mammalian species as a result of increased fetal adrenal cortisol production and decreased metabolism of cortisol to cortisone.[190,213] This has been referred to as the *prenatal cortisol surge*. Plasma ACTH concentrations tend to remain stable, although the pulsatility of ACTH secretion may increase

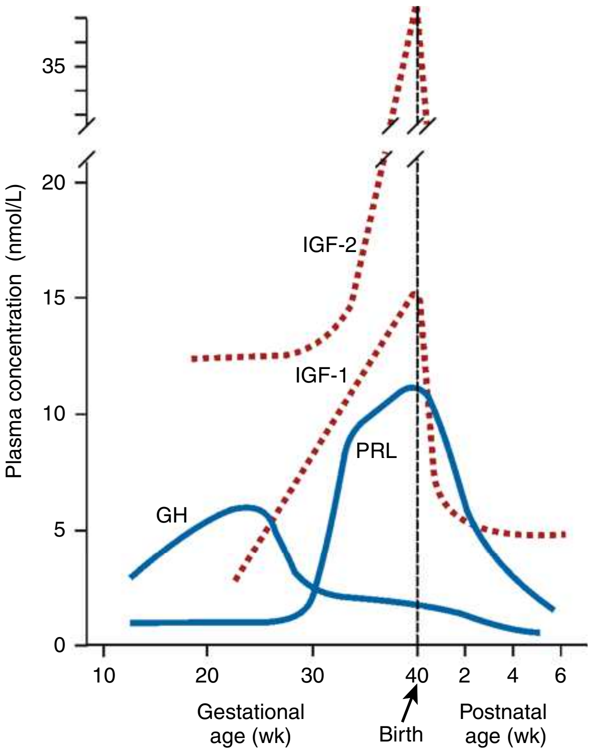

Figure 130.10 Pattern of developmental change in human fetal serum growth hormone *(GH)*, prolactin *(PRL)*, insulin-like growth factor-1 *(IGF-1)*, and IGF-2 levels during midgestation and the perinatal period. The major stimulus to the increasing IGF levels is nutrition. GH, PRL, and placental lactogen *(not shown)* have limited roles in fetal growth.

during this period. The increase in circulating cortisol concentrations is associated with a variety of physiologic responses. These include[213,214,566–571]:

- Increased conversion of T_4 to T_3 by stimulation of hepatic outer-ring iodothyronine deiodinase, leading to increased circulating T_3 concentrations
- Increased epinephrine secretion by sympathetic chromaffin tissue (including adrenal medulla) because of augmented phenylethanolamine transferase (PNMT) activity (which converts norepinephrine to epinephrine)
- Augmented synthesis and secretion of surfactant and maturation of surfactant composition; increases lung liquid reabsorption
- Stimulation of maturation of hepatic gluconeogenic enzyme activities
- Increased β-adrenergic receptor density in a variety of tissues, including lung, heart, and BAT
- Induction and maturation of a variety of gut enzymes for nutrient absorption and maturation of gut transport processes, motility, and structure.

The adaptational effects of the prenatal cortisol surge have led to the current recommendation for prenatal corticosteroid therapy in pregnancies threatened by the risk of preterm delivery. Generally, preterm infants prenatally exposed to augmented glucocorticoid concentrations have lower overall morbidity and mortality than untreated infants.[571] Although antenatal steroids for threatened preterm delivery have clear beneficial effects with a reduction in morbidity and mortality, the long-term consequences of such early high steroid exposure are unknown. The HPA axis is highly susceptible to programming during development and, unlike endogenous glucocorticoids, which are inactivated by placental 11βHSD2, synthetic glucocorticoids readily cross. Longitudinal follow-up of infants of women in preterm labor treated with betamethasone has shown evidence of insulin resistance particularly in female offspring. Antenatal treatment of the fetus of a mother whose previous child had CAH was with dexamethasone administered orally to the mother from 8 to 12 weeks' gestation. This was said to reduce fetal androgen production and hence virilization of female fetuses. There is however a paucity of high-quality evidence with respect to safety and efficacy and hence this should be regarded as experimental, and adverse associations have been reported including neurological abnormalities.[12]

Postnatally, biologically active cortisol predominates over cortisone in the circulation. Healthy term infants have initial pulsatility of cortisol; however, the circadian rhythm of ACTH and cortisol release in neonates is not established until about 3 months of age.[572] Because the circadian system develops *in utero* through exposure to maternal cues, preterm infants lose those cues at an earlier developmental stage than term-born babies.[21] These infants are then exposed to noisy and brightly lit neonatal intensive care units that contrasts markedly with the environment of the term-born infant discharged home within hours to a few days of birth.[573] Preterm infants are said to develop their rhythm around 8 to 12 weeks after being discharged from hospital[574] or at approximately 1 month corrected postnatal age.[575] Use of steroids postnatally to prevent or treat chronic lung disease (CLD) in preterm infants is associated with hyperglycemia, gastrointestinal bleeding, hypertrophic cardiomyopathy, growth failure, and cerebral palsy, and thus cannot be recommended.[576] Trials involving more physiological doses of steroids are underway. Early low-dose hydrocortisone treatment has been reported to improve survival in very preterm infants without pulmonary dysplasia. In an analysis of secondary outcomes of the PREMILOC (Early Low-Dose Hydrocortisone to Improve Survival Without Bronchopulmonary Dysplasia in Extremely Preterm Infants) randomized clinical trial, early low-dose hydrocortisone was not associated with a statistically significant difference in neurodevelopmental outcomes at 2 years of age.[577]

Catecholamine-Mediated Adaptations

Parturition is associated with enormous increases in circulating catecholamine concentrations, which are important for critical extrauterine transitional events. Cord-blood norepinephrine concentrations of 15 nmol/L (2500 pg/mL) and epinephrine values of 2 nmol/L (370 pg/mL) are common after spontaneous delivery of term infants.[578,579] These catecholamine concentrations increase cardiac output and neonatal blood pressure, evoke cardiac ventricular inotropic effects, increase glucagon and decrease insulin secretion, stimulate hepatic glycogenolysis, stimulate BAT thermogenesis, increase free fatty acid (FFA) concentrations, and promote pulmonary adaptation by mobilizing pulmonary fluid and stimulating surfactant synthesis (see Fig. 130.11).

BAT Thermogenesis

BAT is the major site for newborn thermogenesis.[566,580–582] Fetal adipogenesis involves proliferation of preadipocytes and differentiation into mature white- and brown-fat tissues.[583] This process is regulated by several transcription factors activating adipocyte-specific genes, and thyroid hormones regulate many of these genes.[583] Extirpation of this tissue during fetal life is associated with profound neonatal hypothermia. BAT function is coordinated through several endocrine systems. Catecholamines, via β-adrenergic receptors, stimulate fatty acid oxidation and thermogenesis. Mitochondria in BAT express a unique protein, thermogenin (or UCP), which uncouples oxidation from subsequent adenosine diphosphate phosphorylation and thereby promotes the release of heat. Thermogenin is T_3 dependent; BAT expresses MDI-2, which provides for local T_3 production from T_4.223 It was previously thought that BAT involutes soon after birth,

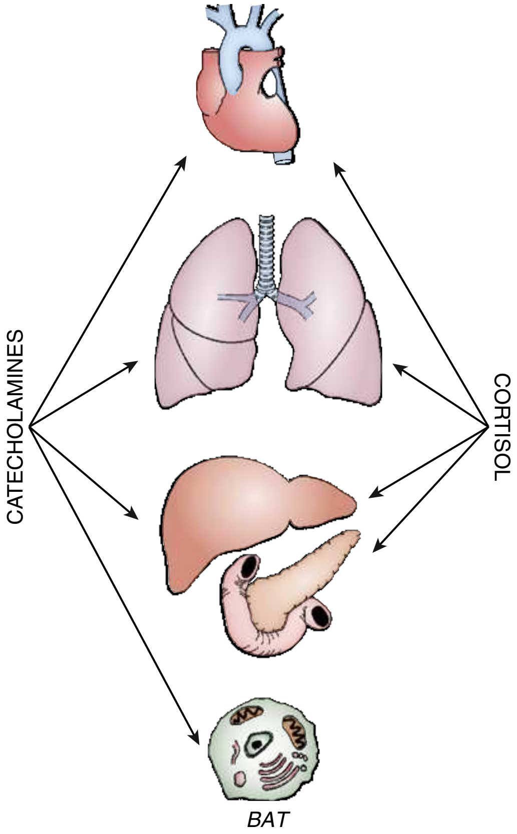

Figure 130.11 Coordinated effects of cortisol and catecholamines mediate the transition to extrauterine life, promoting extrauterine adaptational changes in cardiovascular, pulmonary, hepatic, and pancreatic function and stimulating brown adipose tissue *(BAT)* thermogenesis.

but combined ^{18}F-fluorodeoxyglucose PET (^{18}F-FDG-PET) and CT scans have identified active BAT in adults and shown a strong positive correlation between BAT activity and the basal metabolic rate.[584–586]

Glucose Homeostasis

During the newborn period, the placental source of glucose is abolished. A normal-term infant has an immediate postnatal fall in plasma glucose concentration by 1.4 to 1.7 mmol/L (25 to 30 mg/dL) to a nadir of about 3 to 3.3 mmol/L (55 to 60 mg/dL) by 1 to 2 hours of age; glucose concentrations then steadily rise over the first few days of life to return to the normal range for infants, children, and adults (3.9 to 5.6 mmol/L [70 to 100 mg/dL]).[587] Low glucose concentrations are usually transient, asymptomatic and part of the normal adaptation to extrauterine life. This relative hypoglycemia, along with the augmented catecholamine levels largely caused by the absence of placental degradation, stimulates pancreatic glucagon secretion. These early glucagon and catecholamine surges rapidly deplete available hepatic glycogen stores, so maintenance of blood glucose concentrations in the 12 to 24 hours after birth requires increased hepatic gluconeogenesis. Counterregulatory hormones rapidly become active with high catecholamine, glucagon, GH, and cortisol concentrations, and a fall in insulin, and these changes result in stabilization of blood glucose concentrations by approximately 48 to 72 hours of life.[587–589]

Glucagon increases in the first few hours of life, particularly with protein feeding, which stimulates gut glucagon release and pancreatic glucagon secretion.[588,589] In human infants, glucagon concentrations remain at around 100 ng/L for the first 12 to 24 hours and the glucagon:insulin ratio is high enough to stabilize blood glucose concentrations in the range 2.8 to 4 mmol/L (50 to 70 mg/dL).[589] The high insulin:glucagon ratio stimulates hepatic gluconeogenesis. Secretion of both glucagon and epinephrine appears to be activated in transitional neonatal hypoglycemia in normal neonates. It has been suggested that normal and small for gestational age (SGA) neonates activate neuroendocrine responses to hypoglycemia at plasma glucose concentrations in the range of 50 to 60 mg/dL (2.8 to 3.3 mmol/L).

Plasma glucagon concentrations rise in association with a rapid increase in functionally coupled glucagon receptors. The increase in plasma catecholamines coincident with parturition may be responsible for some of these changes; catecholamines both stimulate glucagon release and inhibit insulin release.[437,590,591] Phosphoenolpyruvate carboxykinase (PEPCK) activity also increases during this period. Thus gluconeogenesis is readily demonstrable in the newborn, where nearly 10% of glucose utilization is accounted for by gluconeogenesis from alanine.[439] The insulin-secretory response to hyperglycemia matures in the neonatal period, and healthy-term infants achieve adult-like regulation of glucose homeostasis within 5 to 7 days of birth.

Low glucose concentrations on the first few days of life are associated with suppressed levels of both ketones and FFA (range 0.3 to 0.5 mmol/L) in normal newborns, and these low levels of ketones and FFA appear to be explained by incomplete suppression of insulin release. The metabolic and hormonal profile of transitional neonatal hypoglycemia indicates that this is a form of hyperinsulinemic hypoglycemia in which the glucose set point for suppression of insulin secretion is reduced to 55 to 65 mg/dL (2.8 to 3.6 mmol/L).[587] Plasma FFA concentrations rise postnatally as a result of the effects of catecholamines and chemical thermogenesis. Oxidation of fatty acids probably provides cofactors (acetyl coenzyme A and the reduced form of nicotinamide adenine dinucleotide) required for gluconeogenesis, as well as sparing glucose for utilization by crucially dependent tissues such as the brain.[435] Failure of this sequence of physiological changes can lead to hypoglycemia, which is most common in the first few hours after birth. It has been reported that lactate may be neuroprotective in at-risk babies with hypoglycemia within the first 48 hours after birth, a time period when ketone bodies are unlikely to provide protection.[592] Premature infants may require up to 2 weeks to achieve glucose homeostasis. Relative hyperinsulinemia may occur in the neonatal period in an infant of a diabetic mother, in SGA and/or asphyxiated or severely stressed infants, or in infants with islet β-cell hyperplasia or CHI.

Neonatal hypoglycemia is common and is usually treated with supplemental feeds or intravenous glucose. Early feeding for prevention of hypoglycemia in at-risk babies (including infants of mothers with diabetes, small and large for gestational age, and preterm) is the mainstay of management. The Sugar Baby study showed that dextrose gel is effective in treating neonatal hypoglycemia without affecting breastfeeding.[593] The pre-hPOD study (hypoglycemia prevention with oral dextrose) reported the first randomized control trial of prophylactic oral dextrose in at-risk babies, showing reduced incidence of neonatal hypoglycemia.[594,595]

Calcium Homeostasis

In utero, active calcium transport from the mother to the fetus takes place through the placenta, responsible for approximately 20% to 30% of calcium stores in the fetus. Neonates must adjust rapidly from a high-calcium fetal environment regulated by PTHrP and calcitonin to a low-calcium environment regulated by PTH and vitamin D. With placental separation, newborn plasma calcium concentrations fall to values approximating 2.3 mmol/L (9 mg/dL) for total calcium and 1.2 mmol/L (4.8 mg/dL) for ionized calcium.[596,597] Plasma PTH concentrations are relatively low and minimally responsive to hypocalcemia during the first 2 to 3 days of life. Calcitonin concentrations, already high in cord blood, increase further and remain high for several days after birth.[597–599] The relatively obtunded PTH response and the high calcitonin concentrations lead to a 2- to 3-day period of transient neonatal hypocalcemia that inhibits calcitonin and stimulates PTH secretion.[598,600]

Calcium homeostasis is also affected in the newborn by a low glomerular filtration rate and reduced renal responsiveness to PTH for several days after birth. These factors limit phosphate excretion and, with high-phosphate milk intake, predispose the neonate to hyperphosphatemia.[598,600] Premature infants tend to have lower PTH and higher calcitonin concentrations, along with more immature kidney function, so neonatal hypocalcemia may be more marked and prolonged. Infants born to mothers with hypercalcemia due to hyperparathyroidism have a high incidence of symptomatic hypocalcemia. These infants have a more marked suppression of parathyroid function and a more prolonged period of transient hypoparathyroidism in the neonatal period. PTH secretion and calcium homeostasis usually normalize within 1 to 2 weeks in full-term infants, but normalization may require 2 to 3 weeks in small, premature infants.

Other Hormonal Adaptations

Delivery of the infant and severing of the placental circulation result in abruptly decreased concentrations of estrogens, progesterone, hCG, and hPL in the newborn.

The decrease in estrogens removes a major stimulus to newborn prolactin release, and PRL concentrations remain low over the next several weeks of life.

GH concentrations are also low in the postnatal period because of delayed hypothalamic-pituitary feedback and control.[62,601] These events probably involve changes in GH sensitivity to both GHRH and somatostatin. Newborn IGF-1 concentrations fall to low values, presumably because of removal of hPL stimulation and placental IGF production.

In male infants, after a transient fall in testosterone as the hCG stimulus decreases, pituitary LH secretion rebounds and there is a secondary surge in testosterone that persists for several weeks.[57,602] In females, a transient secondary surge in FSH may elevate estrogen concentrations.

The dramatic increase in neonatal TSH secretion during the first hour is largely due to the effect of body cooling with extrauterine exposure.[580] In term infants, the TSH surge peaks at 30 minutes at a concentration of about 70 mU/L. The increase in TSH in turn increases thyroidal T_4 and T_3 secretion and enhances thyroidal conversion of peripheral T_4 to T_3. Increased outer-ring (type I) iodothyronine deiodinase activity increases peripheral T_4-to-T_3 conversion.[569,580] T_3 concentrations are maintained in the range 1.6 to 3.4 nmol/L (105 to 220 ng/dL) postnatally. Neonatal serum TSH concentrations are reset to lower prevailing extrauterine values, which requires resetting of the thyroid hormone—TSH negative-feedback control system. T_3 and sulfated iodothyronine production decrease to extrauterine levels by 3 to 4 weeks of age, at which time these hormone concentrations approximate those in adults.[311,317]

KEY POINTS

- Immediate transition to extrauterine life involves the adrenal cortex and ANS. Longer-term transition to an intermittent nutrient supply and transient substrate deficiency requires maturation of secretory control mechanisms for the PTH-calcitonin system and the endocrine pancreas.

FUTURE DIRECTIONS

The management of fetal and neonatal endocrine disorders is an exploding field due to rapid advances in fetal imaging, minimally invasive techniques and genomics. These have revolutionized understanding of the unique endocrine milieu of pregnancy and the natural history of endocrinopathies. Additionally, insight into the mechanisms and pathways involved in developmental endocrinology offers management strategies for preterm infants and those with intrauterine growth retardation. There is growing experience with gene therapy in animals[603] and intraplacental gene therapy, for example, may be effective for growth restriction.[604] Technological progress will undoubtedly have a positive impact on clinical outcomes for patients in the future. This will inevitably bring with it medicolegal and ethical challenges, as well as considerations as to what constitutes innovation versus experimentation, and these complexities must be considered in order to deliver safe and excellent patient care.

INTRODUCTION

Pregnancy alters normal physiology and thereby endocrine testing in a number of ways (Table 131.1). The normal physiologic adaptations of pregnancy include an expanded plasma and red blood cell volume. The disproportionate increase in plasma volume results in a mild generalized hemodilution. The increase in plasma volume begins at 6 to 8 weeks of gestation and reaches its zenith at a 40% increase at 30 to 34 weeks.[1] This increase in plasma volume is accompanied by an increase in cardiac output (CO) that appears to peak in the midgestation. This increase is initially due to an increase in stroke volume and subsequently in heart rate.[2] In the first half of pregnancy, there is a decrease in systemic vascular resistance and blood pressure. These changes serve to optimize blood flow to facilitate fetal growth and development. The increase in CO leads to a comparable increase in renal plasma flow and glomerular filtration rate (GFR). The increase in GFR is apparent by 4 weeks of gestation and increases to 140% to 150% of the nonpregnant state by 6 to 12 weeks.[2,3] GFR increases by another 10% over the remainder of the second trimester, stabilizes in the third trimester, and falls in the last 4 weeks of gestation.[3,4] Changes in serum creatinine concentrations show a similar pattern. In a retrospective study including over 240,000 pregnancies in Canada, the mean serum creatinine concentration dropped in the first trimester (beginning at 4 weeks of gestation), leveled off in the second trimester, and then gradually rose in the third trimester to prepregnancy levels.[5] These changes in GFR alter the clearance of various hormones, thereby changing their serum and urinary concentrations.

In addition to GFR, renal tubular function is also altered. For example, tubular reabsorption of glucose is decreased leading to significant glycosuria despite normal plasma glucose levels.[6] In contrast, tubular reabsorption of sodium is increased due to increased GFR, increased placental progesterone production, increased concentrations of aldosterone and cortisol, and exaggerated postural effects.[3]

Hormone production by the placenta may also profoundly affect circulating levels of other hormonal systems. Estradiol levels increase 100-fold in pregnancy, beginning at 6 to 8 weeks of gestation[7] (Fig. 131.1). These elevated estrogen levels cause an increase in circulating concentrations of a number of hormone-binding globulins produced by the liver, including thyroxine-binding globulin (TBG), corticosteroid-binding globulin (CBG), and sex hormone–binding globulin (SHBG). In such instances, measurements of total (bound plus free) hormones are increased, although free hormone levels are largely unaffected (discussed later). Estrogens also have a direct stimulatory effect on pituitary lactotrophs, with increased production of prolactin (PRL). A number of peptide hormones are produced directly by the placenta, including human chorionic gonadotropin (hCG), chorionic somatomammotropin (previously referred to as placental lactogen), placental growth hormone (GH), chorionic thyrotropin, chorionic adrenocorticotropic hormone (ACTH), chorionic corticotropin-releasing hormone (CRH, corticotropin), urocortin, chorionic gonadotropin-releasing hormone (GnRH), and chorionic somatostatin. Some of these peptides interfere with normal circulating hormone levels. For example, placental GH suppresses pituitary GH secretion indirectly through the stimulation of insulin-like growth factor-1 (IGF-1).[8] Although hCG does not directly affect the pituitary gland, its structure is similar to that of other heterodimer glycoprotein hormones with identical alpha and distinct beta subunits (chains), such as luteinizing hormones (LH) and thyroid-stimulating hormone (TSH, thyrotropin). As such, very high levels of hCG (such as that seen in complete molar pregnancies) may activate the TSH receptor resulting in hyperthyroidism. The placenta also produces

TABLE 131.1 Changes in Normal Physiology That May Affect Endocrine Tests

Cardiovascular

- Increased plasma and RBC volume
- Increased cardiac output
  - Lowered "osmostat" for vasopressin release and thirst

Renal

- Increased GFR and renal plasma flow
  - Increased hormone and substrate clearance
- Altered renal tubular function
  - Decreased Tm for glucose

Placental Hormone Production

- Increased estrogen and progesterone production
  - Increased hormone-binding globulin production
- Stimulation of pituitary lactotrophs
- Production of peptide hormones
  - ACTH, CRH, GnRH, hCG, GH variant, hPL, cTSH, PRL

Placental Enzyme Production

- Vasopressinase

ACTH, Adrenocorticotropic hormone; *CRH*, corticotropin-releasing hormone; *cTSH*, chorionic TSH; *GH*, growth hormone; *GnRH*, gonadotropin-releasing hormone; *hCG*, human chorionic gonadotropin; *hPL*, human placental lactogen; *PRL*, prolactin.

1,25-dihydroxyvitamin D (DHCC), which regulates calcium homeostasis during pregnancy. Placental CRH has numerous actions within the fetoplacental unit, but is likely not involved in maternal ACTH regulation.[9] Placental estrogen, progesterone, lactogen, and GH also function as counterregulatory hormones and cause insulin resistance and accelerated lipolysis. In addition to hormones, the placenta produces enzymes that may affect normal endocrine function. Placental vasopressinase activity leads to the increased production of maternal vasopressin to maintain normal circulating levels.

With this background in mind, the current chapter reviews the changes in normal physiology that occur during pregnancy and the resulting alternations in circulating hormone levels that may create diagnostic difficulties when attempting to evaluate endocrine disorders in pregnant patients.

PITUITARY GLAND

Hypopituitarism

Lymphocytic Hypophysitis. Lymphocytic hypophysitis is a rare primary autoimmune endocrinopathy, more common in women than men, that results in pituitary enlargement. It is characterized histologically by massive infiltration of the pituitary gland by lymphocytes and plasma cells, with destruction of the normal parenchyma. Patients commonly present with symptoms of pituitary mass effect such as headache or visual field changes secondary to compression of the optic chiasm.[10] Traditionally, up to 50% of such cases were thought to affect pregnant women, particularly in the last month of pregnancy and the first 2 months postpartum.[11] More recent studies suggest that far fewer cases are associated with pregnancy.[12] Lymphocytic hypophysitis may be associated with signs of diabetes insipidus in up to 20% cases with or without PRL abnormalities.[11] In more serious cases, it may present with corticotropin deficiency, presenting as fatigue, pallor, or even a life-threatening adrenal crisis.[13] Any symptoms or signs of pituitary mass effect or hypopituitarism in pregnancy warrant serum hormone evaluations and magnetic resonance imaging (MRI). If PRL levels are only modestly elevated (<150 ng/mL) in the presence of a large mass, the diagnosis is unlikely to be a prolactinoma and more likely to be hypophysitis or a nonfunctional pituitary adenoma. Ultimately, the diagnosis may require histological examination to differentiate it from a tumor.[13] Lymphocytic hypophysitis in the postpartum period may be confused with Sheehan syndrome, although such women typically do not have a history of obstetrical hemorrhage.

Sheehan Syndrome. Sheehan syndrome refers to infarction of the pituitary gland following obstetrical hemorrhage. In most cases, presenting symptoms are nonspecific. Some patients present with symptoms of adrenal insufficiency (AI) such as lethargy, anorexia, and/or an inability to lactate in the first few days and weeks after delivery.[14] If the pituitary infarction is incomplete, the development of hypopituitarism may be more insidious and difficult to diagnose. A complete pituitary hormone workup should be performed in any patient with a history of obstetric hemorrhage with signs/symptoms of hypopituitarism. This is a permanent injury. Treatment is lifelong hormonal replacement.

Pituitary Apoplexy. Pituitary apoplexy refers to an acute hemorrhage into the pituitary gland that occurs most often in the setting of a pituitary adenoma. Clinical presentation may include sudden onset of severe headache, diplopia due to pressure on the oculomotor nerves, and panhypopituitarism. Surgical decompression may be required for severe or progressive neurological or visual symptoms.[15] Symptoms may improve immediately after surgical decompression or gradually with expectant management over a period of weeks to months in milder cases as the blood slowly gets reabsorbed.

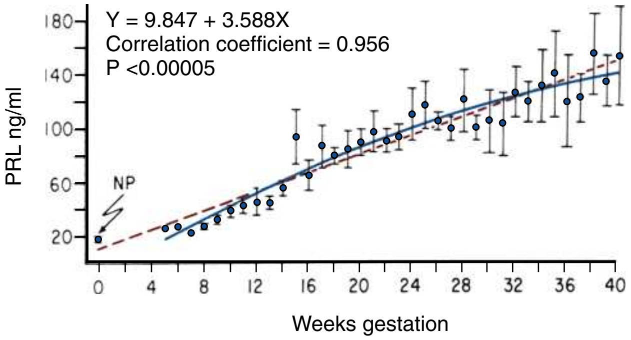

Figure 131.2 Mean ± SEM (*n* = 4) serum prolactin (PRL) concentrations measured serially at weekly intervals as a function of the duration of gestation. (Data from Rigg LA, Lein A, Yen SS. Pattern of increase in circulating prolactin levels during human gestation. *Am J Obstet Gynecol.* 1977;129:454–456.)

Nonfunctional Pituitary Adenoma. These are benign tumors arising from the adenohypophyseal cells and are characterized by an absence of hormonal hypersecretion, both functionally and biochemically. Nonfunctional pituitary adenomas constitute approximately 25% of all pituitary adenomas.[16] The tumor's size or surgical treatment may lead to functional hypopituitarism, which is associated with increased mortality rates.[17]

PROLACTIN

Changes in Prolactin Physiology

During pregnancy, estrogen production by the placenta stimulates lactotroph hyperplasia resulting in an increase in PRL gene expression and PRL protein synthesis.[18] The pituitary volume increases up to 136%.[19] Excessive estrogen production has been implicated in the pathophysiology of hyperprolactinemia and prolactinomas.[20] Progesterone also stimulates PRL secretion.[21] Together, these changes result in a progressive rise in serum PRL levels[22] (Fig. 131.2) that parallels the increase in the size and number of pituitary lactotroph cells within the pituitary. By term, PRL levels may be increased 10-fold relative to prepregnancy levels, with absolute circulating concentrations over 200 ng/mL.[23] These elevated PRL levels are thought to prepare the breast for lactation.

PRL identical to that made by the maternal pituitary is produced also by the decidua during pregnancy, resulting in high amniotic fluid PRL levels.[24] This decidual PRL is not present in maternal blood and its physiologic role may be limited to regulating water and ion transport across extraembryonic membranes.[24] The placenta also produces chorionic somatomammotropin, previously known as placental lactogen. Although it has lactogenic activity, it is structurally more closely related to GH than to PRL. It does not contribute to blood PRL levels during pregnancy.[25]

Prolactinomas in Pregnancy

A prolactinoma (or lactotroph adenoma) is the most common type of pituitary adenoma.[16] There are two major concerns in patients with hyperprolactinemia who conceive:

1. The effect of pregnancy on a preexisting prolactinoma
2. The effect of dopamine agonists on the developing fetus

The Effect of Pregnancy on a Preexisting Prolactinoma

In women with a preexisting prolactinoma, there is a risk of tumor enlargement during pregnancy not only because of estrogen lactotroph hyperplasia but also because of cessation of dopamine agonist treatment. It is estimated that the risk of symptomatic tumor enlargement in pregnancy is 2% for microadenomas but can be as high as 23% in macroadenomas that have not been surgically treated or irradiated (Table 131.2). Monitoring of PRL levels in pregnancy is controversial, but such patients should be closely monitored for clinical symptoms of pituitary enlargement (headaches and visual changes). If a patient develops symptoms, a pituitary MRI without contrast should be performed (Fig. 131.3). If the prolactinoma is noted to be enlarged, then dopamine agonist treatment is recommended as first line with surgery typically reserved for failed medical management.[26]

TABLE 131.2 Effect of Pregnancy on Prolactinomas

Tumor Type	Prior Therapy	Number	Symptomatic Enlargement
Microadenomas	None	658	18 (2.7%)
Macroadenomas	None	214	49 (22.9%)
Macroadenomas	Yes	148	7 (4.8%)

The Effect of Dopamine Agonists on a Developing Fetus

Maternal and fetal hormone levels are derived from their respective pituitary glands. As such, dopamine agonist treatment will suppress PRL levels in both the fetal and maternal compartment, although such medications have not been shown to adversely affect fetal growth and development. Decidual PRL production is not affected by dopamine agonist treatment and amniotic fluid PRL levels remain unchanged. Although dopamine agonists are typically stopped once pregnancy is confirmed, the existing safety data are reassuring. Data from over 6000 pregnancies suggest that the administration of bromocriptine during the first month of pregnancy does not harm the fetus.[27] In another study of children followed up to 9 years after *in utero* exposure to bromocriptine, no adverse effects were noted.[28] Although there are more limited data available for cabergoline, the reports that do exist are reassuring with no apparent increased risks to the pregnancy or the fetus.[26]

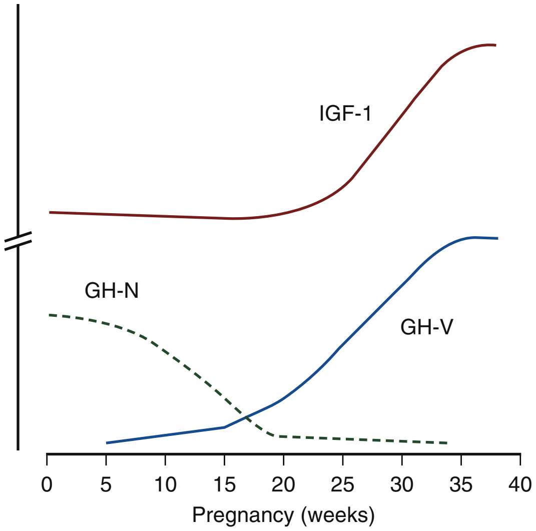

Figure 131.4 Relative changes of GH-V, GH-N, and insulin-like growth factor-1 (IGF-1) in the maternal circulation during pregnancy.

Prolactin and Antipsychotic Medication

The high prevalence of hyperprolactinemia with the use of antipsychotic medications relates to the blockade of D2 receptors. Compared with second-generation antipsychotics, first-generation medications are associated with higher PRL levels, with the exception of risperidone and paliperidone.[29,30] Antipsychotic use in pregnancy is uncommon and is seen in <1% of pregnant women in the first trimester.[31] These medications do not seem to confer an additional risk of congenital fetal malformations, with the possible exception of risperidone that has been associated in some studies with an increased risk of congenital anomalies, in particular cardiac defects.[31]

Breastfeeding and Prolactin

Nipple stimulation during breastfeeding increases serum PRL secretion, likely via a neural pathway. This effect is proportional to the increase in lactotroph hyperplasia that occurs during pregnancy. In the first few weeks postpartum, serum PRL concentrations may increase up to 300 ng/mL above baseline in response to suckling. This response is blunted over time such that, by 6 months after delivery, the increase in PRL in response to suckling is typically less than 10 ng/mL above baseline.[32]

KEY POINTS

- Prolactinoma is the most common type of pituitary adenoma seen in pregnancy.
- The risk of symptomatic tumor enlargement in pregnancy is 2% for microadenomas and up to 23% in macroadenomas.

GROWTH HORMONE

Changes in GH Physiology During Pregnancy

In humans, there are two separate genes coding for different variants of GH that differ by 13 amino acids. GH-N is produced by the pituitary and is responsible for postnatal growth. GH-V is released from the placenta and is the predominant form of GH in the maternal circulation during pregnancy[33] (Fig. 131.4). It can be detected in the maternal circulation as early as 5 weeks' gestation.[34] Beginning at 15 to 20 weeks, GH-V levels rapidly increase and GH-N levels become undetectable. Levels of GH-V peak at 35 to 37 weeks' gestation. The increase in hepatic production of IGF-1 in pregnancy is attributed to high levels of GH-V.[35] The decrease in GH-N is a result of negative feedback from GH-V and IGF-1.[36] In contrast to the pulsatile release of GH-N by the anterior pituitary, GH-V release by the syncytiotrophoblast and extravillous trophoblast cells is continuous in nature.[33]

Both GH-N and GH-V are inhibited by hyperglycemia.[37] In pregnancies complicated by gestational diabetes, GH-V (but not GH-N) levels decrease significantly following an oral glucose load.[35] GH-V relaxes arteries including those supplying the uterus, which results in an increased blood supply to the fetus.[38] Interestingly, GH-V levels are significantly lower in pregnancies complicated by intrauterine growth restriction,[39] but significantly elevated in women with severe preeclampsia.[53] Initial studies were unable to detect GH-V in the fetal circulation, suggesting an indirect role in regulating fetal growth.[35] However, more recent studies were able to measure GH-V in umbilical cord blood samples, but at levels much lower than in the maternal circulation.[39] The likely source is directly from the syncytiotrophoblast rather than transplacental passage from the maternal circulation.[35]

GH Deficiency

The effect on the fetus of low levels of GH is less concerning after 15 to 20 weeks' gestation when GH-V levels increase.[40] The rise in GH-V is unaffected by GH supplementation in GH-deficient patients.[41] Interestingly, women with underlying GH-N deficiency have normally rising levels of IGF-1 during pregnancy.[42] Successful pregnancies have been reported with GH replacement in the first trimester with tapering in the second trimester as well as with no GH replacement in pregnancy.[43] As such, GH replacement during pregnancy is not routinely recommended.[40]

GH Excess

In patients with GH excess, GH-N secretion is not subject to negative feedback and circulating levels do not decrease during pregnancy as GH-V levels rise.[40] It may be difficult to diagnose GH excess during pregnancy because commonly used diagnostic assays do not differentiate GH-N from GH-V. If a specific assay is unavailable, the definitive diagnosis of GH excess may have to be deferred to the immediate postpartum period, since GH-V becomes undetectable within 30 to 60 minutes of delivery.[34] Continued pulsatile secretion of GH during pregnancy suggests elevated GH-N, although this can be difficult to detect.[36] Of note, thyrotropin-releasing hormone (TRH) stimulates secretion of GH-N, whereas GH-V is not responsive to TRH in pregnant patients with acromegaly.[36] Elevated GH in pregnancy has been associated with gestational diabetes and hypertension.[44] An additional concern regarding acromegaly in pregnancy is enlargement of the causal pituitary adenoma resulting in neurological and/or visual symptoms.[45] Bromocriptine and octreotide have been safely used to treat acromegaly in pregnancy.[46]

KEY POINTS

- GH-V is released from the placenta and is the predominant form of GH in the maternal circulation during pregnancy. GH-N is produced by the pituitary and is responsible primarily for postnatal growth.
- In contrast to the pulsatile release of GH-N by the anterior pituitary, GH-V release by trophoblast cells is continuous.

Vasopressin

Changes in Vasopressin Physiology During Pregnancy. Plasma osmolality is the main driver of vasopressin release (see Chapter 12). In nonpregnant women, normal plasma osmolality is 275 to 290 mOsm/kg and the osmotic threshold for vasopressin release is 280 to 285 mOsm/kg. Thirst is triggered at a plasma osmolality approximately 5 mOsm/kg above the threshold for vasopressin release, at which time maximal urine concentration will have already occurred. In normal pregnancy,

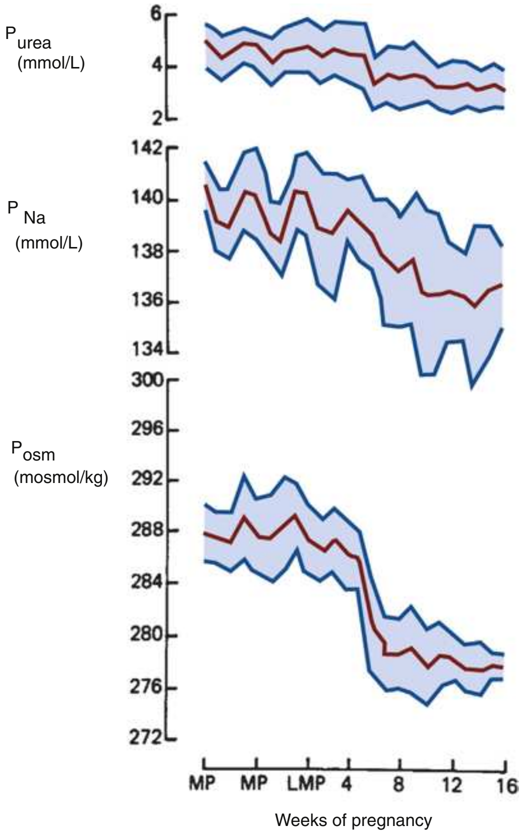

Figure 131.5 **Mean values (±SD) for plasma urea *(Purea)*, sodium *(PNa)*, and osmolality *(Posm)* measured at weekly intervals from before conception to the first trimester in nine women with a successful obstetric outcome.** *LMP,* Last menstrual period; *MP,* menstrual period. (Data from Davison JM, Vallotton MB, Lindheimer MD. Plasma osmolality and urinary concentration and dilution during and after pregnancy: evidence that lateral recumbency inhibits maximal urinary concentrating ability. *Br J Obstet Gynaecol.* 1981;88:472–479.)

the average plasma osmolality is decreased by 5 to 10 mOsm/kg.[47] A decrease in plasma osmolality can be detected as early as the first missed menstrual period and a further decrease by 5 to 10 mOsm/kg is typically seen by the 10th week of gestation, at which time it plateaus for the remainder of pregnancy[48] (Fig. 131.5). The decrease in plasma osmolality results from an increase in total body water and plasma volume expansion of greater than 1.5-times normal.[49] The threshold for vasopressin release is about 6 mOsm/kg lower during pregnancy and thirst is triggered at a plasma osmolality about 10 mOsm/kg lower during pregnancy compared to the nonpregnant state[50] (Fig. 131.6).

Vasopressinase is a cysteine aminopeptidase produced by trophoblast cells during pregnancy that rapidly metabolizes vasopressin.[51,52] Vasopressinase production begins in the seventh week of gestation and levels rise 1000-fold between 7 and 40 weeks, coincident with the increasing placental mass.[52] In normal pregnancies, increased synthesis and release of vasopressin by the posterior pituitary is sufficient to overcome the effects of the vasopressinase.[52] As such, plasma levels of vasopressin during pregnancy are similar to that in nonpregnant women at 1 to 2 pg/mL, despite the 3- to 4-fold increase in clearance.[51] Vasopressinase is metabolized by the liver, which accounts for the higher circulating levels seen in patients with acute or chronic liver dysfunction.[49] Circulating vasopressinase levels become undetectable 5 to 6 weeks after delivery.[52]

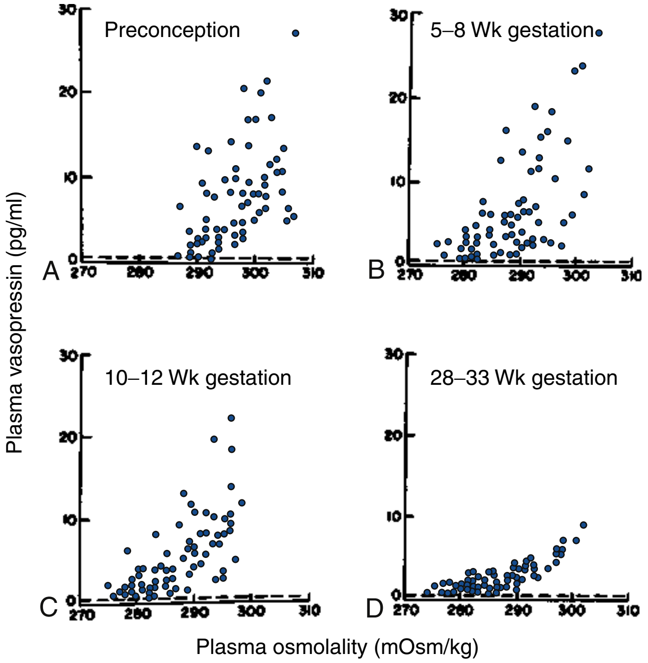

Figure 131.6 **Relationship of plasma arginine vasopressin to plasma osmolality during a 2-hour hypertonic saline infusion in eight women studied serially before and during pregnancy.** Each point is an individual plasma determination. *Dashed lines* indicate the lower limit of detection for arginine vasopressin. (Data from Lindheimer MD, Barron WM, Davison JM. Osmoregulation of thirst and vasopressin release in pregnancy. *Am J Physiol.* 1989;257:F159–F169.)

Diabetes Insipidus of Pregnancy. Gestational diabetes insipidus (GDI) occurs when the increased release of vasopressin from the posterior pituitary is not sufficient to overcome the elevated levels of vasopressinase resulting in a functional deficiency of vasopressin, the hormone required to reabsorb water from the renal glomerular filtrate and concentrate the urine. Patients present with hypotonic polyuria and excessive water consumption.[51,52] GDI affects 2 to 4 per 100,000 pregnancies and is seen most commonly at the end of the second trimester or during the early third trimester.[53] Additional risk factors include multifetal gestations (because there is a larger placental mass to synthesize vasopressinase) and pregnancies complicated by preeclampsia/hemolysis, elevated liver enzymes, low platelet count [HELLP] syndrome or acute fatty liver of pregnancy (because liver dysfunction decreases the metabolism of vasopressinase).[54] GDI usually resolves spontaneously within 4 to 6 weeks of delivery.[53] Acute postpartum DI is rare but has been described in association with placental abruption and after delivery with a sudden release of placental vasopressinase into the bloodstream.[55] The treatment for GDI is desmopressin, a synthetic form of vasopressin that has been structurally modified to make it resistant to degradation by vasopressinase.[56] The dose of desmopressin is similar to or slightly higher than that required for nonpregnant patients. The medication can often be discontinued 4 to 6 weeks after delivery when vasopressinase levels decrease and GDI resolves clinically.[56] Desmopressin appears to be safe in pregnancy and breastfeeding.[57]

Pregnancy-Induced Exacerbation of Preexisting Diabetes Insipidus. Vasopressinase levels increase 1000-fold between 7 and 40 weeks' gestation, which may unmask a preexisting predisposition towards DI.[40] Patients with a history of neurosurgery, head trauma, or a family history of DI are at elevated risk.[51] A water deprivation test, which compares urinary osmolality after dehydration and after administration of vasopressin, may be useful to confirm the diagnosis in nonpregnant patients, but is not recommended during pregnancy.

Diagnostic tests should therefore be limited to measurements of urinary and plasma osmolality. Treatment should be initiated early and not delayed unnecessarily[51] (see Chapter 12 for further discussion of the management of DI).

Syndrome of Inappropriate Antidiuretic Hormone Secretion. Syndrome of inappropriate antidiuretic hormone secretion (SIADH) is rare in pregnancy. Of 18 reported cases of SIADH and hyponatremia in pregnancy, 13 were associated with preeclampsia.[58] Women with preeclampsia are total body fluid overloaded, but intravascularly depleted because of a loss of vascular integrity and third spacing of fluid. The resultant low circulating blood volume may lead to a nonosmotic release of ADH.[59] This may be compounded by the resetting of the osmostat during pregnancy whereby the average plasma osmolality is decreased by 5 to 10 mOsm/kg.[47] Hyponatremia may increase the risk of seizures in patients with preeclampsia[59] (see Chapter 18 for the treatment of SIADH).

KEY POINTS

- In normal pregnancy, the average plasma osmolality is decreased by 5 to 10 mOsm/kg.
- Vasopressinase is produced by placental trophoblasts during pregnancy and rapidly metabolizes vasopressin.
- Vasopressinase levels increase 1000-fold between 7- and 40-weeks' gestation, which may unmask preexisting DI.

THYROID GLAND

Thyroid Hormones and Thyroid Regulation

Changes in Thyroid Physiology During Pregnancy. Pregnancy is associated with a number of changes in the thyroid gland and in levels of circulating thyroid hormones[60] with the ultimate objective of ensuring normal fetal growth and development.[61] Thyroid hormone is critically important in regulating placentation and fetal neurodevelopment, although the relative contributions of the maternal and fetal thyroid axes remain uncertain.[61,62]

Pregnancy is associated with a 10% to 40% increase in the size of the maternal thyroid gland.[63] Increased estrogen levels during the first trimester increase hepatic production of thyroid-binding globulins (TBGs) and decrease their metabolism.[64] This results in a 2-fold increase in circulating TBG levels. Most of the circulating thyroid hormone is bound to TBG. In addition, pregnancy is associated with an increase in iodine utilization, and in thyroid hormone production, which is driven in part by the thyroid stimulatory effects of hCG. hCG is a member of the same family of glycoprotein hormones as TSH, with a common alpha subunit and a unique but homologous beta subunit. As a result, hCG has weak thyroid-stimulating activity.[65] This effect along with the increase in volume of distribution during the first half of gestation[66] results in a decrease in circulating thyroid hormone levels before a steady state is reached around midgestation. In order to maintain adequate circulating levels of biologically active–free (unbound) thyroid hormone, the thyroid gland undergoes substantial changes in thyroid hormone metabolism, iodine uptake, and hypothalamic-pituitary-thyroid axis regulation.[60] The ability to compensate for the increased demands of pregnancy relies on adequate iodine intake and on an intact functional thyroid gland.

Iodine is an absolute requirement for thyroid hormone synthesis and pregnant women have increased dietary iodine requirements. Although dietary intake in Western countries is generally considered adequate in terms of iodine repletion, some studies suggest that over 50% of US women may have suboptimal urinary iodine concentrations.[67] Even the United Kingdom was recently classified as a "mildly iodine deficient" region by the World Health Organization (WHO).[68] The WHO, American Thyroid Association, and Endocrine Society recommend an intake of 250 mcg iodine daily during pregnancy and lactation. For this reason, prenatal vitamins containing 150 to 250 mcg iodine are recommended in the preconception period as well as throughout pregnancy and lactation.[69] Excessive iodine ingestion (defined as >500 mcg/day) should be avoided as this may cause fetal or neonatal goiter.[70]

Severe iodine deficiency may result in fetal and/or maternal goiter and has been associated with increased rates of pregnancy loss, stillbirth, and increased perinatal mortality[71] as well as an adverse effect on fetal and neonatal neurodevelopment. Indeed, iodine deficiency is the leading cause of preventable intellectual deficits globally.[72] Women with mild-to-moderate iodine deficiency are at increased risk of developing a goiter. A clinical diagnosis of goiter in pregnancy should prompt further investigation. Use of radioactive iodine to evaluate a goiter may be useful in the nonpregnant patient, but can be difficult to interpret as iodine uptake is markedly increased in pregnancy.[73] More importantly, use of radioactive iodine is absolutely contraindicated in pregnancy as it freely crosses the placenta and will irreversibly damage or destroy the fetal thyroid, which has an avidity for iodine 20 to 50 times more than the maternal thyroid. Notably, the small tracer dose is not sufficient to cause significant injury if given inadvertently to a pregnant patient.[74] The treatment of women with thyroid cancer using radioactive iodine does not seem to have a detrimental effect on subsequent pregnancies, provided that the pregnancy occurs more than 6 months following the I^{131} treatment.[98]

The fetal thyroid gland and hypothalamic-pituitary-thyroid axis develop independently of maternal thyroid status. At 11 to 12 weeks of gestation, the fetal thyroid gland begins to concentrate iodine. In addition to iodine, the placenta is freely permeable to medications used to treat hyperthyroidism, such as propylthiouracil (PTU), methimazole, and propranolol. In contrast, very little TSH and triiodothyronine (T3) is able to cross the placenta.[60] The prohormone, thyroxine (T4), crosses the placenta in somewhat larger (although still very small) amounts such that, in late gestation, large doses of T4 have been shown to ameliorate the adverse effects of congenital hypothyroidism caused by an enzyme defect or agenesis of the thyroid gland.[60] More commonly, intraamniotic injection of T4 may be used to treat fetal goiter associated with congenital hypothyroidism.[75]

As noted previously, thyroid-stimulating activity is increased in the serum of women in the first trimester of pregnancy as a result of the intrinsic thyroid-stimulating activity of hCG.[76] This may result in elevated circulating T4 and T3 levels as well as a transient clinical hyperthyroidism, which may present as hyperemesis gravidarum, severe nausea, and vomiting of pregnancy with associated weight loss and electrolyte disturbances. The markedly elevated levels of hCG seen with gestational trophoblastic neoplasms may also cause hyperthyroidism, a phenomenon first described by Tisne et al. in 1955.[77]

Alterations in Thyroid Function Tests During Pregnancy. Most thyroid hormone in the circulation is bound and therefore biologically inactive. T4 is 75% bound to TBG, 10% to 15% bound to albumin, and 10% to 15% bound to transthyretin (prealbumin); only about 0.04% is unbound (free) and thus biologically active. Increased estrogen levels in pregnancy result in increased production of TBG by the liver and in a commensurate increase in serum TBG levels, which plateaus in mid-gestation. In addition to the increased production of TBG by hepatocytes, there is also an increase in TBG sialylation resulting in a decrease in plasma clearance.[78] This increase in TBG results in higher

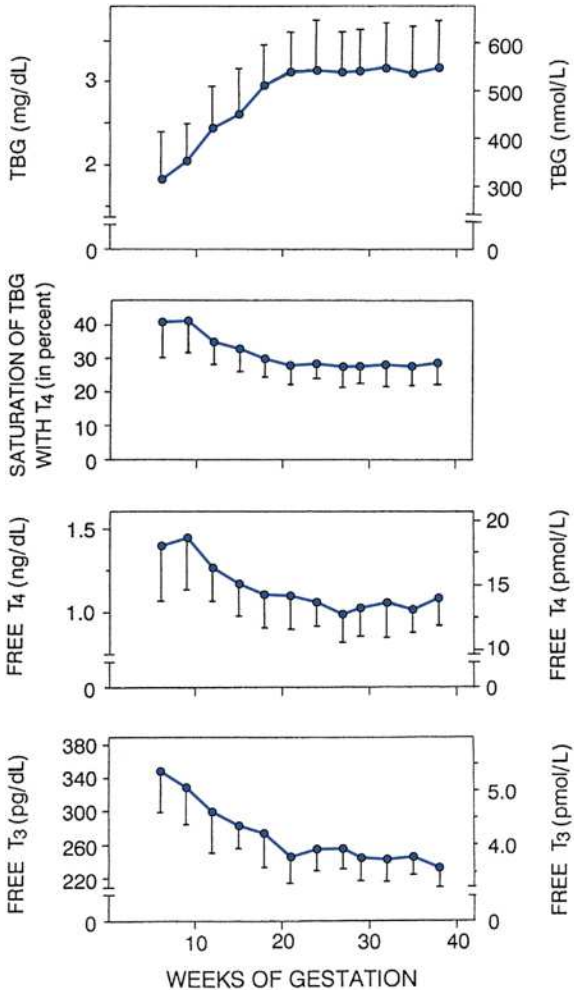

Figure 131.7 **Data collected in 606 normal pregnancies in Brussels are illustrated, showing the progressive rise in serum thyroxine-binding globulin *(TBG)* in the first part of gestation, accompanied by a progressive decrease in the free T index (saturation level of TBG by *T4*), and free T4 and *T3* concentrations.** Brussels is an area with restricted iodine intake, so the quantitative reduction in free hormone concentration observed in the second part of pregnancy is more pronounced than in areas without iodine deficiency. (Data from Glinoer D. Thyroid regulation during pregnancy. In Delange F, Dunn JT, Glinoer D ed. *Iodine Deficiency in Europe: a Continuing Concern.* NATO ASI Series (vol 241). New York: Plenum. 1993, pp. 181–190. © Plenum Publishing Corporation.)

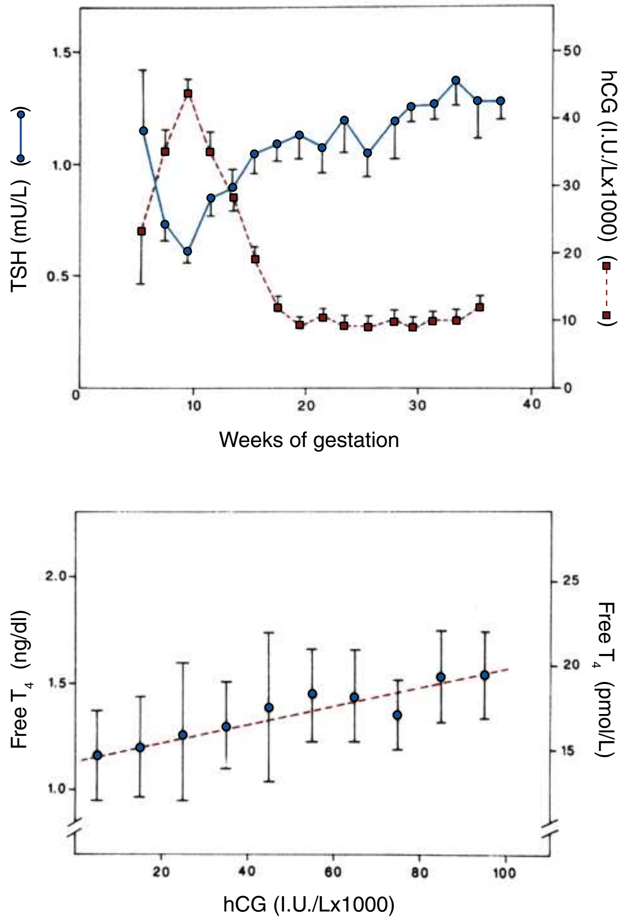

Figure 131.8 **Upper graph, serum thyroid-stimulating hormone (TSH) and human chorionic gonadotropin (hCG) as a function of gestational age in 606 healthy pregnant women.** Between 8 and 14 weeks of gestation, the changes in hCG and TSH levels are mirror images of each other and there is significant negative correlation between the individual TSH and hCG levels ($P < 0.001$). Each point gives the mean value (±SE) of individual determinations pooled for 2 weeks. Lower graph, scattergram of free thyroxine (T4) levels in relation to hCG concentrations in the first half of gestation. Each point represents the mean (±1 SD) free T4 values, determined between 6 and 20 weeks = plotted for 10,000 IU/L increments in hCG. The *dashed line* represents the linear regression curve ($P < 0.001$). (Data from Glinoer D, DeNayer P, Bourdoux P, et al. Regulation of maternal thyroid during pregnancy. *J Clin Endocrinol Metab*. 1990;71:276–287. Copyright © The Endocrine Society.)

total T4 measurements beginning at 4 to 6 weeks of gestation[60] (Fig. 131.7). The metabolic activity of thyroid hormone correlates with the free hormone concentration. Free T4 (fT4) levels have been reported to be unchanged, increased, or decreased during pregnancy, although they usually remain within the normal range[60,79] (Fig. 131.7). The differences between these reports may relate to relative iodine deficiencies in the populations studied,[55] to the stage of pregnancy at which the measurements were made,[60,79] or to the assay being used. fT4 levels are typically minimally elevated or in the high-normal range in the first trimester and then return to baseline and even below baseline in the latter half of pregnancy, in parallel with changes in hCG[60] (Fig. 131.8). Of note, some of the commercially available fT4 immunoassays are not accurate during pregnancy and should not be used in this population.[70] Some investigators recommend using the total T4 assay and then adjust by multiplying by 1.5 during the second and third trimesters.[70] If circulating fT4 levels are measured in pregnancy, it is recommended that assay-specific and trimester-specific pregnancy reference ranges be applied.[69]

Under physiological conditions (preserved thyroid function and adequate iodine availability), the increase in TBG concentrations is almost double the magnitude of the increase in maternal thyroxine. This discrepancy (i.e., a greater increase in TBG than in T4 levels) results in a progressively decreasing T4/TBG ratio over time, resulting in a physiological decrease in fT4 and fT3 concentrations of 10% to 15%.[80] T3 is also bound to TBG, but with somewhat less affinity than T4. The end result is the same pattern of increase in total T3 levels as seen with T4 during pregnancy.[80] TSH levels are decreased during the first trimester of pregnancy (Fig. 131.8), likely due to the increased fT4 levels as a result of hCG directly stimulating the TSH receptor.[60] In the first trimester, the normal range for TSH is 0.1 to 2.5 mU/L.[70] TSH levels have been shown to vary slightly depending on different

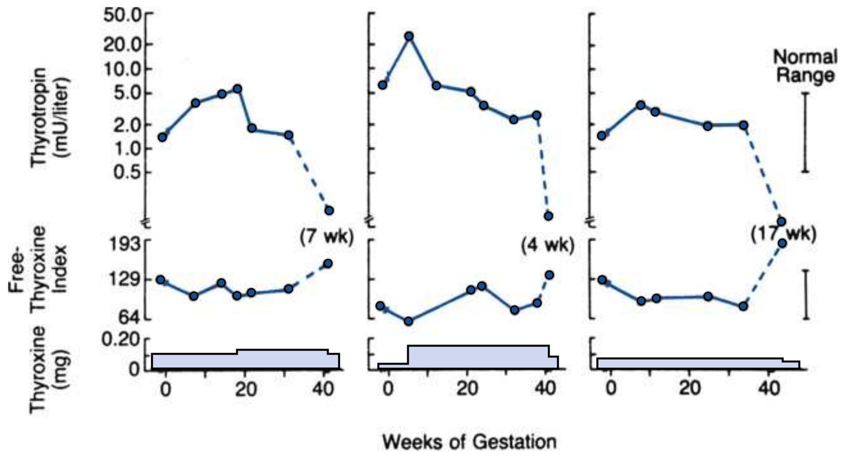

Figure 131.9 **Representative patterns of changes in thyroid function and thyroxine dose during pregnancy in women with hypothyroidism.** The left and middle panels show the results for two women who required an increase dose of thyroxine in pregnancy. The right panel shows the results for a woman whose thyroxine dose was not changed during pregnancy. The normal ranges for serum thyrotropin and free thyroxine index are indicated by the vertical bars on the right side of the figure. The discontinuity marks indicate the beginning and end of pregnancy. The *dashed line* represents the change between the last gestation and the first postpartum values (number of weeks postpartum is noted in parentheses). (Data from Mandel SJ, Larsen PR, Seely EW, Brent GA. Increased need for thyroxine during pregnancy in women with primary hypothyroidism. *N Engl J Med*. 1990;323:91–96; © 1990, Massachusetts Medical Society. All rights reserved.)

methods of analysis, although this variation does not appear to be clinically significant.[81] One approach to reducing the variability related to different assays and different laboratories is to use the multiple of medians (MoM) calculation, which divides an individual value by the population median.[82]

How often to measure thyroid hormones levels during pregnancy is controversial. In women with significant iodine deficiency, close monitoring may be indicated as fT4 levels may fall and TSH levels rise in the last trimester.[83] T4 turnover is increased during pregnancy.[79] In patients receiving thyroxine replacement, TSH levels should be checked every 1 to 2 months and the medication dose adjusted accordingly.[70] In one study, 75% of patients needed to increase their thyroxine dose during pregnancy[84] (Fig. 131.9), although studies have failed to demonstrate whether such medication adjustments actually translate into improved outcomes compared to increasing the dosing empirically as pregnancy progresses.[85] Checking TSH levels more frequently than every 1 to 2 months is generally unhelpful as it takes several weeks for changes in medication dosing to be reflected in realignment of the thyroid axis.

Hyperthyroidism

Diagnosis of Hyperthyroidism in Pregnancy. The clinical diagnosis of hyperthyroidism may be more difficult in pregnancy since many of the symptoms and signs are nonspecific. Tachycardia, warm skin, systolic flow murmurs, and heat intolerance are common to both hyperthyroidism and pregnancy. A goiter is a structural enlargement of the thyroid gland, but does not in of itself tell you about thyroid function. Features that are more suggestive of hyperthyroidism include weight loss, marked tachycardia[86] (particularly a heart rate greater than 120 beats/min), eye signs (proptosis, lid lag), and an audible bruit over the thyroid gland.[70,79] Infiltrative dermopathy and ophthalmopathy are specific for Graves disease. The changes in circulating thyroid hormone levels discussed earlier may cause further diagnostic difficulty. Total T4 and T3 levels are generally elevated, because of the presence of excess TBG. TSH concentrations are generally reduced during the first trimester of pregnancy because of the effect of hCG and negative feedback from elevated levels of fT4.[60] Despite these limitations, it is important to make the diagnosis of hyperthyroidism promptly and accurately to allow timely treatment, since untreated or poorly controlled hyperthyroidism has detrimental effects on fetal and neonatal outcome.[69,87]

Graves Disease. Graves disease is an autoimmune disease caused by circulating anti-TSH-receptor antibodies (TRAb) that activate the receptor, thereby stimulating thyroid hormone synthesis and secretion as well as thyroid growth, resulting in goiter. Other symptoms may include eye disease (orbitopathy) and occasionally a dermopathy referred to as pretibial myxedema. The presence of TRAb in serum and orbitopathy on clinical examination distinguishes this disorder from other causes of hyperthyroidism.

Most cases of hyperthyroidism in pregnancy are due to Graves disease.[70,79] Graves hyperthyroidism affects 0.2% of all pregnancies.[79] Fetal/neonatal hyperthyroidism occurs in 1% to 5% of women with active or a history of Graves disease and is associated with adverse fetal and neonatal outcomes if untreated.[88] Maternal serum TRAb can be measured in the first and third trimesters and may be helpful in predicting which infants are at high risk of developing fetal/neonatal Graves disease.[89] TRAb are immunoglobulin G (IgG) antibodies that can cross the placenta and cause fetal hyperthyroidism, although this is rare. Features of intrauterine hyperthyroidism include fetal tachycardia, fetal goiter, poor growth, and craniosynostosis.[90] Thioamide medications used to treat the mother may also cross the placenta and cause fetal hyperthyroidism.

All fetuses of women with Graves disease should be closely monitored in pregnancy for signs of fetal hyperthyroidism and by ultrasound to evaluate growth and fetal heart rate.[91] In women with active Graves disease in pregnancy and serum TRAb levels greater than 2- to 3-fold the upper limit of normal, fetal thyroid ultrasound should be considered in the second and third trimesters to evaluate for fetal goiter.[89] In equivocal cases, fetal blood sampling may be required to confirm the diagnosis.

Hyperthyroidism and Hyperemesis Gravidarum. Pregnant patients with hyperthyroidism may present with nausea and vomiting. Hyperemesis gravidarum may also be associated with biochemical evidence of hyperthyroidism in up to two-thirds of cases.[70,79] Only

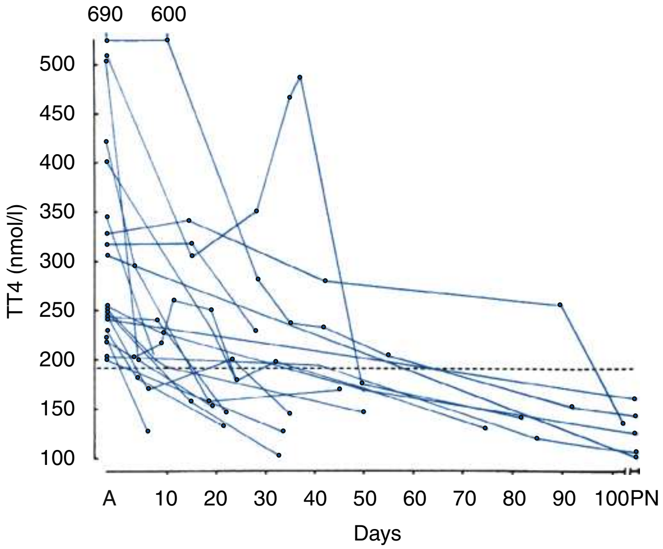

Figure 131.10 **Changes in plasma total thyroxine concentration in 20 subjects with hyperemesis on admission (A) and during the course of their pregnancy.** The interrupted line represents the mean (±SD) value seen in normal pregnancy. (Data from Swaminathan R, Chin RK, Lao TT et al. Thyroid function in hyperemesis gravidarum. *Acta Endocrinol* [Copenh]. 1989;120:155–160.)

10% to 20% of these patients will manifest clinically with thyrotoxicosis. The severity of hyperemesis appears to correlate directly with the degree of thyroid dysfunction.[92] In most patients, fT4 levels decrease to normal or near normal levels within 35 days (range, 6 to 133 days) of pregnancy, generally in parallel with the decrease in circulating hCG levels[93] (Fig. 131.10). Most patients with hyperthyroidism-associated hyperemesis have no goiter and no eye findings; as such, the clinical diagnosis can be challenging.[70]

Treatment. Women with moderate-to-severely symptomatic hyperthyroidism due to Graves disease, toxic adenoma, toxic multinodular goiter, or gestational trophoblastic disease require treatment. Such patients will almost always have TSH values below 0.05 mU/L and trimester-specific total T4/T3 and fT4 concentrations that exceed 1.5 times the upper limit of normal for nonpregnant patients. Treatment should be focused on controlling symptoms as well as decreasing thyroid hormone synthesis and release. Symptoms of hyperthyroidism result primarily from increased beta-adrenergic tone and include such clinical features as palpitations, tachycardia, tremulousness, and anxiety. Treatment with beta-adrenergic blocking agents (beta-blockers) such as metoprolol or propranolol can be highly effective in managing such symptoms. Although generally regarded as safe in pregnancy, beta-blockers have been weakly associated with fetal growth restriction and hypoglycemia; as such, they can be weaned once the hyperthyroidism is well controlled with thionamides.[94]

Thioamides are the treatment of choice for hyperthyroidism in pregnancy. They act at the level of the thyroid gland to inhibit the synthesis, storage, and release of thyroid hormone. Specifically, they inhibit the organification of iodine to tyrosine residues within thyroglobulin and the coupling of iodotyrosines. The two most commonly used thioamides are methimazole and PTU. Both cross the placenta and appear to have similar effects on the fetal thyroid.[95] In general, methimazole is preferred to PTU, except during the first trimester. Both drugs are weakly associated with an increased risk of birth defects of 2% to 3%.[96] The embryopathy associated with methimazole appears to be more severe (including aplasia cutis and dysmorphic faces) and therefore PTU is preferred for treatment in the first trimester.[69] However, PTU has been associated with hepatotoxicity and so its use is often limited to the first trimester.[97] A thyroidectomy can be performed if the hyperthyroidism is refractory to medical management. If necessary, this is best done in the second trimester.

Thyroid Storm. Thyroid storm is a rare, life-threatening condition characterized by severe clinical manifestations of thryotoxicosis.[98] It is seen most commonly in patients with known hyperthyroidism and may be precipitated by an acute event such as trauma, infection, or parturition. The maternal and perinatal mortality rate can be as high as 10% to 30%. Treatment involves both supportive care (often in an intensive care unit [ICU] setting) as well as the administration of beta-blockers, a thioamide, and iodine.[99] Glucocorticoids are also useful as they reduce peripheral conversion of the prohormone (T4) to the active hormone (T3), promote vasomotor stability, and may improve the autoimmune process of Graves disease.[100]

Hypothyroidism

Diagnosis of Hypothyroidism in Pregnancy. Subclinical hypothyroidism (defined as biochemical evidence of hypothyroidism without clinical features) has been reported in 1.7% of pregnant women, whereas overt hypothyroidism complicates 2 to 10 per 1000 pregnancies.[101] Pregnancy may confound the typical clinical manifestations of hypothyroidism such as fatigue, cold intolerance, constipation, and weight gain.[69] Other symptoms such as muscle cramps or dry skin may be more suggestive of the diagnosis.[70,102] Because of the changes in thyroid physiology during pregnancy and the substantial population differences in reference ranges, thyroid function tests should be interpreted using population-based, trimester-specific reference ranges for TSH and using assay- and trimester-specific reference ranges for serum fT4. If internal or transferable trimester-specific reference ranges are not available, then an upper limit for TSH of 4.0 mU/L may be used.[69] Overt primary hypothyroidism is defined as an elevated trimester-specific TSH concentration with a decreased fT4 concentration (using reference range for pregnant women). In patients with hypothyroidism, total T4 levels in pregnancy should be interpreted with caution since the increase in circulating TBG concentrations may cause the total T4 levels to be in the normal range.[102] Established replacement doses of thyroxine may need to be increased, because of the increased clearance of thyroxine during pregnancy.[84]

Indications for Treatment and Management. Overt maternal hypothyroidism is associated with an increased risk of adverse pregnancy outcomes[103] as well as detrimental effects on fetal neurocognitive development.[104] As such, early identification and treatment is important. The data regarding subclinical hypothyroidism are more controversial. Subclinical hypothyroidism has been inconsistently associated with adverse pregnancy outcomes including preterm delivery[105] and infant neurodevelopment.[104] There is also a weak and inconsistent association with miscarriage, although the presence of antithyroid peroxidase antibodies (TPOAb) in this population appears to strengthen this association.[106,107] In a large prospective study of more than 4600 subjects, Negro et al.[106] reported that subclinical hypothyroidism increased the risk of pregnancy complications in TPOAb-positive women, and that treatment of TPOAb-positive women with a TSH >2.5 mU/L resulted in a significant reduction in pregnancy complications. A separate randomized controlled trial (RCT) reported a decrease in preterm delivery and pregnancy loss rates in euthyroid (TSH <4.2 mU/L). TPOAb-positive women were treated with thyroid replacement beginning in the first trimester of pregnancy.108 However, other studies have failed to show an association between subclinical hypothyroidism and adverse pregnancy outcomes.[62] Because of the risk of adverse pregnancy outcomes with subclinical hypothyroidism, some, but not all, national consensus bodies have advocated for routine first trimester screening and treatment.[70,109]

Hypothyroidism and Infertility. There has been considerable debate regarding the association of subclinical hypothyroidism and TPOAb status and pregnancy loss in the infertile population. While one systematic review suggested a strong association between TPOAb positivity and miscarriage,[107] two recent large, well-designed RCTs failed to confirm this association.[110,111]

Fetal Thyroid Gland. The thyroid gland is formed from all three germ cell layers. The majority of critical events related to thyroid morphogenesis happen within the first 60 days postconception. Consequently, most developmental thyroid abnormalities result from morphogenetic errors during this time frame. Ectopic thyroid tissue can result from abnormal thyroid migration due to abnormal morphogenesis of the heart or from anomalous interactions between the thyroid primordium and the heart.[112] Thyroglobulin synthesis can be detected in the fetal thyroid by 4 to 6 weeks of gestation, TRH synthesis by 6 to 8 weeks, iodine trapping by 8 to 10 weeks, and TSH release with T4 synthesis by 12 weeks.[113]

KEY POINTS

- Subclinical hypothyroidism has been reported in 1.7% of pregnant women while overt hypothyroidism complicates 2 to 10 per 1000 pregnancies.
- Poorly controlled maternal hypothyroidism is associated with an increased risk of adverse pregnancy outcomes as well as detrimental effects on fetal neurocognitive development.
- The association between subclinical hypothyroidism and adverse pregnancy events is more variable; as such, universal screening in pregnancy is controversial.

ADRENAL GLAND

Regulation of Glucocorticosteroid Synthesis

Changes in the Adrenal Glands. The demand for steroid production increases during pregnancy. Maternal estrogen and cortisol levels are elevated in pregnancy and the fetus requires steroids for normal growth and development.[114] Although the maternal adrenal glands do not increase in size or weight during pregnancy, the size of the zona fasciculata—that region of the adrenal glands responsible for glucocorticoid synthesis—does increase.[114]

Corticotropin-Releasing Hormone Physiology During Pregnancy. The high levels of free cortisol in the maternal circulation during pregnancy are the result of elevated levels of CRH. As pregnancy progresses, CRH levels rise exponentially to concentrations that are 1000 times higher than in nonpregnant women and peak during labor.[115] The source of this CRH is 2-fold. First, the maternal hypothalamus releases excess CRH in response to the physiological and psychological stresses of pregnancy.[116] Second, CRH is produced by the placenta and released into the maternal (and fetal) compartments in increasing amounts as placental size increases over time.[117] The effects of elevated CRH levels are attenuated in part by an increase in CRH-binding protein in the plasma and by negative feedback and desensitization of the anterior pituitary to high levels of CRH.[118] Despite these attenuations, the 1000-fold rise in CRH leads to a 1.5-fold rise in plasma free cortisol.[115]

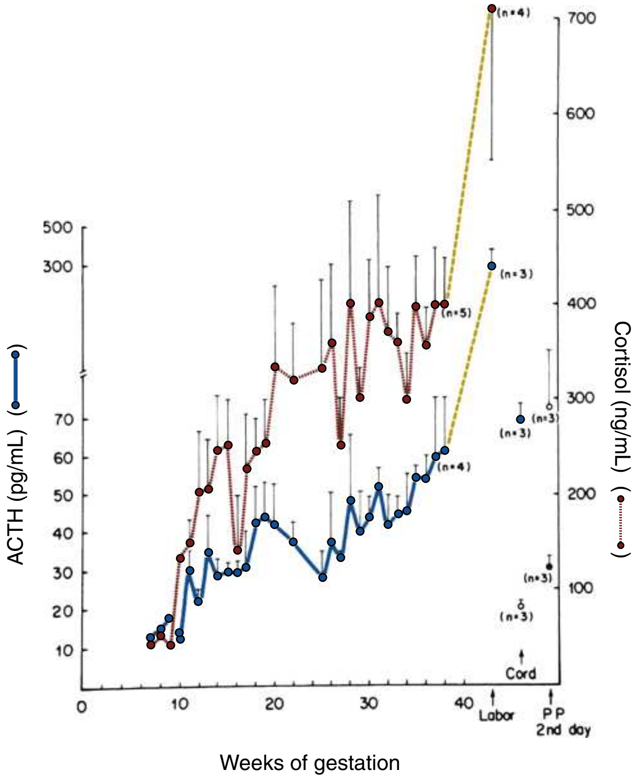

Figure 131.11 Plasma concentration of adrenocorticotropic hormone (ACTH) and cortisol during normal pregnancy. Blood samples were obtained weekly at 8 AM to 9 AM from five normal pregnant women and from three women during labor and on the second postpartum day. In addition, umbilical cord plasma was obtained from the newborn infants of three of these subjects. The mean plasma concentrations for ACTH are denoted by *blue circles*, whereas plasma cortisol levels are denoted by *red circles*. The vertical bars correspond to the magnitude of the standard error of the mean. (Data from Carr BR, Parker CR Jr, Madden JD, et al. Maternal plasma adrenocorticotropin and cortisol relationships throughout human pregnancy. *Am J Obstet Gynecol*. 1981;139:416–422.)

CRH has also been implicated in myometrial contractility and the timing of labor. At term, while circulating CRH levels continue to rise, CRH-binding protein levels decrease, leading to an increase in bioavailable (free) CRH. This switch occurs at an earlier time point in women destined to deliver preterm and later in women who deliver postterm.[119]

Adrenocorticotropic Hormone Physiology During Pregnancy. ACTH, a 39-amino acid polypeptide, is secreted by the anterior pituitary in response to CRH from the hypothalamus. ACTH is formed from cleavage of a precursor peptide, proopiomelanocortin (POMC), along with several other related peptides, β-endorphin and α-melanocyte-stimulating hormone (MSH).[120] During pregnancy, there is increased production of ACTH and β-endorphin from both the anterior pituitary and the placenta.[114,121] Plasma ACTH levels rise 3-fold over the course of pregnancy and peak during labor and delivery.[122] The rise in plasma ACTH occurs despite rising levels of plasma cortisol, suggesting that ACTH secretion in pregnancy is not subject to the normal negative feedback mechanisms.[121,122] In the third trimester, there is no apparent correlation between ACTH and CRH, but ACTH and cortisol levels have a strong positive correlation and maintain a diurnal pattern with ACTH pulses leading cortisol pulses by about 30 minutes.[123] In pregnancy, the ACTH/cortisol ratio is lower than in nonpregnant women. Interestingly, in women with preeclampsia, the ACTH/cortisol ratio is elevated and mirrors that in nonpregnant women.[124]

Cortisol Physiology During Pregnancy. High levels of estrogen during pregnancy stimulate hepatic production of CBG.[114] Circulating levels of CBG are 2-fold higher during pregnancy than in the nonpregnant state, which results in increased total plasma cortisol.[114,125] By the end of pregnancy, total plasma cortisol levels are nearly 3-fold higher than nonpregnant levels[125] (Fig. 131.11). However, only free cortisol, that fraction not bound to CBG, is metabolically active. In the third trimester, plasma free cortisol levels are elevated 1.5- to 4-times that in nonpregnant women.[125] Twenty-four–hour urinary free cortisol levels increase throughout pregnancy and are 3-fold higher in the third trimester than in the nonpregnant state.[125] The diurnal cortisol pattern observed outside of pregnancy is maintained during pregnancy,[126] although pregnancy is associated with an upward shift in the curve with the nadir of cortisol secretion higher than the nonpregnant peak of cortisol secretion.[126] Clinically, the physiological hypercortisolism of pregnancy presents as maternal fatigue, weight gain, hyperglycemia, edema, and emotional lability.[114] Because so many of these features can be considered normal during pregnancy, it can be challenging to detect symptoms of pathologic hypercortisolism.[114]

Cushing Syndrome. Cushing syndrome is rare in pregnancy with only approximately 214 cases in the published literature. Of these, 28% were due to pituitary adenomas, 44% to adrenal adenomas, and 10% to adrenal carcinoma.[127] Several cases of transient pregnancy-induced Cushing syndrome have been reported due to overexpression of LH/hCG receptors in the adrenal glands.[128]

Diagnosing Cushing syndrome during pregnancy can be challenging because many of the symptoms—fatigue, weight gain, peripheral edema—are common in pregnancy.[129] Additionally, laboratory tests traditionally used to confirm the diagnosis are not valid in pregnancy.[129] Moreover, some of the screening tests such as the low-dose dexamethasone suppression test and 24-hour urinary free cortisol level can be difficult to interpret during pregnancy, although monitoring of the diurnal free plasma cortisol pattern may have more utility.[129–131] To illustrate this point, the 1-mg overnight dexamethasone suppression test causes a mean reduction in serum cortisol of 87.1% in nonpregnant patients.[130] However, in pregnancy, the mean cortisol reduction is 82.9% during the first trimester, 43.5% during the second trimester, and 37.3% during the third trimester.[130] These data suggest that, while the overnight dexamethasone suppression test may have some utility in the evaluation of pregnant patients suspected of having Cushing syndrome, the normal values implemented outside of pregnancy must be adjusted.[130] Similarly, in nonpregnant patients, 24-hour urinary free cortisol levels greater than 4-fold the upper limit of normal are suggestive of Cushing syndrome.[129] In pregnancy, however, 24-hour urinary free cortisol levels increase to 3-fold normal and patients with Cushing syndrome in pregnancy have a mean 24-hour urinary free cortisol level that is typically 8-fold normal (range 2- to 22-fold).[132] Because of the overlap in 24-hour urinary free cortisol levels among pregnant patients with and without Cushing syndrome, especially in early pregnancy, the recommendation is to use a 24-hour urinary free cortisol level threshold in the second and third trimesters of greater than 3-fold the upper limit of normal to diagnose Cushing syndrome.[129] The nightly nadir in plasma cortisol is maintained during pregnancy, although at a higher value, but is lost in patients with Cushing syndrome.[133] Elevated evening plasma cortisol levels and loss of the diurnal cortisol pattern may be helpful in suggesting the diagnosis during pregnancy.[131] However, no reliable thresholds for evening cortisol levels have been developed for the diagnosis. Although there is no universally agreed-upon diagnostic algorithm for Cushing syndrome in pregnancy, it has been suggested that women who screen positive for Cushing syndrome using 24-hour urinary free cortisol or midnight cortisol level and have a borderline plasma ACTH proceed with diagnostic testing to differentiate Cushing syndrome from Cushing disease (pituitary adenoma), whereas those with a low ACTH level undergo imaging of the adrenal glands.[129]

Diagnostic tests include the 8-mg dexamethasone suppression test, CRH stimulation test, and inferior petrosal sinus sampling (IPSS). In nonpregnant patients with elevated cortisol levels, a low ACTH level is suggestive of an adrenal etiology while patients with ACTH-secreting tumors have normal or elevated levels of ACTH.[129] In pregnancy, however, adrenal causes of Cushing syndrome are not regularly associated with a decrease in ACTH levels likely due to placental CRH that is not suppressed by hypercortisolism.[129] The 8-mg dexamethasone suppression test may help differentiate an adrenal etiology of Cushing syndrome from Cushing disease in pregnancy. In a study by Lindsay et al., pregnant patients were administered an 8-mg dexamethasone suppression test. All patients with an adrenal cause of Cushing syndrome showed at least an 80% decrease in plasma cortisol, whereas 3/7 patients with Cushing disease did not suppress plasma cortisol.[132] Outside of pregnancy, ACTH-secreting pituitary tumors respond to CRH stimulation while adrenal adenomas and ectopic ACTH-secreting tumors do not.[134] Several studies have demonstrated a rise in plasma cortisol in pregnant patients with Cushing disease during a CRH stimulation test without any adverse effects.[129,131] There is limited research on IPSS in pregnancy likely due to the risk of ionizing radiation. However, the high diagnostic accuracy of IPSS may prove useful considering the challenges with interpreting laboratory values of ACTH and cortisol during pregnancy.[129] With regard to imaging, MRI has been used successfully in pregnancy to localize adenomas in the adrenal glands and pituitary without adverse consequences.[131] Ideally, gadolinium should be used to obtain optimal images. Failure to use this contrast medium will decrease the sensitivity of MRI for detecting pituitary adenomas from 52% to 38%.[135]

Despite the diagnostic challenges, it is imperative to diagnose Cushing syndrome during pregnancy because of the severe maternal and fetal morbidity associated with this condition. Maternal complications include hypertension, preeclampsia, diabetes, wound infection, fractures, cardiac failure, and psychiatric disorders.[132] Fetal complications include spontaneous abortion, preterm birth, intrauterine growth restriction, and stillbirth. In one case series, the live birth rate was 76% (59/78) when no treatment was administered and increased to 89% (50/56) for women who received treatment at an average gestational age of 20 weeks.[132] For women with an adrenal etiology, surgery in the form of unilateral or bilateral adrenalectomy is more successful than medical therapy with an overall fetal loss rate of 12.5% with surgery compared with 20.8% with medical treatment.[127] Patients who decline surgery can be treated with metyrapone, which should be titrated to achieve a 24-hour urinary cortisol level within the normal pregnancy range.[136] Although metyrapone is effective for treating hypercortisolism, it may exacerbate hypertension.[137] Ketoconazole has also demonstrated success in lowering cortisol levels during pregnancy without detrimental effects to the fetus.[138] However, ketoconazole has known teratogenicity in animal models and should be reserved for patients who require emergency treatment and are intolerant of metyrapone.[129] Women with a pituitary adenoma (Cushing disease) can be successfully treated with transsphenoidal surgery and/or medical management.[127]

KEY POINTS

- Screening and diagnostic tests for Cushing syndrome are confounded by the normal physiological changes in ACTH, CRH, and cortisol levels and their respective regulatory pathways.
- Elevated evening plasma cortisol levels and loss of the diurnal cortisol pattern may be helpful in diagnosing Cushing syndrome in pregnancy.

Adrenal Insufficiency. AI (Addison disease) is rare in pregnancy with only about 100 cases reported in the literature.[129] The most common cause in developed countries is autoimmune adrenalitis, whereas destruction of the adrenal glands bilaterally by tuberculosis is more common worldwide.[139] At least seven pregnancies associated with autoimmune polyglandular syndrome type 2 (APS 2) have also been reported.[129] Administration of exogenous corticosteroids is the most common cause of secondary AI, and there have been several reports of maternal adrenal suppression after administration of betamethasone to women at risk of preterm birth.[129,140] The diagnosis of I during pregnancy may be challenging because many of the symptoms—fatigue, vomiting, and depression—are attributed to the pregnancy itself.[139] It is common in pregnancy for serum sodium levels to decrease by up to 5 mEq, but any further hyponatremia should prompt an evaluation for AI.[141] Normal potassium levels should not preclude a workup for AI.[141,142] Pregnant patients may also present with persistent vomiting that may be attributed to hyperemesis gravidarum rather than AI.[141] There should be a low threshold to evaluate patients for AI who have a personal or family history of autoimmune disease and signs or symptoms consistent with the diagnosis.[142]

One of the laboratory tests for diagnosing AI is a plasma cortisol level drawn between 8:00 and 9:00 AM. In the nonstressed general and pregnant populations, an early morning plasma cortisol level <3 μg/dL is indicative of AI in the appropriate clinical context and a value >19 μg/dL effectively excludes the diagnosis.[140] Patients with morning cortisol levels between 3 and 19 μg/dL should undergo low-dose corticotropin stimulation testing.[140] The low-dose corticotropin test has successfully diagnosed AI in pregnant patients using a cortisol threshold of >30 μg/dL.[140] A rise in ACTH to 200 to 2000 pg/mL is also suggestive of AI.[143] The CRH stimulation test, metyrapone stimulation test, and insulin tolerance test are not recommended for use in pregnancy.[129]

Patients with AI should be treated throughout pregnancy. Labor and delivery are stressful events with increased steroid requirements. During pregnancy, patients should receive glucocorticoid supplementation with cortisone acetate 25 to 37.5 mg/day or hydrocortisone 20 to 30 mg/day in two or three daily doses as well as mineralocorticoid replacement with fludrocortisone 0.05 to 0.1 mg/day.[143] For those with severe nausea and vomiting, hydrocortisone 50 mg IM or dexamethasone 1 mg IM should be administered.[143] During labor, "stress-dose steroids" in the form of hydrocortisone 50 mg IV should be administered. Patients who have a vaginal delivery should receive an additional dose of oral cortisone acetate 25 to 50 mg.[143] In the event of cesarean delivery, patients should receive up to 100 mg of hydrocortisone every 6 hours for at least 24 hours with the dose decreased by half on the second day postoperatively followed by a taper to an oral regimen within 3 days.[143]

Changes to the Renin-Angiotensin-Aldosterone System in Pregnancy. The renin-angiotensin system (RAS) adapts to changes in the maternal cardiovascular system during pregnancy. As early as 6 weeks' gestation, systemic vascular resistance decreases and heart rate increases.[144] Pregnancy is associated with a 47% increase in blood volume but a decrease in blood pressure, despite a 20% increase in CO.[144,145] GFR increases 40% to 60% during pregnancy and corresponds to an increase of 20,000 to 30,000 mEq/day of sodium filtration.[146] Overall, total body sodium increases 3 to 4 mEq/day leading to a net gain of 900 to 1000 mEq, and total body potassium increases by 300 to 320 mEq by the end of pregnancy.[146] Progesterone levels increase throughout pregnancy and, by term, circulating concentrations range from 100 to 200 ng/mL. Much of this comes from the placenta, which produces approximately 250 mg of progesterone daily.[147] The effects of progesterone are multiple, including smooth muscle relaxation, which accounts for the generalized decrease in vascular tone, and decreased sodium reabsorption by competitively inhibiting aldosterone receptors in the renal tubule.[148,149] Estrogen levels also increase during pregnancy, which stimulates hepatic synthesis of angiotensinogen and offsets the natriuretic effects of progesterone and elevated GFR.[150] In response to these physiological changes associated with pregnancy, the RAS must adjust to maintain sodium and volume homeostasis.

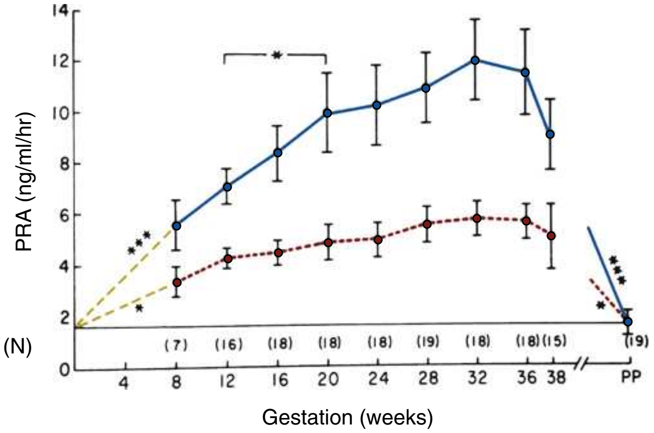

Figure 131.12 Sequential changes in plasma renin activity (PRA) (*blue line*) and in PRA normalized to the postpartum substrate values (*red line*) (mean ± SE) throughout pregnancy. $^{*}P < 0.05$; $^{***}P < 0.001$. (Data from Wilson M, Morganti AA, Zervondakis I et al. Blood pressure, the renin-aldosterone system and sex steroids throughout normal pregnancy. *Am J Med.* 1980;68:97–104.)

Renin is produced predominantly in the kidneys under the influence of estrogen.[129] Plasma renin activity (PRA) increases 7-fold during pregnancy and almost half of this increase is attributed to an increase in renin substrate.[151] By the end of pregnancy, mean plasma renin substrate increases 4-fold[151] (Fig. 131.12). hCG stimulates prorenin secretion by the placenta and ovary.[152] Moreover, studies have shown that, in response to an IV saline infusion and change to an upright posture, pregnant subjects exhibited a change in circulating renin concentrations consistent with that in nonpregnant subjects, but with significantly less sodium excretion. This suggests that estrogen-mediated stimulation of renin synthesis is not sufficient to account for the increased PRA observed in pregnancy, and that a physiological need for increased sodium reabsorption in pregnancy likely also has a role to play.[153] The uteroplacental unit expresses components of the RAS and disruption of the uteroplacental RAS system may contribute to reduced placental blood flow in pregnancies complicated by preeclampsia and intrauterine growth restriction.[154]

Estrogen stimulates hepatic production of angiotensinogen.[150] As estrogen levels rise in pregnancy, so do circulating levels of angiotensinogen. The correlation coefficient of angiotensinogen and estradiol-17β is 0.60 and that for estriol is 0.68.[155] Increased angiotensinogen leads to higher circulating levels of angiotensin II and diminished negative feedback of angiotensin II production.[150] Interestingly, oxidized angiotensinogen has a higher affinity for renin than reduced angiotensinogen.[156] In patients with preeclampsia, the oxidized:reduced angiotensinogen ratio increases above the baseline of 6:4, which may explain in part the pathogenesis of hypertension in this population.[156] Monomeric angiotensinogen (molecular weight [MW] 61.5 kDa) is the predominant form in nonpregnant women. In pregnancy, angiotensinogen can form high MW polymers.[150] Such high MW polymers comprise 4% of circulating angiotensinogen in reproductive age women, 16% in pregnant women, and up to 28% in pregnant women with hypertension.[157] The interaction between renin and

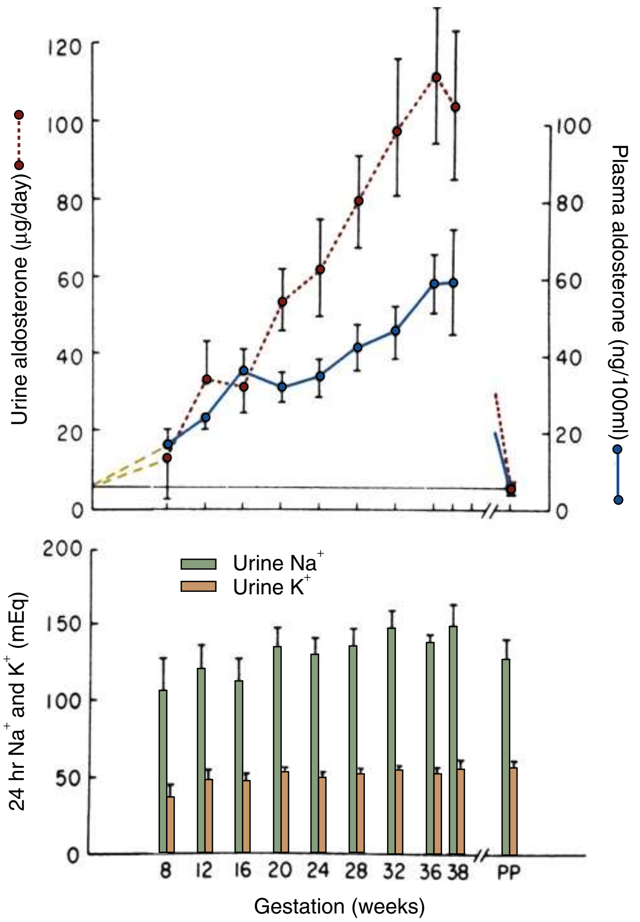

Figure 131.13 Sequential changes throughout pregnancy in plasma aldosterone, urine aldosterone, urinary sodium, and potassium (mean ± SE). (Data from Wilson M, Morganti AA, Zervondakis I et al. Blood pressure, the renin-aldosterone system and sex steroids throughout normal pregnancy. *Am J Med*. 1980;68:97–104.)

angiotensinogen to produce angiotensin I is reduced when angiotensinogen is in its multimeric form.[158] Therefore although circulating angiotensinogen levels are increased in pregnancy, the rate at which angiotensinogen reacts with renin depends both on the redox state of angiotensinogen and on its polymerization with other proteins.

Angiotensin I is converted to angiotensin II by angiotensin-converting enzymes (ACE). ACE activity remains stable throughout pregnancy at approximately 30.6 nmol/min/mL.[159] The isoform, ACE2, converts angiotensin II into angiotensin-(1-7).[160] Levels of ACE2 in plasma are difficult to measure, because it is located primarily within endothelial cells and its catalytic activity in plasma is inhibited.[150] ACE2 is also present in syncytiotrophoblasts and may regulate the release of angiotensin-(1-7) from the placenta into the maternal circulation, thereby contributing to maternal vasodilation.[160] In the third trimester, plasma angiotensin-(1-7) is increased by 34% and plasma angiotensin II by 50% compared to nonpregnant women.[161] In preeclampsia, plasma angiotensin-(1-7) and angiotensin II levels are reduced, but angiotensin II levels are higher than in nonpregnant women and 50% higher than angiotensin-(1-7), suggesting a shift in the balance of hormones that regulate vasodilation in such women.[161]

During pregnancy, elevated progesterone levels cause plasma aldosterone concentrations to increase 5- to 7-fold in the first trimester and up to 10- to 20-fold in the third trimester[162] (Fig. 131.13). Aldosterone is not tightly bound to proteins such that the increase in plasma aldosterone corresponds to an increase in bioactive steroid.[162] Pregnant women demonstrate an amplified response to renin compared with nonpregnant women and have a significant increase in plasma aldosterone concentration:plasma renin concentration (PAC:PRC) ratio.[163] Of note, women with gestational hypertension have lower renin and aldosterone levels than normotensive women, but a 2-fold increase in the PAC:PRC ratio.[163] The amount of aldosterone synthesized is inversely proportional to dietary sodium intake in diets containing 25 to 225 mEq sodium per day, whereas diets containing <10 mEq sodium per day are associated with a further increase in aldosterone secretion.[164] It is estimated that 0.6% to 0.8% of pregnant women have primary hyperaldosteronism, but it is a challenging diagnosis to make due to changes in the RAS during pregnancy and the fact that up to 10% of women develop pregnancy-induced hypertension, which alters RAS signaling.[114] Low renin levels in conjunction with elevated aldosterone, hypokalemia, hypertension, and/or an adrenal mass on imaging suggest primary hyperaldosteronism.[114] Progesterone is a competitive antagonist of aldosterone in the distal convoluted tubule of the kidney. As such, primary hyperaldosteronism can be masked in pregnancy and only become clinically apparent in the postpartum period.[114] Options for the treatment of primary hyperaldosteronism in pregnancy include potassium supplementation, antihypertensive medication, and adrenalectomy if a localized adenoma is identified.[165] Calcium channel blockers are the first choice for antihypertensive therapy. Spironolactone and ACE inhibitors are best avoided due to their potential teratogenic effects on the fetus.[165]

KEY POINTS

- Plasma renin activity increases 7-fold during pregnancy.
- Elevated levels of progesterone cause aldosterone production to increase 5- to 7-fold in the first trimester and 10- to 20-fold in the third trimester.

Adrenal Medulla

Catecholamine Physiology During Pregnancy and Pheochromocytoma. Pheochromocytoma is a rare but potentially fatal neuroendocrine tumor of chromaffin cells of the adrenal medulla with an incidence of 1 in 50,000 pregnancies.[166–168] Chromaffin cells originate from neural crest tissue and are capable of synthesizing, storing, and secreting catecholamines. Neuroendocrine chromaffin cell tumors may also be found in sympathetic ganglia, where they are known as paragangliomas. Approximately 40% of these tumors occur in young women and are associated with pathogenic germline genetic mutations, including multiple endocrine neoplasia type 2 (MEN 2), von Hippel-Lindau syndrome, neurofibromatosis, or succinate dehydrogenase subunit gene mutations.[169] Catecholamines including norepinephrine, epinephrine, and dopamine are produced from tyrosine precursors. They function as neurotransmitters in the sympathetic nervous system and are potent systemic cardiac and vasoactive compounds. Catecholamines play a crucial role in the maternal adaption to pregnancy and especially labor and delivery. Whether circulating catecholamine levels are increased in pregnancy is unclear,[170] even in the setting of preeclampsia.[171] What is clear is that urinary catecholamine levels increase during labor and remain elevated for the first 2 days postpartum.[172]

Only a small fraction of maternal catecholamines cross the placental barrier, with levels in umbilical cord blood less than 10% of that in the maternal circulation.[173] The placenta therefore plays a key role in protecting the fetus from high levels of circulating catecholamines during pregnancy, including in the setting of a pheochromocytoma. It is hypothesized that the high concentrations in the maternal circulation in labor result in high catecholamine levels in the fetus at the time of birth, which may assist the fetus in adapting to early postnatal life.[174]

Maternal mortality from pheochromocytoma has decreased dramatically over the past four decades, due in large part to improve diagnosis. If the diagnosis is made in the antepartum period, maternal mortality rate is 4% compared with 25% in cases diagnosed postpartum.[175] A recent systematic review including 135 cases reported maternal and fetal mortality rates of 8% and 17%, respectively.[176] As in nonpregnant patients, symptoms may be vague or more classic with intermittent paroxysms of hypertension, flushing, tremors, and anxiety due to episodic release of catecholamines (see Chapter 99). The first suspicion of pheochromocytoma may occur with severe hypertension or shock during induction of anesthesia, labor, or surgery. Failure to consider this diagnosis can have serious consequences.[167,176,177] Diagnosis in pregnancy can be particularly challenging since it can be confused with gestational hypertension or preeclampsia. At the onset of hypertension prior to 20 weeks, the absence of proteinuria, edema, or hyperuricemia as well as evidence of episodic signs/symptoms is suggestive of pheochromocytoma.[177] Once the diagnosis is suspected clinically, appropriate biochemical testing should be performed.

Measurement of 24-hour urinary fractionated metanephrines and catecholamines or plasma metanephrines can be used to confirm the diagnosis as for nonpregnant patients[166–168] (see Chapter 99). If there is a low index of suspicion, then urinary fractionated catecholamines and metanephrines would be appropriate. If the index of suspicion is high, plasma fractionated metanephrines should be measured. To decrease the false-positive rate, the plasma should be drawn supine using an indwelling cannula placed at least 30 minutes prior.[178] Elevated urinary or plasma metanephrines or normetanephrines have a 98% to 99% sensitivity but a lower specificity.[167] Antihypertensive medications such as methyldopa and labetalol can interfere with the measurement if a liquid chromatography (LC)-electrochemical detection assay is used, but not if the measurement is performed using LC-MS/MS (liquid chromatography tandem mass spectrometry) technology. Other medications, such as tricyclic antidepressants, can interfere with neuronal norepinephrine uptake resulting in a false-positive result.[177]

Once the diagnosis has been confirmed biochemically, every effort should be made to localize the tumor. Both computed tomography (CT) and MRI are suitable, but MRI is generally preferred in pregnancy because it avoids exposing the fetus to ionizing radiation.[166,179] Once the tumor has been located, surgical removal should be considered. This is best done antenatally in the second trimester or in the postpartum period.[177,178] All such patients should be referred for genetic counseling.

KEY POINTS

- Approximately 40% of patients with a neuroendocrine chromaffin cell tumor (pheochromocytoma or paraganglioma) have an underlying pathogenic germline genetic mutation.
- At the onset of hypertension prior to 20 weeks, the absence of proteinuria, edema, or hyperuricemia as well as evidence of episodic signs/symptoms is suggestive of a pheochromocytoma.
- Measurement of 24-hour urinary fractionated metanephrines and catecholamines or plasma metanephrines can be used to confirm the diagnosis as for nonpregnant patients.

PARATHYROID GLANDS

Regulation of Calcium During Pregnancy

Calcium is actively transferred from the maternal circulation to the fetoplacental unit throughout pregnancy, with 80% transferred in the third trimester and an estimated 300 to 350 mg/day transferred in the final 6 weeks of gestation.[180] In healthy adults, approximately 25% of daily calcium intake is absorbed by the gastrointestinal tract. During pregnancy, the efficiency of intestinal calcium absorption doubles in order to meet the demands of the fetus and palcenta.[180] The expansion of intravascular volume during pregnancy leads to a decrease in serum albumin and hence a decrease in serum total calcium concentration.[180] However, ionized calcium and albumin-corrected serum calcium levels do not change in pregnancy and it is these measurements that should be used to accurately assess maternal calcium status during pregnancy. The increased GFR in pregnancy leads to an increase in urinary calcium excretion.[180] Urinary calcium increases significantly from 4.3 ± 2.2 mmol/day prior to pregnancy to 6.2 ± 3.7 mmol/day in the third trimester.[181] Despite demands of the fetoplacental unit for calcium and the significant rise in urinary calcium excretion, maternal bone mineral density does not change significantly during pregnancy.[181]

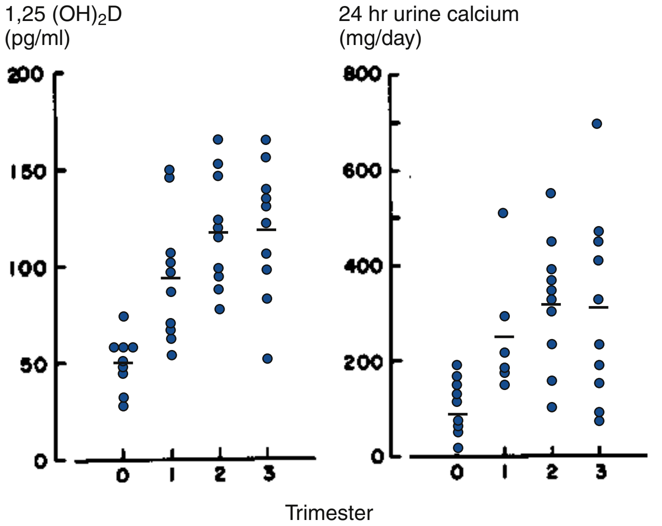

Figure 131.14 Circulating 1,25-dihydroxyvitamin D concentration and 24-hour calcium excretion during pregnancy by trimester. The values for both determinations were significantly increased ($P < 0.05$) during pregnancy (trimesters 1 to 3) when compared with postpartum values (trimester 0). (Data from Gertner JM, Couston DR, Kliger AS, et al. Pregnancy as state of physiologic absorptive hypercalciuria. *Am J Med.* 1986;81:451–456.)

Longitudinal studies of women in North America and Europe have demonstrated that circulating parathyroid hormone (PTH) levels in pregnancy are low-normal in the first trimester (1.3 ± 0.3 pmol/L) and either increase to mid-normal in the second trimester (2.3 ± 0.4 pmol/L) before decreasing to first trimester levels by term or remain suppressed throughout pregnancy.[182,183] Serum 1,25-dihydroxycholecalciferol (DHCC, calcitriol) levels increase 2- to 3-fold in pregnancy[182] (Fig. 131.14). High levels of DHCC explain in part the increase in intestinal absorption of calcium seen during pregnancy, which in turn suppresses the release of PTH.[180] Outside of pregnancy, PTH is the main regulator of renal Cyp27b1 gene expression, which codes for the enzyme 1α-hydroxylase that catalyzes the conversion of vitamin D to its active form, DHCC. Without sufficient PTH, DHCC levels remain low.[180] However, the low- to mid-normal levels of PTH in pregnancy suggest that PTH is not the primary factor responsible for the upregulation of Cyp27b1 expression and the subsequent increase in DHCC[180] (Fig. 131.15). Animal models suggested that the hormones estrogen, PRL, and placental lactogen also contribute to the increase in Cyp27b1 gene expression.[184]

25-Hydroxyvitamin D levels remain unchanged in pregnancy despite greater conversion to DHCC and significant transplacental

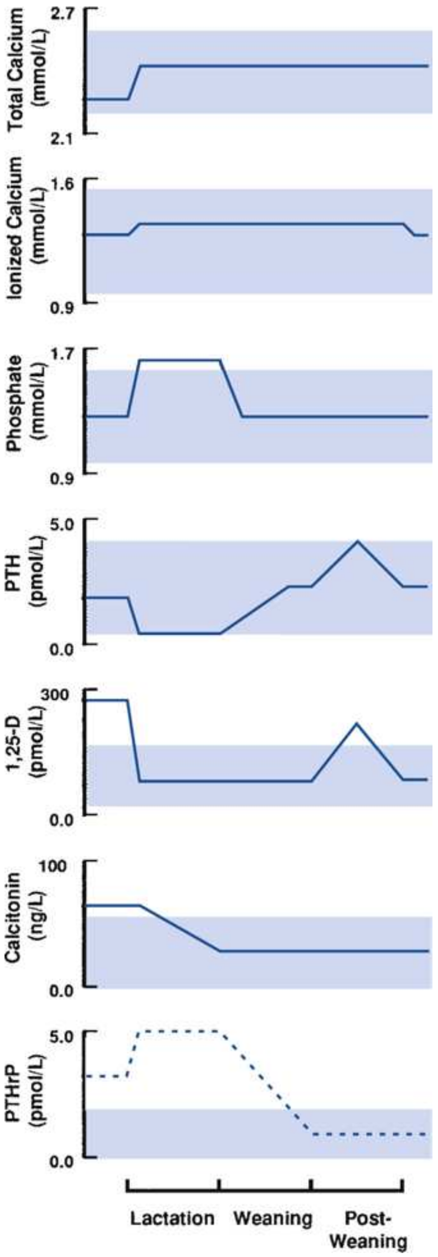

Figure 131.15 **Schematic illustration of the longitudinal changes in calcium, phosphate, and calcitropic hormone levels that occur during human pregnancy.** Normal adult ranges are indicated by the *shaded areas. PTH,* parathyroid hormone; *PTHrP,* parathyroid hormone-related peptide. (Data from Kovacs CS, Kronenberg HM. Maternal-fetal calcium and bone metabolism during pregnancy, puerperium, and lactation. *Endocr Rev.* 1997;18:832–872; Copyright © The Endocrine Society.)

transfer to the fetus.[180] Supplementation with up to 5000 IU of vitamin D during pregnancy does not change maternal serum calcium, albumin-corrected calcium, PTH, or DHCC levels.[180] Interestingly, 25-hydroxyvitamin D levels are approximately 30% lower in twin pregnancies.[185]

High estrogen levels in pregnancy stimulate calcitonin production by the parafollicular cells (C cells) of the thyroid gland. Calcitonin regulates calcium and phosphate levels in the blood by opposing the action of PTH. Circulating calcitonin levels are 3- to 5-fold higher in pregnant than in nonpregnant women.[186] In addition to C cells of the thyroid, the placenta is also a significant source of calcitonin.[187] In women with a history of total thyroidectomy, serum calcitonin levels are undetectable outside of pregnancy, but increase to 16 pg/mL in pregnancy, which exceeds the normal level of 11 pg/mL in nonpregnant women with an intact thyroid gland.[188]

Parathyroid Hormone–Related Protein

Parathyroid hormone–related protein (PTHrP) is produced by the parathyroid glands and placenta and acts to increase circulating calcium levels by promoting osteoclast-induced bone resorption.[189] Other tissues have been proposed as a potential source of PTHrP during pregnancy including the breasts, amnion, decidua, myometrium, umbilical cord, and other fetal tissues, but the evidence is inconclusive.[180] Measuring circulating PTHrP levels can be challenging because it is rapidly degraded. As such, plasma samples for PTHrP measurements should be collected in chilled ethylenediaminetetraacetic acid (EDTA) tubes containing a protease inhibitor such as aprotinin, transported immediately to the laboratory on ice, spun in a refrigerated centrifuge within 15 minutes, separated, and stored frozen until assayed.[190] Improper handling may lead to inaccurately low measured levels of PTHrP.[190] There are three full-length isoforms of PTHrP that result from alternative splicing of a single gene, referred to as $\text{PTHrP}^{1\text{-}139}$, $\text{PTHrP}^{1\text{-}141}$, and $\text{PTHrP}^{1\text{-}173}$.[191] A fourth isoform ($\text{PTHrP}^{1\text{-}36}$) arises from posttranslational processing of any of the three full-length molecules.[191] The most widely used commercial assays measure $\text{PTHrP}^{1\text{-}86}$, which will detect all three full-length isoforms but not $\text{PTHrP}^{1\text{-}36}$.[180] Despite these technical challenges, PTHrP levels increase during pregnancy from a mean of 0.8 ± 0.1 pmol/L in the first trimester to 2.0 ± 0.2 pmol/L at term.[182] Interestingly, this increase is significantly blunted in patients with preeclampsia.[192] Elevated levels of estradiol promote PTHrP production through a direct effect on gene transcription.[193]

Vitamin D Deficiency

The optimal level of 25-hydroxyvitamin D in pregnancy is unknown. The observed decrease in PTH and increase in DHCC appear to be programmed responses to pregnancy and not secondary to 25-hydroxyvitamin D deficiency.[180] Indeed, vitamin D deficiency does not decrease intestinal calcium absorption until the serum 25-hydroxyvitamin D concentration falls below 10 nM.[194] This is because calcium absorption is regulated by DHCC and not 25-hydroxyvitamin D, and the secondary hyperparathyroidism of vitamin D deficiency stimulates renal CYP27b1 gene expression to increase DHCC.[194] Dawodu et al. investigated women with vitamin D deficiency (with a mean baseline 25-hydroxyvitamin D level of 20.5 nM) who were randomized to receive either 400 IU, 2000 IU, or 4000 IU of vitamin D daily throughout pregnancy. At delivery, circulating 25-hydroxyvitamin D levels were 40 nM, 65 nM, and 90 nM, respectively, although no differences were noted in maternal serum calcium or birth weight.[195] There are conflicting data regarding vitamin D deficiency and preeclampsia.[180] Studies have not demonstrated a consistent difference in cord blood calcium or phosphorus, PTH, or birth weight in vitamin D-supplemented mothers compared with placebo-supplemented mothers.[180]

Hypercalcemia

Primary hyperparathyroidism occurs in approximately 0.03% of pregnancies.[196] Symptoms of the resulting hypercalcemia include fatigue, nausea, and constipation, which can be attributed to pregnancy.[180] Severe hypercalcemia can present as hyperemesis gravidarum, acute pancreatitis, renal stones, or recurrent urinary tract infections.[197] Due to the dilutional decrease in calcium and albumin levels along with the reduction in PTH production, pathologic hypercalcemia can be masked in pregnancy.[180] A diagnosis of primary hyperparathyroidism can be made with an elevated ionized or albumin-corrected calcium level in conjunction with a nonsuppressed PTH level.[180] The hypercalcemia caused by primary hyperparathyroidism may be exacerbated by pregnancy because both conditions increase intestinal absorption of calcium, hypercalciuria, and some, albeit mild, bone resorption.[180] Transfer of excess calcium across the placenta and incorporation into the developing fetal skeleton can reduce the maternal complications of hypercalcemia.[180] After delivery, mothers may develop an acute hypercalcemic crisis.[198] The increase in circulating calcium in patients with hypercalcemia leads to suppression of the fetal parathyroid glands, which predisposes to neonatal hypocalcemic tetany once the prenatal supply of calcium is removed.[198] Primary hyperparathyroidism is not associated with adverse pregnancy events, including miscarriage, pregnancy-induced hypertension, polyhydramnios, and/or large-for-gestational age infants.[196] The recommended treatment for asymptomatic women with primary hyperparathyroidism, regardless of pregnancy status, is parathyroidectomy.[199] The decision of whether to perform surgery antenatally (ideally in the second trimester) or postpartum should be individualized.[180] In addition to primary hyperparathyroidism, other potential causes of hypercalcemia that should be considered include excessive production of PTHrP by the placenta[200] or mammary tissues.[201]

KEY POINTS

- A diagnosis of primary hyperparathyroidism can be made with an elevated ionized or albumin-corrected calcium level in conjunction with a nonsuppressed PTH level.
- The transplacental transfer of calcium to the fetoplacental unit and incorporation of calcium into the developing fetal skeleton serve to decrease the maternal complications of hypercalcemia.

CONCLUSION

A thorough knowledge of the many complex physiologic and endocrine changes of pregnancy is fundamental to ensure a timely diagnosis of the pathologies described in this chapter. Ultimately this will allow for expeditious initiation of treatment and optimal maternal and fetal outcomes.

BACKGROUND

Autoimmune polyglandular syndromes (APSs) are characterized by functional impairment of multiple glands owing to a targeted immune-mediated inflammation and destruction characterized by insidious presentation, circulating autoantibodies, and lymphocytic infiltration into the affected organ, eventually leading to organ failure. Presentation can occur from early infancy to old age, and new components can appear throughout life. There is a huge variation in patterns and frequencies of autoimmunity in affected individuals, and APS tends to aggregate in families, pointing to strong heritability. A number of immune-related genes associate with APS, but environmental factors also play a decisive role.

Endocrine glands are commonly affected, but organ-specific autoimmunity can affect almost any tissue of the body, including skin, liver, muscles, and joints. The combination of multiple insufficiencies was described already in 1908 by Claude and Gourgerot who reported a patient with insufficiencies involving the pancreatic islets, thyroid gland, gonads, adrenal glands, and anterior pituitary.[1] In 1926 Schmidt documented the association between adrenocortical failure and chronic lymphocytic thyroiditis,[2] later extended to type 1 diabetes mellitus (T1DM).[3] In the 1950s autoantibodies were described, the first being those directed against thyroglobulin. Later, important diagnostic biomarkers were described, including autoantibodies directed against thyroid peroxidase,[4] glutamic acid decarboxylase-65,[5] and 21-hydroxylase,[6] all tissue-specific enzymes with key functions in the affected organs.

Scrutiny of a large case series led to subclassification of polyglandular syndromes in 1980, when Neufeld and Blizzard defined three types of APS based on clinical features[7] (Table 132.1). APS type 1 (APS-1) was characterized by the combination of Addison disease, hypoparathyroidism, and chronic mucocutaneous candidiasis and showed autosomal recessive inheritance. APS type 2 (APS-2) was coined for Addison disease combined with autoimmune thyroid disease and/or T1DM, whereas in APS type 3 (APS-3) autoimmune thyroid disease was the defining component in combination with other organ-specific insufficiencies, including T1DM, pernicious anemia, and alopecia. We have now come to appreciate that APS can be broadly separated into monogenic forms, such as APS-1, immune dysregulation polyendocrinopathy enteropathy X-linked (IPEX), and others to be described in this chapter, and APS-2, which includes the other combinations.

KEY POINTS

- Autoimmune polyglandular syndromes are defined as conditions with more than one endocrinopathy in an individual. These conditions tend to aggregate in families, pointing to strong heritability, and can be broadly separated into monogenic forms (e.g., autoimmune polyglandular syndrome type 1 and immune dysregulation polyendocrinopathy enteropathy X-linked) and those where several genes are involved (autoimmune polyglandular syndrome type 2).

THE BASIS OF AUTOIMMUNE DISEASE

This section gives a brief synopsis of the normal immune response, the mechanisms underlying tolerance to self, and the causes of autoimmunity; more comprehensive reviews can be found elsewhere.[8-10]

TABLE 132.1 Classification of the Main Autoimmune Polyendocrine Syndromes

	Autoimmune Polyglandular Syndrome Type 1	Autoimmune Polyglandular Syndrome Type 2	Immune Dysregulation Polyendocrinopathy Enteropathy X-Linked
Main components	Chronic mucocutaneous candidiasis, primary adrenal insufficiency, hypoparathyroidism	Primary adrenal insufficiency, autoimmune thyroid disease, T1DM	Autoimmune enteropathy neonatal T1DM, eczema
Other associated manifestations	Primary ovarian insufficiency, autoimmune thyroid disease, T1DM Gastritis, enteritis with malabsorption, hepatitis, pancreatitis, pneumonitis, nephritis Vitiligo, alopecia, nail dystrophy, enamel hypoplasia, keratitis, retinitis	Autoimmune gastritis, alopecia, vitiligo, celiac disease, primary ovarian insufficiency	Autoimmune thyroid disease, hemolytic anemia, thrombocytopenia, nephritis
Prevalence	1:100,000	1:100	1:1,000,000
Typical age of onset	Childhood, adolescence	Adolescence to adulthood	Infancy
Treatment	Replacement of hormones, antifungal therapy, immunosuppressive therapy for hepatitis, malabsorption, nephritis, pneumonitis, and keratitis	Replacement of hormones	Replacement of hormones, bone marrow transplantation
Complications and mortality	Adrenal and hypocalcemic crises, malignancies in mouth and esophagus	Adrenal crises, diabetic complications	Infections
Genes and inheritance	*AIRE*, autosomal recessive and dominant	Polygenic, MHC, and others	*FOXP3*, X-linked
Immune phenotype	Autoantibodies against interferon omega and alpha (>95%), and organ-specific intracellular proteins	Autoantibodies against 21-hydroxylase, GAD-65, IA-2, TSH receptor, and thyroid peroxidase	Autoantibodies against GAD-65, villin, hormonin, interferon omega, and nuclear receptors, lymphocytosis, eosinophilia, overproduction of cytokines, elevated IgE level

AIRE, Autoimmune regulator; *APS-1*, autoimmune polyglandular syndrome type 1; *APS-2*, autoimmune polyglandular syndrome type 2; *FOXP3*, forkhead box P3; *GAD*, glutamic acid decarboxylase-65; *IA-2*, protein tyrosine phosphatase-like protein islet antigen-512; *IPEX*, immune dysregulation polyendocrinopathy enteropathy X-linked; *MHC*, major histocompatibility complex; *T1DM,* type 1 diabetes mellitus; *TSH*, thyroid-stimulating hormone.

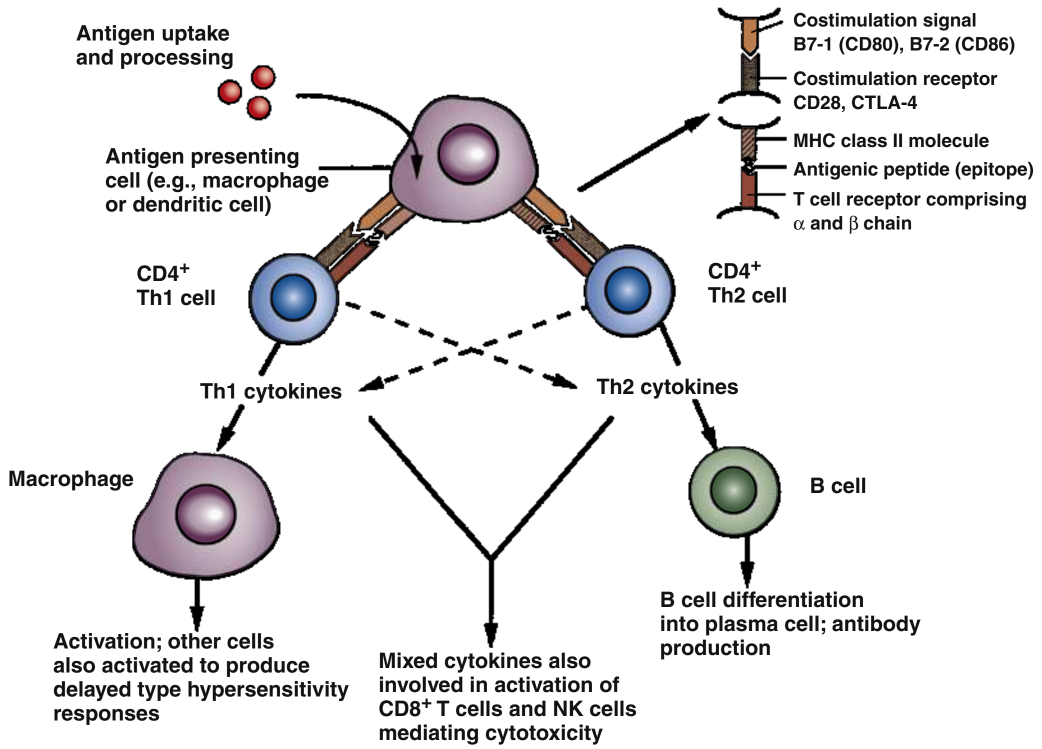
The Normal Immune Response

There are two broad types of immune response: innate and adaptive. The innate response is nonspecific and allows the body to respond immediately to a wide range of pathogens through pattern recognition receptors and complement activation. The adaptive response is directed against specific antigens on a pathogen by clonal expansion of T and B lymphocytes. This response is slower, but has the capacity for long-term memory of the antigen through the generation of memory lymphocytes. Although the adaptive response is primarily directed against pathogens, occasional errors may result in a response against self-antigens and cause autoimmune disease.

The first step in an adaptive immune response involves presentation of the antigen by an antigen-presenting cell (APC), such as a dendritic cell or macrophage, to a CD4$^+$ T helper (Th) cell, which recognizes the antigen by means of a T-cell receptor (TCR) with unique antigen specificity (Fig. 132.1). TCR diversity is generated by complex gene recombination from a large number of potential segments. APCs take up antigen by simple phagocytosis or via specific surface receptors and process them into peptides of eight to 12 amino acids; these antigenic epitopes bind to major histocompatibility complex (MHC) class II molecules expressed constitutively by the APC. The MHC (termed HLA in humans) is a complex of genes that have fundamental immunologic importance because they encode polymorphic molecules capable of binding a large range of T-cell epitopes, and the particular MHC class II alleles that are inherited determine which epitopes an APC can present to a T-cell.

Many other molecules are involved in antigen presentation and act as stabilizers, signal transducers, or second signals (Fig. 132.2). Interaction of a number of adhesion molecule ligands and receptors, such as intercellular adhesion molecule-1 (ICAM-1, CD54)/lymphocyte function-associated antigen-1 (LFA-1, CD11a/CD18) and LFA-3 (CD58)/CD2, allows initial binding of the T-cell to an APC. CD4 binds to a nonpolymorphic region on the MHC molecule to stabilize the complex formed with the TCR. CD3 is expressed by all T-cells and serves to initiate the intercellular events after TCR ligation. Finally, second signals determine whether the T-cell response proceeds, or is terminated because of the absence of an essential costimulator or the presence of an inhibitory signal. The best defined costimulatory pathway involves the binding of CD80 or CD86 on the APC with CD28 on the T-cell, which results in a stimulatory second signal. In contrast, TCR engagement (signal 1) without CD28 engagement (signal 2) results in T-cell anergy, a process in which the T-cell is inactivated by an antigen; it remains alive, but is no longer responsive. Cytotoxic T lymphocyte antigen type-4 (CTLA-4, CD152) is expressed by activated T-cells and can outcompete CD28 for binding CD80 or CD86, resulting in an inhibitory second signal and T-cell anergy. Another important regulatory checkpoint is via programmed death protein 1 (PD1, CD279) expressed on T-cells; engagement with the PD-ligand 1 (CD274) expressed by APCs and other cells also results in T-cell inactivation through anergy. Which of these signal pathways are engaged depends on the maturity of the T-cell and the type of APC involved, and this helps determine the exact outcome from antigen presentation.

Activated CD4$^+$ T-cells can follow one of two main functional pathways, Th1 or Th2, which are characterized by their pattern of cytokine production (Fig 132.1). Th1 cells mediate delayed-type hypersensitivity



Antigen uptake and processing
Antigen presenting cell (e.g., macrophage or dendritic cell)
Costimulation signal B7-1 (CD80), B7-2 (CD86)
Costimulation receptor CD28, CTLA-4
MHC class II molecule
Antigenic peptide (epitope)
T cell receptor comprising α and β chain
CD4+ Th1 cell
CD4+ Th2 cell
Th1 cytokines
Th2 cytokines
Macrophage
B cell
Activation; other cells also activated to produce delayed type hypersensitivity responses
Mixed cytokines also involved in activation of CD8+ T cells and NK cells mediating cytotoxicity
B cell differentiation into plasma cell; antibody production

responses through their interaction with macrophages and cytotoxic CD8$^+$ T-cells. The latter are activated through TCR binding to epitopes synthesized within the target cell and presented by MHC class I molecules. CD8$^+$ T-cell–mediated cytotoxicity is typically directed against viral or malignancy-related antigens expressed by target cells, but can also be involved in the destruction of healthy cells in autoimmune diseases. Th2 cells promote antibody production by B-cells. Th1 and Th2 responses are mutually inhibitory through the action of their respective cytokines. TCR affinity and ligand density, the nature of the APC, and cytokines like interleukin (IL)-4 and IL-12 determine which pathway is followed. Although this Th1/Th2 paradigm has been useful, it is too simplistic, and many Th cells cannot be classified by such a simple dichotomy. For instance, the Th17 subset produces IL-17, which helps initiate and mediate inflammatory responses, including autoimmunity. IL-23 derived from dendritic cells and macrophages is critical to the activation of Th17 cells, as well as having additional proinflammatory effects of its own.[11] Another subpopulation of T-cells has an important role in controlling and terminating the immune response. The first such regulatory T-cell (Treg) subset to be described is generated in the thymus and is critical to prevention of autoimmunity. These "natural," or thymic, Tregs are CD4$^+$ CD25$^+$ and also express the transcription factor forkhead box P3 (Foxp3), as well as CTLA-4. A second, induced Treg subset differentiates in the periphery in response to specific antigen and is involved in mucosal immunity and also in controlling autoimmune responses. Other Treg populations have been reported, including a FoxP3$^-$ subset and a CD8$^+$ subset.[9]

B-cells produce antibodies after differentiation into plasma cells, a process that is regulated by Th2 cytokines and CD40/CD40 ligand interaction with a helper T-cell. In the secondary lymphoid organs, the follicular helper subset of CD4$^+$ T-cells primes B-cells, and this pathway is critical to germinal center formation and antibody affinity maturation. Up to 10^7 different antibody specificities can be generated in humans by recombination and somatic mutation of the immunoglobulin genes, an even greater diversity than that seen in TCRs. During an immune response, these processes ensure selection of the most appropriate antibodies so that IgG molecules with the highest affinity for antigen are produced. Antibodies generally recognize conformational rather than linear epitopes on intact antigen. As well as antibody production, B-cells are important APCs because they are able to take up specific antigens via surface-bound immunoglobulin and enter into cognate recognition of appropriate T-cells. This type of antigen presentation may be important in diversifying the T-cell response and may also help prevent autoimmunity, as an autoantibody-producing B-cell will not become activated unless there also an autoantigen-specific Th cell present.

Natural killer cells are the third type of lymphocyte; they do not express TCRs or surface immunoglobulins, and their function is to destroy cells with altered surface antigens, for example, tumor cells. Through expression of CD16, a receptor for the Fc region of immunoglobulins, natural killer cells can also kill target cells that have antibody bound to cell surface antigens, a process called antibody-dependent cell-mediated cytotoxicity. Such cytotoxicity can be an effector mechanisms in the destruction of autoantibody-coated tissue cells in autoimmunity.

Self-Tolerance

The adaptive immune system provides a specific way of responding to a pathogen that is retained through memory T- and B-cells to allow a rapid response in future to the same pathogen. At the same time, the immune system must not respond to the body's own autoantigens, which is achieved through a series of self-tolerance mechanisms discussed later. The trade-off for the immune system's astonishing ability to respond to a universe of exogenous antigens is that these self-tolerance mechanisms may occasionally fail, resulting in autoimmune disease.

Central Tolerance

During T-cell maturation, the thymus is responsible for positively selecting T-cells to constitute the immune repertoire and negatively selecting and removing autoreactive T-cells.[12] Positive selection depends on immature T-cell recognition of MHC molecules expressed by thymic cortical epithelial cells. The T-cells then become either CD4$^+$ or CD8$^+$, depending on which MHC class they bind most strongly to, whereas failure to bind leads to apoptosis. As the T-cells mature, they move to the thymic medulla, where they encounter medullary epithelial cells and dendritic cells that, remarkably, can express and present an array of self-antigens that are otherwise tissue-specific. High-affinity TCR engagement at this stage results in apoptosis, and hence the elimination of self-reactive T-cells; self-reactive T-cells with lower TCR affinity differentiate into natural Treg cells. This process cannot operate for autoantigens, which are exclusively expressed in the periphery or appear later in development, nor is it always successful. Thus, the self-reactive T-cell repertoire is thinned out rather than eliminated. Thymic expression of a cluster of self-antigens is controlled by the transcription factor autoimmune regulator (AIRE). The critical part played by AIRE in self-tolerance is demonstrated by the effect of mutations in the *AIRE* gene, which result in APS-1, as discussed in detail later.

Peripheral Tolerance

Four broad mechanisms, classed as ignorance, deletion, anergy, and suppression, ensure that the self-reactive T-cells that escape central tolerance are held in check to prevent autoimmunity.[13] The relative importance of these mechanisms varies according to self-antigen.

1. In immunological ignorance, T-cells reactive to certain self-antigens are normally harmless because they cannot physically come into contact with a sequestered autoantigen, or because localized expression of Fas ligand induces apoptosis in potentially auto-aggressive lymphocytes entering the site (also called immunologic privilege). Such Fas ligand expression is seen in Sertoli cells, corneal cells, and the placental trophoblast.
2. Immature dendritic cells can take up self-antigens and present these to naïve T-cells in lymph nodes, resulting in either their deletion or conversion to Tregs. Lymph node stromal cells may play a similar regulatory role.
3. Anergy can occur when self-antigen presentation occurs without a costimulatory second signal. Aberrant expression of MHC class II molecules in the absence of costimulatory expression occurs in tissue cells in response to cytokines released during an inflammatory response, thereby preventing the initiation of an autoreactive T-cell response. Anergy mediated through the activation of CTLA-4 or PD1 pathways is also important, as shown by the development of autoimmunity in some patients with cancer who are treated with inhibitors of these immune checkpoints (see later).
4. Active T-cell-mediated suppression of self-reactivity was first clearly demonstrated in animal studies: autoimmune thyroiditis or diabetes can be induced in some strains of mice and rats by experimental T-cell depletion and can be prevented by the transfer of T-cells from healthy animals. Characterization of the T-cell subset responsible for suppressing these autoimmune responses led to the discovery of Tregs. The importance of these cells in human self-tolerance is shown by loss-of-function mutations in the *FOXP3* gene expressed by Tregs, which results in multiple autoimmune diseases called IPEX, discussed later. Tregs exert their suppressive effects through several pathways, including cytokines (especially transforming growth factor-β, IL-10, and IL-35), cytolysis, metabolic effects, and modulation of dendritic cells.

This overview has focused on T-cell tolerance, as these cells lie at the heart of the immune response and have been the most studied in the context of autoimmunity, but B-cell self-tolerance is also important. The B-cell repertoire is controlled by both central tolerance during development in the bone marrow and peripheral tolerance in the lymph nodes, involving both deletion and anergy. Self-reactive B-cells that evade tolerance will not initiate an autoreactive response unless the tolerance of corresponding self-reactive CD4$^+$ T-cells fails. Defects in B-cell tolerance may underlie some of the features of autoimmune diseases like systemic lupus erythematosus (SLE).

KEY POINTS

- Autoimmune disease arises when the normal mechanisms to maintain tolerance to self-antigens fail. This failure may be either at the level of central (or thymic) tolerance or peripheral tolerance, in which a combination of T-cell ignorance, deletion, anergy, and suppression normally ensures that any autoreactive T-cells that escape central tolerance are held in check to prevent autoimmunity.

Pathogenesis of Autoimmune Disease

There are over 100 autoimmune diseases that together affect 5% to 10% of the population, and each one is the result of a breakdown of in normal self-tolerance. Loss of tolerance is complex, with a wide variety of both genetic and environmental factors impinging adversely on one or more of the tolerance mechanisms discussed earlier. Some autoimmune diseases show a rising incidence, which is thought to be the result of changes in environmental factors. Many of the genes that are associated with susceptibility to autoimmunity control antigen presentation (MHC genes) or immunoregulatory responses, although some genes are tissue-specific and determine the site of autoimmune disease, for instance through altering expression of specific autoantigens. Around two thirds of the susceptibility loci so far identified are common to multiple autoimmune diseases.[14] The clustering of diseases in APS-2, discussed later, is primarily the result of this sharing of genetic predisposition. Genetic and environmental factors also act together with the existential factors of age, sex, and parity. Growing older results in lowered T- and B-cell production and function, as well as an increased chance of encountering etiological environmental factors. Immune responses including autoimmunity are generally stronger in women than men because of the effects of sex hormones and immune response genes on the X chromosome, and pregnancy causes a variety of altered immune responses to tolerate the fetal semiallograft. As a result, most autoimmune diseases typically occur in adulthood and are more common in women. Particular genetic and environmental factors explain exceptions to this, such as T1DM.

A feature of most autoimmune diseases is a long prodromal phase before disease becomes evident, and there may be intermittent periods of spontaneous remission, indicating that loss of self-tolerance is not absolute, at least initially. This prodromal phase can often be identified by the presence of circulating autoantibodies in the absence of clinical features, although there may be biochemical evidence of tissue injury, for example, elevation in thyroid-stimulating hormone (TSH) levels in subclinical autoimmune hypothyroidism despite normal thyroid hormone levels. The possibility of an initial phase of reversibility has led to attempts to improve prediction of those at risk and the development of new treatments for some severe autoimmune diseases using monoclonal antibodies targeting key cytokines and cells, aimed at tipping the balance back to normal self-tolerance.

Most autoimmune diseases are caused by tissue-specific destruction, using the same pathways that are involved in the normal immune response to a pathogen. Once an autoimmune response is initiated, aberrant expression of chemokines and adhesion molecules help localize autoreactive lymphocytes to the target organ, and tissue injury occurs through T-cell–mediated cytotoxicity and cytokine release, ultimately leading to atrophy and fibrosis. In multisystem diseases like SLE, immune complex deposition with complement fixation is a particularly important pathway of autoimmune damage. Autoantibody production may also contribute to tissue injury through complement activation or antibody-dependent cell-mediated cytotoxicity, although the absence of tissue injury in neonates born to women with autoantibodies that are placentally transferred indicates that any such role lies in exacerbating rather than initiating an autoimmune disease. In normal circumstances many autoantigens are inaccessible to autoantibodies; such sequestration only disappears once inflammation begins. The exception is a small group of primarily autoantibody-mediated diseases like Graves disease and myasthenia gravis, in which the functional effects of the antibody on an accessible receptor (the TSH receptor or the acetylcholine receptor, respectively) can be seen in neonates born to affected mothers as well.

KEY POINTS

- Genetic and environmental factors, together with aging, sex, and parity, contribute to the loss of self-tolerance in autoimmunity. Sharing of genetic factors involved in susceptibility to such diseases leads to clustering within an individual and within families. In most autoimmune disorders there is a long prodromal phase before disease becomes evident, which can often be identified by the presence of circulating autoantibodies in the absence of clinical features and sometimes by biochemical evidence of subclinical tissue injury.

AUTOIMMUNE POLYGLANDULAR SYNDROME TYPE 1

Definition

APS-1, also called autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) (OMIM 240300), is a monogenic autosomal recessive disease characterized by early-onset organ-specific autoimmunity.[15,16] Traditionally the diagnosis was made when two of the three main components—primary adrenocortical insufficiency, hypoparathyroidism, and chronic mucocutaneous candidiasis—were present (diagnostic dyad), or one component was present and there was a sibling with APS-1. After identification of the causative gene, *AIRE*,[17,18] the diagnosis can be made by uncovering pathogenic variants. Using sequencing in diagnostics has revealed that the phenotypic variation is much wider than earlier appreciated.[19]

Inheritance is usually autosomal recessive, requiring two disease-causing variants in the gene. However, autosomal dominant inheritance has been reported.[20,21] In these cases, one mutation is sufficient to cause the syndrome, often with later onset and milder phenotype without the diagnostic dyad.

Pathogenesis

AIRE was named before its function had been studied, but the name turned out to be fitting. AIRE is mainly expressed in thymic medullary epithelial cells and has two major functions. It enhances the expression of tissue-specific proteins, and so displays such peptides on MHC class II for developing T-cells. T-cells that recognize self-peptides will either undergo apoptosis or become Tregs that have an important role in harnessing autoreactivity.[22] When AIRE is missing or functions abnormally because of a mutation, autoreactive T-cells can escape into the periphery and cause autoimmunity later in life. AIRE may also have a similar role in lymph nodes,[23] creating another layer of immunological tolerance.

Currently more than 130 different mutations are known, spread throughout the gene[24] (Fig. 132.3). The most common is the so-called Finnish major mutation, a nonsense variant p.R258X (c.769C>T) leading to premature mRNA decay and no protein expression. It is the most common mutation worldwide and is especially prevalent in the Finnish, Russian, and Polish populations. The 13-bp deletion in exon 8 (p.L323SfxX51, c.967–979del13) is more common in Norway, the British Isles, and North America. Founder mutations occur among Persian Jews, Sardinians, and Sicilians. Most patients have two disease-causing mutations, and carriers with one mutation do not have excessive autoimmunity as far as we know. However, some mutations can cause APS-1 in heterozygosity by a dominant negative effect, causing the disease to be transmitted in a dominant fashion.[20,21] Intriguingly, these mutation are located in certain domains of AIRE, particularly in the first PHD-zinc finger.

Mutation carriers develop a number of autoantibodies that can be broadly divided into cytokine- and organ-specific autoantibodies. Autoantibodies against type 1 interferons including interferon-omega and several interferon-alpha species are present in almost all patients and develop very early in life, even before 1 year of age.[25,26] Thus, detection of such antibodies is an effective screening tool to diagnose patients. The majority of patients also display autoantibodies against IL-22, IL-17A, and IL-17F.[27,28] A correlation between these autoantibodies and chronic mucocutaneous candidiasis has been reported, but is uncertain because most patients have had periods with chronic candidiasis, and the frequency of anti-IL-22 is more than 90%. Another group of affected enzymes are neurotransmitter-synthesizing enzymes such as glutamic acid decarboxylase-65, tyrosine hydroxylase, tryptophan hydroxylase, and aromatic L-amino acid decarboxylase (DOPA decarboxylase), which are associated with alopecia, enteritis, and hepatitis, respectively (Table 132.2). NACHT leucine-rich-repeat protein 5 (NALP5) is highly expressed in parathyroid cells and is associated with hypoparathyroidism.[29] The mouse ortholog, called maternal antigen that embryos require (MATER) is also expressed in ovaries and is associated with premature ovarian insufficiency. Fig. 132.3 The autoimmune regulator (AIRE) protein with its functional domains and reported mutations. AIRE harbors four major subdomains: the homogeneously staining region or caspase recruitment domain/homodimerisation domain (CARD/HSR, amino acids 1–105); the SAND domain (for Sp100, AIRE-1, NucP41/75 or NucP41/75, DEAF-1, amino acids 181–280); and two plant homeodomain (PHD)–type zinc fingers (amino acids 296–343 and 434–475). In addition, the AIRE protein contains four LXXLL domains that are found on coactivators of nuclear receptors (amino acids 7–11, 63–67, 414–418, 516–520) and a nuclear localization signal (amino acids 100–189). AIRE acts in a multiprotein complex and was early recognized as a transcription factor, as it localizes to the cell nucleus. The functions of the different domains of AIRE are shown in the boxes. Founder and common mutations are shown in blue, including c.254A>G (Persian Jewish), c.415C>T (Sicilian), c.607C>T (Sardinian), c.769C>T (Finnish), and c.967-979del13 (Norwegian, British, North American). Dominant negative mutations are shown in red. Gross deletions and gross insertions are not included. (Slightly modified from Bruserud O, Oftedal BE, Wolff AB, et al. AIRE-mutations and autoimmune disease. *Curr Opin Immunol.* 2016;43:8–15.)

channel regulator expressed in the terminal alveoli, is associated with bronchiolitis,[30] as is BPIFB1, a protein involved in innate immunity in the airways.[31] Another member of this protein family, BPIFA2, was recently found to be associated with dry mouth and "Sjøgren-like" symptoms in patients with APS-1.[32] Reactivity to surface receptors is also seen, such as the calcium-sensing receptor, which can result in hypoparathyroidism.[33]

KEY POINTS

- Autoimmune polyglandular syndrome type 1 is defined by the presence of two of the three manifestations—adrenal insufficiency, chronic candidiasis, and hypoparathyroidism—or the presence of a disease-causing variant in the autoimmune regulator gene. Interferon type I autoantibodies are a highly specific diagnostic biomarker. Inheritance is autosomal recessive or dominant; the latter forms are generally milder, with similarities to autoimmune polyglandular syndrome type 2.

Clinical Features

Typically, APS-1 manifests itself in childhood with chronic mucocutaneous candidiasis followed by hypoparathyroidism and adrenal insufficiency.[34] However, in recent years we have come to appreciate that the presentation is highly variable, even within the same family.[19,35,36] A major explanation is that screening for interferon autoantibodies and the development of next-generation sequencing have allowed diagnosis of patients with atypical disease, patients with late debut disease, and sometimes patients who are lacking the diagnostic dyad.

The prevalence of APS-1 is approximately 1:100,000 in most countries, and epidemiological surveys are scarce. In some populations with founder mutations, higher prevalence is observed, including Finns (1:25,000), Sardinians (1:14,000), and Persian Jews (1:9000). The natural history is highly variable, with between one to over 20 different components in an individual patient. Some features, such as chronic diarrhea, keratitis, autoimmune hepatitis, periodic rash with fever, or

TABLE 132.2 Characteristics of Autoimmune Polyendocrine Syndrome Type 1

Components	Clinical Features	Diagnosis	Key Autoantigens
Chronic mucocutaneous candidiasis	Chronic recurrent candidiasis of mucous membranes, skin and nails	Detection of *Candida* in culture	Interleukin-22
Primary adrenal insufficiency	Hyperpigmentation, salt craving, hyponatremia, hyperkalemia	Low cortisol, elevated ACTH, failed synacthen testing	21-hydroxylase
Primary ovarian insufficiency	Early menopause (<40 years of age), primary amenorrhea	Elevated FSH and LH, low estrogen	Side-chain cleavage enzyme, 17-hydroxylase, NALP-5
Prostatitis	Perineal pain, discharge	Clinical signs, imaging	Transglutaminase-4
Autoimmune thyroid disease	Hypothyroidism (Graves disease extremely rare)	Elevated TSH, low free thyroxine	Thyroid peroxidase
Type 1 diabetes mellitus	Hyperglycemia, lack of insulin	Fasting serum glucose >7 mmol/L, HbA1c >48 mmol/mol	IA-2
Hypophysitis	Secondary adrenal insufficiency and hypothyroidism; hypogonadotropic hypogonadism, growth failure	Decreased pituitary hormones	Tudor domain-containing protein 6
Gastritis	Achlorhydria, vitamin B12 deficiency, iron deficiency	Low vitamin B_{12}, abnormal FBC and iron levels	Intrinsic factor and parietal cell (H^+/K^+-ATPase)
Enteritis with malabsorption	Chronic steatorrhea, obstipation	Increased fat in stools	Tryptophan hydroxylase
Autoimmune hepatitis	Jaundice	Abnormal liver function tests	CYP1A2 and AADC
Exocrine pancreatitis	Chronic steatorrhea, malabsorption	Decreased fecal elastase	
Pneumonitis	Dyspnea	Peribronchiolar infiltrates on computed tomography, respiratory failure	KCNRG and BPIFB2
Nephritis	Reduced kidney function, proteinuria	Interstitial nephritis	Aquaporin-2, HOXB7, NFAT5
Vitiligo	Ranging from patchy to total nonsegmental distribution	Clinical signs	Tyrosinase, tyrosinase-related proteins, AADC, transcription factors (SOX9, SOX10)
Alopecia	Ranging from patchy to total or universal distribution	Clinical signs	Tyrosine hydroxylase
Enamel dysplasia	Ranging from small pits on some teeth to lack of enamel	Clinical signs	Protein phosphatase 4
Retinitis	Reduced vision	Ophthalmological signs of retinitis	Interphotoreceptor retinoid-binding protein
Keratitis	Extreme light sensitivity	Clinical signs	
Nail dystrophy		Clinical signs	
Skeletal metaplasia		Clinical signs	

AADC, Aromatic L-amino acid decarboxylase; *ACTH,* adrenocorticotropic hormone; *CYP1A2*, cytochrome P450 family 1 subfamily A member 2; *BPIFB2*, bactericidal/permeability-increasing fold-containing B1FSH protein, follicle-stimulating hormone; *FBC,* full blood count; *FSH,* follicle-stimulating hormone; *HbA1c* , glycated hemoglobin; *HOXB7*, human homeobox B7 transcription factor; *IA-2,* protein tyrosine phosphatase-like protein islet antigen-512; *KCNRG*, putative potassium channel regulator; *LH*, luteinizing hormone; *MHC*, major histocompatibility complex; *NALP-5*, NACHT, LRR and PYD domains-containing protein 5; *NFAT5*, nuclear factor of activated T-cell 5 transcription, *SOX*, SRY-related HMG-box; *TSH,* thyroid-stimulating hormone.

severe constipation, may dominate the initial picture before any of the major components develop.[36] Thus, a low threshold for autoantibody testing or sequencing of *AIRE* is recommended.

Chronic Mucocutaneous Candidiasis

Chronic superficial infection with *Candida albicans* is usually the first of the major components of APS-1 to appear.[34] It affects mucous membranes, skin, and nails, but never causes deep, systemic *Candida* infections. In mild forms only angular cheilitis is seen, but in more severe cases the whole mouth is involved, with white or grey plaques of yeast and hyperkeratosis. In the atrophic form the mucosa is erythematous with leukoplakic areas or nodules that may develop into squamous cell carcinomas; this is a significant cause of death, especially if the patient smokes and overuses alcohol.[37,38] Candidiasis may also only be confined to the esophagus, causing problems with swallowing caused by overgrowth or strictures, sometimes requiring dilation. A reddish and watery rash may affect the skin of the hands and face. The fingernails may be affected and females may suffer from genital candidiasis.

The diagnosis is based on the signs and symptoms, as well as culture of *C. albicans*. It is very important to treat oral candidiasis to prevent cancer development, which includes practicing good oral hygiene and refraining from smoking and excessive alcohol. This is also important because the majority of patients develop enamel hypoplasia of the permanent teeth,[19] and many have a mild Sjøgren-like syndrome with reduced saliva production.[32] Infrequent bouts of *Candida* can be effectively treated with azole preparations such as fluconazole and ketoconazole, but with regular use there is a risk of drug resistance. Thus, for recurrent and chronic cases, treatment with nystatin and amphoterizin B in combination is an alternative, with pulsed prophylaxis with either of these drugs; alternatively, chlorhexidine mouthwash can be applied. A biopsy should be taken if mucositis with an ulceration fails to respond to treatment within 2 weeks. Angular cheilitis can be treated with azole, chlorhexidine, or amorolfine creams. *Candida* esophagitis usually heals with the discussed treatment regimen in 1 to 2 weeks. If not, endoscopy should be considered. Female genital candidal infection usually responds to a short course of vaginal fluconazole.

Hypoparathyroidism

Hypoparathyroidism is the second most common major manifestation and can be the first endocrine component. The combination of hypocalcaemia, hyperphosphatemia with normal or low parathyroid hormone, and normal plasma creatinine is diagnostic. Symptoms of hypocalcaemia may be vague in the beginning, with muscle cramps during infections, intermittent mild paraesthesia, and clumsiness. Frank hypocalcemia, sometimes with seizures, can be triggered by a febrile illness and fasting. APS-1 should be considered in every patient with acquired hypoparathyroidism because it may be the only component in some patients. Half of patients harbor autoantibodies against NALP5,[29] and some also have autoantibodies against the calcium-sensing receptor.[33]

Hypoparathyroidism is treated with vitamin D derivatives, calcium, and magnesium. Alphacalcidol ($T_{½}$ 2 days) and calcitriol ($T_{½}$ 1 day) are recommended because of their relatively short half-lives. Calcium supplementation in divided doses of 100 to 500 mg elementary calcium outside meals is suggested, preferably calcium citrate, as it helps calcium stay in solution in the urine. Likewise, a daily supplement of magnesium and cholecalciferol should be given to avoid deficiencies and to cover other functions of vitamin D. Therapy is aimed at maintaining plasma calcium in the lower half or slightly below the normal range (total 2.10–2.30 mmol/L, ionized 1.05–1.15 mmol/L), urinary calcium in the normal range, and plasma magnesium in the upper half of its normal range (0.85–1.00 mmol/L). Hypercalcemia may damage the kidneys, particularly if the patient is not well hydrated. Serum calcium should be checked quarterly and when symptoms indicate hypo- or hypercalcemia.

Patients with hypoparathyroidism and adrenal insufficiency may develop hypercalcemia as a result of sodium deficiency and/or dehydration. Increase in glucocorticoid dose tends to cause hypocalcaemia, and vice versa. Increased calcium intake or additional alphacalcidol or calcitriol may be required if glucocorticoid doses remain high for more than 24 hours.

Adrenal Insufficiency

Adrenocortical insufficiency most commonly appears after mucocutaneous candidiasis and hypoparathyroidism, typically between 5 and 15 years of age, but may appear later. The prevalence in different published cohorts is around 70%.[19,37] The characteristic symptoms are fatigue, salt craving, hypotension, weight loss, and an increased pigmentation of the skin and mucous membranes. Biochemically, symptomatic patients display low basal plasma cortisol, elevated adrenocorticotropic hormone (ACTH), low aldosterone, and elevated plasma renin activity. Hyponatremia is common, sometimes in combination with hyperkalemia. Of note, hypocortisolism and hypoaldosteronism may appear dissociated years apart. Just like in the more common form of autoimmune Addison disease, most patients display autoantibodies against 21-hydroxylase.[6,39] In addition, many APS-1 patients also have antibodies against side-chain cleavage enzyme.[39] Autoantibodies can be present years before biochemical or clinical evidence of adrenal insufficiency and call for intensified follow-up of adrenal function. Adrenal insufficiency should be diagnosed before a potentially fatal adrenal crisis develops.

Replacement therapy with hydrocortisone and fludrocortisone should be individualized to provide optimal well-being and safety in the patient's life situation, including incidents of sickness and stress. All patients should be provided with a steroid acute card; a common European card is available for adults and children. The patient and her/his close family should be equipped with syringes for self-injection of hydrocortisone. Glucocorticoid treatment influences calcium and glucose levels. Thus, treatment of hypoparathyroidism and diabetes mellitus may have to be adjusted. For details, see Chapters 39 and 52.

Gonadal Insufficiency

Primary ovarian insufficiency manifests particularly early, and some patients have primary amenorrhea, with either a complete failure of, or arrested, pubertal development. Others develop premature menopause, with a median age of 16 years.[40] Adrenal insufficiency was more common in APS-1 patients with ovarian insufficiency then those without.[40] The biochemical findings are typically elevated plasma follicle-stimulating hormone and luteinizing hormone and low estrogen levels. Ovarian insufficiency is associated with presence of autoantibodies against side-chain cleavage enzyme and NALP5 and are typically present before clinical symptoms develop.[39] Estrogen replacement should be started at pubertal age, with gradually increasing doses to maintain a normal pace of female development. Periodic gestagen should be added at the appropriate stage. There are reports of cases where pregnancies have occurred even several years after menopause, but patients should be encouraged not to delay plans if they wish to have a child. Storing of ovarian tissue may be an option for future pregnancies.

Testicular insufficiency does occur, albeit more seldom and mostly at an adult age, with a maximum prevalence of approximately 25%, as seen in the Finnish series.[39] The blood-testis barrier may protect the Leydig cells from an autoimmune attack, but lack of *AIRE* may affect fertility by disrupting scheduled apoptosis of testicular germ cells.[41] Recently, male APS-1 patients were found to harbor autoantibodies against transglutaminase-4.[42] *Aire* knockout mouse models display severe prostatitis; but so far there are no reports of autoimmune prostatitis in APS-1.

Other Endocrinopathies

The prevalence of diabetes mellitus varies between different populations, from a few percent to one-third, being more common in countries and populations with high prevalence of T1DM. The presence of autoantibodies against the IA-2 tyrosine phosphatase-like protein, but not glutamic acid decarboxylase (GAD), is predictive for the development of diabetes.[39] Thyroid autoantibodies are common, and hypothyroidism is relatively common after puberty, reaching a prevalence of one third by middle age.[37] Graves disease is very rare. Autoimmune hypophysitis is seen with lack of different pituitary hormones, including growth hormone, which may need replacement to ensue normal growth.[35]

Gastrointestinal Manifestations

Autoimmune gastritis with pernicious anemia is a common entity that affects approximately 30% by middle age,[37] associated with autoantibodies to parietal cells and/or blocking intrinsic factor. Vitamin B12 and iron status should be checked, and replacement given if indicated. A definite diagnosis can be made by gastroduodenoscopy and biopsy. Celiac disease has been reported in a few patients[43] but is uncommon. Conversely, autoimmune enteropathy is common and manifests with chronic or recurrent diarrhea and steatorrhea, as well as periodic or chronic constipation. Absence of enterochromaffin cells is typical, and patients have autoantibodies against tryptophan hydroxylase, the rate-limiting enzyme in serotonin biosynthesis.[44] Aberration in serotonin levels could explain changes in intestinal motility. Paneth cells are also affected, and levels of defensins are decreased,[45] perhaps explaining the alterations in the microbiome observed in these patients.[46] Exocrine pancreatitis occurs in a small percentage of patients, usually associated with insulin deficiency. Typically, subnormal levels of secretin-stimulated lipase are found. Replacement of pancreatic enzymes may improve diarrhea, and immunosuppression has been reported to improve exocrine pancreatic function.[47,48] Malabsorption can seriously disturb replacement therapy with steroids, vitamin D preparations, and calcium, and requires close follow-up.

Autoimmune hepatitis is a serious complication that is reported to affect around one fifth of the patients and usually manifests in childhood.[37] After careful scrutiny, a recent survey from the National Institutes of Health revealed that approximately 40% of patients are affected by autoimmune hepatitis.[49] Severity ranges from slightly elevated plasma alanine amino transferase levels to fulminant hepatitis. High levels should prompt liver biopsy. Autoantibodies against CYP1A2 correlate with the presence and severity of the autoimmune hepatitis.[35] CYP2D6, the autoantibody marker for isolated autoimmune hepatitis type 2, is not seen in APS-1.[50] If a biopsy reveals active hepatitis, immunosuppressive therapy with steroids, azathioprine, or other immunosuppressants is indicated.[16,49]

Ectodermal Manifestations

There are several ocular manifestations associated with APS-1, such as chronic keratitis, dry eye, ptosis, cataract, iridocyclitis, retinal detachment, and optic atrophy. Keratitis appears early and can be the first manifestation, and can lead to blindness if not treated appropriately. Symptoms include intense photophobia, blepharospasm, and reduced lacrimation. The etiology is presumably autoimmune, and treatment consists of immunosuppression with local glucocorticoids, or topical cyclosporin A. Sometimes corneal transplantation is warranted. Retinitis is rarer and linked to the presence of autoantibodies to interphotoreceptor retinoid-binding protein.[51]

Alopecia is the most frequent skin manifestation and is usually more severe than in isolated cases. Approximately 40% are affected by middle age. Loss of all hair on the head (alopecia totalis) or even the whole body (alopecia universalis) is not uncommon. It can sometimes be reversible, especially when immunosuppressive therapy is given for other components. Alopecia correlates with the presence of autoantibodies against tyrosine hydroxylase, which is highly expressed in hair follicles.[52]

Vitiligo is also common, and its prevalence approached one-third of the Finnish cohort.[37] It is of variable extent and distribution, but tends to include most of the skin. The contrast to surrounding normal skin may fade, yet the patients often feel it to be disfiguring on the face and hands. Vitiligo correlates with autoantibodies against transcription factors SOX9 and SOX10.[53] Periods with maculopapular, morbilliform, or urticarial rash with fever come early.[36,37] Skin biopsies have reveal lymphoplasmacytic vasculitis.[43] Punctate nail dystrophy is common, without evidence of *Candida* infections.[34]

Enamel hypoplasia of permanent teeth is one of the most common manifestations of APS-1 and is present in 70% to 80% of patients.[19] It can be mild, with transverse grooves or rows of pits alternating with normal enamel. In severe cases, all enamel is hypoplastic. The enamel defects predispose to further damage and caries. Extensive dental repair is often necessary and should be promptly performed. Even this manifestation is probably autoimmune, and recently autoantibodies against protein phosphatase-4, involved in odontogenesis, have been detected in APS-1 patients.[54]

Other Manifestations

Aplasia or hypoplasia of the spleen occurs in up to 20% of patients[37,55] and renders them susceptible to bacterial infections. Vaccination for *Pneumococcus pneumonia*, *Haemophilus influenzae*, and meningococcus is recommended. Autoimmune hemolytic anemia,[37,43] hypoplastic anemia,[35,37] and autoimmune thrombocytopenia[56] have been reported in a few patients. Autoimmune bronchiolitis is an underappreciated life-threatening component of APS-1. Careful pulmonary investigation in a single center revealed that approximately 40% of patients had pneumonitis.[57] Lung biopsy revealed interstitial lymphoid infiltrates around bronchioles. Patients display autoantibodies against the BPIFB2 and KCNRG proteins. Beneficial effects of steroid and rituximab treatment have been reported. Reversible metaphyseal dysplasia with growth retardation and severe progressive myopathy have been observed in isolated cases.

Natural Course and Mortality

The overall mortality is increased,[58] but the course of the disease varies widely. Some patients have very mild disease and are not diagnosed before adult age, whereas others develop multiple and severe manifestations early on. Life expectancy depends on the severity of the disease, the quality of management, including psychosocial support, and the ability of the patient and family to assume responsibility. There is an increased risk of death from oral/esophageal squamous cell carcinoma, acute adrenal and hypocalcemic crises, complications such as pneumonitis, hepatitis, and renal failure, and accidents.[19,35,37,57,59] A recent Finnish survey revealed that standard mortality rates were increased approximately ten times, more so for younger age groups. The cumulative mortality rate up to 60 years of age was over 80%, compared with less than 10% for the general population.[59]

Diagnosis and Management

The traditional diagnostic criterion of the diagnostic dyad remains valid[34] (Table 132.2), but leaves many cases unrecognized. Some patients never develop more than one of these components, or the components manifest at a late stage. Initial presenting components can be chronic diarrhea, keratitis, periodic rash with fever, severe constipation, autoimmune hepatitis, pneumonitis, alopecia, or vitiligo[34,37] Any of these "minor" components in a child should alert clinicians to look for other manifestations and check autoantibodies directed against interferon-omega or -alpha, which are positive in almost all patients. We recommend securing the diagnosis by sequencing *AIRE*.

Every patient should, in addition to a local doctor's follow-up, be seen by appropriate specialists, particularly an endocrinologist and an oral specialist, at least once annually, and know to contact them immediately when new symptoms appear. Ideally, the follow-up should be sufficiently centralized so that the responsible specialists have adequate experience with several APS-1 patients. The goal is to safeguard the patient's physical and psychosocial well-being, as well as recognize and treat components at an early stage. Patient education to avoid and treat acute complications such as adrenal and hypocalcemic crises is important. All patients should be equipped with an acute care card or bracelet and steroids for self-injections and be well informed about components that might develop in the future.

KEY POINTS

- Autoimmune polyglandular syndrome type 1 often develops in childhood. Manifestations other than the main can appear first, such as intermittent fever with rash, hepatitis, intestinal malabsorption, keratitis, enamel hypoplasia, alopecia, vitiligo, and premature ovarian insufficiency. Treatment is replacement of missing hormones, antifungal treatment, and immunosuppression for some components. Mortality is increased because of adrenal insufficiency, hypocalcemic crises, complications owing to organ-specific autoimmunity (liver, lungs), and carcinoma of the mouth and esophagus.

TABLE 132.3 Immune Dysregulation Polyendocrinopathy Enteropathy X-Linked and Immune Dysregulation Polyendocrinopathy Enteropathy X-Linked-like Syndromes

Gene	Manifestations	Pathway	Inheritance
FOXP3	IPEX—T1DM, enteropathy, eczema, cytopenias, nephritis, autoimmune hypothyroidism, recurrent infections	Defective IL-2 signaling and Treg function	X-linked
CD25 (IL2R)	Type 1 diabetes, thyroiditis, enteropathy, eczema, cytopenias, recurrent infections	Defective IL-2 signaling and Treg function	Autosomal recessive
CTLA4	Enteropathy, hemolytic anemia, pneumonitis, lymphadenopathy, and hypogammaglobulinemia, autoimmune thyroid disease	Defective CTLA-4 function in Tregs	Autosomal dominant, haploinsufficiency, dominant negative effect
LRBA	Enteropathy, hemolytic anemia, splenomegaly, T1DM	Defective CTLA-4 cycling in the cell increases lysosomal degradation	Autosomal recessive
STAT1	CMC, thyroiditis, T1DM, eczema, enteropathy	Inhibited Th17 cell differentiation	Autosomal dominant, gain of function
STAT3	T1DM, enteropathy, celiac disease, autoimmune thyroid disease, hemolytic anemia, autoimmune thrombocytopenia	Increased Th17 cells, reduced Foxp3$^+$ Tregs	Autosomal dominant, gain of function
STAT5b	Growth hormone insensitivity, thyroiditis, enteropathy, eczema, cytopenias, recurrent infections	Defective IL-2 signaling pathway	Autosomal recessive
ITCH	Developmental delay, dysmorphic features, autoimmune hypothyroidism, hepatitis, enteropathy	Reduced TGF-β–mediated Foxp3 expression	Autosomal recessive
BACH2	Enteritis, pneumonitis, infections	Defective immunoglobulin class switching, lymphocyte maturation defect	Autosomal dominant, haploinsufficiency

CMC, Chronic mucocutaneous candidiasis; *CTLA-4*, cytotoxic T lymphocyte antigen-4; *Foxp3*, forkhead box P3; *IL*, interleukin; *IPEX*, immumodysregulation polyendocrinopathy enteropathy X-linked; *T1DM*, type 1 diabetes mellitus; *TGF*, transforming growth factor; *Th*, T helper; *Treg*, T regulatory cell.

IMMUMODYSREGULATION POLYENDOCRINOPATHY ENTEROPATHY X-LINKED

Immumodysregulation polyendocrinopathy enteropathy X-linked (IPEX; OMIM 304790) is an exceedingly rare syndrome characterized by early-onset T1DM, autoimmune enteropathy with diarrhea and malabsorption, and dermatitis.[60,61] Eosinophilia and elevated IgE levels are common, and some patients develop renal disease with membranous glomerulonephritis or interstitial nephritis. Other manifestations are alopecia, autoimmune thyroiditis, hepatitis, exocrine pancreatitis, and different autoimmune cytopenias.[62] Many of the components overlap with APS-1 but in general develop much earlier. IPEX is caused by mutations in the *FOXP3* gene, located on the X chromosome, which is a key transcription factor needed for Treg development.

IPEX patients develop a number of autoantibodies, some of which overlap with those found in APS-1. Examples are glutamic acid decarboxylase and islet cell antibodies associated with T1DM. Many develop autoantibodies against harmonin and villin,[63] proteins involved in anchoring intestinal villi, also expressed in the proximal tubules of the kidney. Intriguingly, they also display autoantibodies against interferon-omega and a number of nuclear receptors, including HNFA1, mutations of which cause maturity-onset diabetes of the young.[64]

High-throughput DNA sequencing technology has uncovered other unique monogenic syndromes with endocrine manifestations. Examples are loss-of-function mutations in genes such as *CD25*, which encodes the receptor for IL-2, as well as *STAT5b*,[65] *ITCH*,[66] *BACH2*,[67] *CTLA-4*, and *LRBA*, and gain-of-function mutations in *STAT1*[68] and *STAT3*,[69] all of which affect Treg function (Table 132.3).

KEY POINTS

- Immumodysregulation polyendocrinopathy enteropathy X-linked is caused by mutations in the forkhead box protein 3 gene and lack of functional T regulatory cells. The disease starts early, often in infancy, with components such as type 1 diabetes, enteritis, and dermatitis. Eosinophilia, elevated IgE, and autoantibodies against villin and harmonin are common. Bone marrow transplantation is often needed.

AUTOIMMUNE POLYGLANDULAR SYNDROME TYPE 2

Definition

As originally described, Schmidt syndrome comprises the occurrence of Addison disease together with autoimmune thyroid disease and/or T1DM and has been regarded as synonymous with APS-2 (OMIM 269200). Addison disease was the index disorder in originally separating APS-1 from APS-2 and has been regarded as an essential component.[7] A broader definition has since developed, with the description of multiple autoimmune diseases in patients with autoimmune thyroid disease, T1DM, or Addison disease. Attempts to subdivide patients have been made, such as those with "incomplete" forms of APS-2 or additional types like APS-3 (autoimmune thyroid disease plus another organ-specific autoimmune disease excluding Addison disease) and APS- 4 (Addison disease plus another organ-specific autoimmune disease excluding autoimmune thyroid disease and T1DM), but no classification has been universally adopted. The picture is rendered still more complex by the existence of subclinical autoimmune disease and the temporal evolution of the various components, and the past division of autoimmune diseases into organ-specific or non–organ-specific is artificial. In our view, the term APS-2 should be reserved for the occurrence of at least two autoimmune endocrinopathies—Addison disease, autoimmune thyroid disease, T1DM—in the same patient.[16] There is an increased risk of developing another autoimmune disease with any of these components in isolation, and so APS-2 represents a dense and distinctive clustering of autoimmunity within a wider set of disease associations. The key features are summarized in Table 132.4.

Pathogenesis

APS-2 is primarily caused by genetic polymorphisms controlling antigen presentation and immunoregulation, which are associated with susceptibility to multiple autoimmune diseases. Tissue-specific gene polymorphisms, genetic heterogeneity in susceptibility to the underlying components, and environmental factors, which are also associated with these diseases, determine the exact pattern of autoimmunity in an individual patient. Although APS-2 is often multigenerational, the

TABLE 132.4 **Characteristics of Autoimmune Polyendocrine Syndrome Type 2**

Components	Clinical Features	Diagnosis	Autoantigens
Primary adrenal insufficiency	Hyperpigmentation, salt craving, hyponatremia, hyperkalemia	Low cortisol, elevated ACTH, failed synacthen testing	21-hydroxylase
Autoimmune thyroid disease	Hypothyroidism and Graves disease	Elevated TSH, low free thyroxine Suppressed TSH, elevated free thyroxine	Thyroid peroxidase TSH receptor
Type 1 diabetes mellitus	Hyperglycemia, lack of insulin	Fasting serum glucose >7 mmol/L, HbA1c >48 mmol/mol	Glutamic decarboxylase-65, islet cell antigen-2, zinc transporter-8
Primary ovarian insufficiency	Early menopause (<40 years of age), primary amenorrhea	Elevated FSH and LH, low estrogen	21-hydroxylase
Gastritis	Achlorhydria, vitamin B12 deficiency, iron deficiency	Autoimmune gastritis type A on biopsy	Intrinsic factor and parietal cell (H^+/K^+-ATPase)
Celiac disease	Malabsorption, iron and vitamin B12 deficiency	Villous atrophy and lymphocytic infiltration on biopsy	Transglutaminase-2
Exocrine pancreatitis,	Chronic steatorrhea, malabsorption	Decreased fecal elastase	
Vitiligo	From patchy to total nonsegmental distribution	Clinical features	Tyrosinase, tyrosinase-related proteins, SOX10
Alopecia	From patchy to total or universal distribution	Clinical features	Tyrosine hydroxylase
Others (<1%)	Autoimmune hypophysitis, chronic autoimmune hepatitis, myasthenia gravis, primary biliary cirrhosis, rheumatoid arthritis, serositis, Sjögren syndrome, systemic lupus erythematosus	As for isolated disorders	As for isolated disorders

ACTH, Adrenocorticotropic hormone; *FSH,* follicle-stimulating hormone; *HbA1c*, glycated hemoglobin; *LH,* luteinizing hormone; *SOX,* SRY-related HMG-box; *TSH,* thyroid-stimulating hormone.

pattern of heritability is unclear. The components of APS-2 differ in their relative strength of heritability, with Addison disease being the most strongly based on additive genetic effects and autoimmune thyroid disease the least, especially in the case of Graves disease.[70] Almost all genetic studies to date have been limited to White populations.

The HLA genotype DR3-DQ2, DR4-DQ8 has been individually associated with type 1 diabetes, Addison disease, and autoimmune thyroid disease, as well as with celiac disease, and therefore predisposes to APS-2.[16] More detailed analysis has been performed on APS-2 cohorts that have been defined through a particular combination of clinical features. In one large German cohort, the DR3-DQ2/DRB1*04:04-DQ8 genotype was associated with classical Schmidt syndrome, whereas the DR3-DQ2/DRB1*04:01-DQ8 genotype was associated with APS-3; protective HLA genotypes also differed between these two subdivisions.[71] DRA1*0101/DRB1*0301 shows the strongest association in susceptibility to the combination of type 1 diabetes and autoimmune thyroid disease, and it has been suggested that this allele encodes an HLA molecule with a flexible pocket that can bind both islet cell and thyroid autoantigens.[72]

A number of non-HLA genes involved at multiple points in the immune response have been associated with each of the three components of APS-2. These include polymorphisms in *CTLA4, PTPN22* (encoding lymphoid tyrosine phosphatase), *CD25* (encoding the IL-2 receptor), *NALP1* (encoding NACHT leucine-rich repeat protein), *BACH2* (encoding BTB domain and CNC homolog 2), and *STAT4* (encoding signal transducer and activator of transcription 4).[15,73-75] Attempts have been made to determine whether there is an exaggerated association when the components are present in APS-2 rather than occurring in isolation, and this may be the case for *CTLA-4* and *PTPN22* polymorphisms.[76] However, in the case of *BACH2* polymorphisms, a stronger association with APS-2 over isolated Addison disease appeared in Norwegian, but not British, patients, and significant heterogeneity has also been seen in the association of *STAT4* polymorphism with Addison disease in various European populations. Polymorphisms in these genes have also been associated in various combinations with the other autoimmune components seen in APS-2 (Table 132.4). As one example, of 55 genes known to be associated with vitiligo, 14 have also been implicated in type 1 diabetes and/or autoimmune thyroid disease, and 17, which partially overlap, have been implicated in at least one of the other autoimmune components seen in APS-2.[77] Over 100 genes may contribute to vitiligo, and similar numbers are likely to be involved in the other autoimmune disorders, helping explain the variability of the autoimmune phenotype of APS-2.

Further variability is contributed by environmental factors, but no studies have yet looked at APS-2 systematically, as it has been assumed that genetic factors play a more dominant role in etiology than in the individual diseases. Some environmental factors are component-specific (e.g., iodine intake and autoimmune thyroid disease). Alcohol consumption and smoking are examples of more general effects, as alcohol is protective in autoimmune thyroid disease, SLE, and rheumatoid arthritis, whereas smoking is a risk factor for Graves disease, SLE, and rheumatoid arthritis, as well as for celiac disease. The autoimmune response in APS-2 is directed against the same autoantigens as in the isolated forms of each disease: the key autoantigens are 21-hydroxylase in Addison disease, thyroid peroxidase, and thyroglobulin in autoimmune hypothyroidism, the TSH receptor in Graves disease, and glutamic acid decarboxylase 65 and the protein tyrosine phosphatases IA-2 and IA-2β in T1DM. The pathogenetic mechanisms are also identical. Autoantibodies against interferons and cytokines are rare.[78]

KEY POINTS

- Autoimmune polyglandular syndrome type 2 is the occurrence of at least two autoimmune endocrinopathies—Addison disease, autoimmune thyroid disease, type 1 diabetes mellitus—in the same patient, and often aggregates in families. Multiple genes are involved, in particular human leukocyte antigen variants and immune genes such as *CTLA-4, PTPN-22,* and *BACH2.*

Clinical Features and Diagnosis

The exact prevalence of APS-2 is unknown, owing to the use of different classifications and the existence of subclinical disease, but it is much more common than APS-1. APS-2 occurs in 60% to 70% of patients with autoimmune Addison disease,[79,80] whereas around 15% of type 1 diabetes patients have autoimmune thyroid disease.[81] APS-2 is two to three times more common in women, and the age of onset is typically between 20 and 60 years old, with T1DM usually occurring earliest and autoimmune hypothyroidism occurring latest. The clinical features and diagnosis of each component of APS-2 are identical to those of the individual diseases. Although a family history of autoimmune disease is more common in APS-2, it is often absent, with some family members having autoantibodies but no clinically evident disease. The occurrence of nonendocrine autoimmune conditions in a patient is also a clue (Table 132.4).

Premature ovarian insufficiency in APS-2 occurs only in those with Addison disease and is associated with P450 side-chain cleavage enzyme and/or 17α-hydroxylase antibodies directed against shared steroid cell antigens in the adrenal and ovary; these antibodies are much less frequent in APS-2 than in APS-1.[79,80] An autoimmune basis for premature ovarian insufficiency not related to steroid cell autoimmunity is currently unclear, and although there is an association of this condition with autoimmune thyroid disease and other autoimmune diseases like SLE, a distinct association with APS-2 is not firmly established.[82] In contrast to APS-1, male hypogonadism is not a feature of APS-2, and autoimmune hypoparathyroidism also appears to be absent, although 2% of APS-2 patients have autoantibodies to the calcium-sensing receptor.[78] Autoimmune hypophysitis is a rare disorder, but 2% of such patients have APS-2, and a further 10% have autoimmune thyroid disease, Addison disease, or T1DM in isolation.[83] Vitiligo occurs in 5% to 10% of APS-2 patients and alopecia in 3% to 10%, a lower frequency than in APS-1, and chronic autoimmune hepatitis is much less common.[15,84] Pernicious anemia is also less common in APS-2; it occurs in 0.5% to 5% of patients, particularly in association with autoimmune thyroid diseases.[85] In contrast, celiac disease, Sjögren syndrome, rheumatoid arthritis, and SLE have been associated with APS-2 but not with APS-1.[86]

Management

The treatment of each disease component in APS-2 follows standard lines. There may be a greater risk of adrenal crisis in Addison disease occurring in the setting of APS-2, more often in those with T1DM than in isolated Addison disease, suggesting the need for enhanced advice on preventative measures in this group.[87] Unusual hypoglycemia in a patient with T1DM may herald Addison disease in a patient with unsuspected APS-2, and care is needed when initiating levothyroxine replacement in undiagnosed or inadequately treated Addison disease to avoid precipitating an adrenal crisis. Concurrent celiac disease may be the cause of fluctuating levothyroxine requirements or unexplained vitamin D or iron deficiency, as well as increased need for hydrocortisone and fludrocortisone.

The main importance of recognizing APS-2 lies in the approach to screening both patients (Table 132.5) and their families. The usually long prodromal phase in the development of autoimmune disease means that screening can identify those at risk and lead to treatment at an early stage. In patients with APS-2, follow-up depends on whether Addison disease is present. Annual screening of all patients with Addison disease should include testing for thyroid peroxidase antibodies and TSH, glucose and HbA1c, and full blood count and vitamin B12.[88] In patients with APS-2, but without Addison disease, 21-hydroxylase antibodies should be measured every 3 to 5 years. Biochemical testing should be undertaken with a Synacthen test or basal cortisol and ACTH level if 21-hydroxylase antibody-positive, with regular follow-up thereafter. If overt Addison disease does not develop within 20 years, the risk for future disease is minimal.[89] In all types of APS-2, follow-up should include a careful history and examination to detect any newly emerging autoimmune condition (Table 132.5), with appropriate testing as required. Given the frequency of asymptomatic celiac disease and the risk of malignancy, IgA tissue transglutaminase-2 antibodies should be measured at the time of diagnosis in APS-2.[85,90] There is no well-established protocol for family screening in APS-2, as the inheritance is so variable. First-degree family members should be made aware of the possibility of developing an autoimmune condition, and screening should be offered to those who wish. Such screening should include measurement of thyroid peroxidase antibodies and TSH, basal glucose and HbA1c, and 21-hydroxylase antibodies if the proband has Addison disease. High-throughput multiplexed autoantibody assays are being developed that should simplify and improve screening in the future.[91]

TABLE 132.5 Screening Schedule in Autoimmune Polyendocrine Syndrome Type 2

Frequency	Evaluation
Annual	Physical exam Hemoglobin, electrolytes, creatinine, cholesterol, triglyceride, HbA1c, TSH, thyroid peroxidase antibodies, ferritin, plasma renin activity
Every third year	*Addison disease* (if not present): 21-hydroxylase antibodies *Celiac disease*: transglutaminase-2 autoantibodies *Premature ovarian insufficiency*: side-chain cleavage autoantibodies (females <40 years of age) *Autoimmune gastritis*: parietal cell and intrinsic factor–blocking autoantibodies, full blood count, vitamin B_{12}

HbA1c, glycated hemoglobin; *TSH,* thyroid-stimulating hormone.

KEY POINTS

- Management of autoimmune polyglandular syndrome type 2 consists of standard hormone replacement for each component, together with annual screening to detect any emerging asymptomatic autoimmune disorder (Table 132.5) and ensuring that first-degree family members are aware of their possible risk.

IMMUNE CHECKPOINT INHIBITOR-INDUCED POLYENDOCRINOPATHY

Immune checkpoint inhibitors (ICIs) are therapeutic monoclonal antibodies that inhibit the CTLA-4 or PD1 pathways. Ipilimumab is a CTLA-4 inhibitor, nivolumab and pembrolizumab inhibit PD1 and atezolizumab, avelumab and duvalumab inhibit PD-ligand 1. ICIs inhibit T-cell activation, resulting in enhanced T-cell responses against tumor cells, but with the unwanted effect of reducing the capacity for these pathways to maintain self-tolerance. In practice, these agents are very effective in a range of different cancers, but they also cause a variety of autoimmune disorders, including those affecting the endocrine system.[92,93] Thyroid dysfunction occurs in 5% to 10% of ICI-treated patients. The frequency is greatest with the anti-PD1 agents, especially when given in combination with CTLA-4 inhibition. It presents most commonly as hypothyroidism, often preceded by destructive thyroiditis; Graves disease is much less common and needs to be distinguished from the thyrotoxic phase of destructive thyroiditis before any treatment is started. Hypophysitis occurs in around 1% of patients following ICI treatment, and is associated most strongly with ipilimumab, especially when given in combination with PD1 inhibitors. T1DM after anti-PD1 treatment is uncommon, and rare after CTLA-4 inhibition. A few cases of T1DM have been reported in patients with preexisting autoimmune thyroid disease, as has the concurrent development of T1DM together with thyroid disease, hypophysitis, vitiligo, or other autoimmune disorders. Addison disease is rare after ICI treatment, but in five such cases one had preexisting autoimmune thyroid disease, and two developed concurrent hypophysitis.[92] Polyendocrinopathy after ICI treatment is rare, but could be a model for APS-2, in which some shared genetic predisposition leads to disease, and may offer fresh insights into understanding why particular types of autoimmune disease arise.

KEY POINTS

- Immune checkpoint inhibitors are therapeutic monoclonal antibodies used in cancer treatment that inhibit the CTLA-4 or PD1 immunoregulatory pathways and can cause a variety of endocrine disorders by removing the brakes on T-cell activation.

Conclusion, 2254

Multiple endocrine neoplasia (MEN) is characterized by the occurrence of tumors involving two or more endocrine glands within a single patient.[1] The disorder has previously been referred to as *multiple endocrine adenopathy* or *pluriglandular syndrome*. However, glandular hyperplasia and malignancy may also occur in some patients, and the term *multiple endocrine neoplasia* is preferred. Four major forms of MEN, referred to as MEN types 1 to 4 (MEN1 to MEN4) are recognized, and each form is characterized by the development of tumors within specific endocrine glands (Table 133.1).[1] Thus, combined occurrence of tumors of the parathyroid glands, the pancreatic islet cells, and the anterior pituitary gland is characteristic of MEN1, which is also referred to as *Wermer syndrome*. In addition to these tumors, adrenal cortical tumors, thymic, bronchial, and gastric carcinoid tumors, meningiomas, facial angiofibromas, collagenomas, lipomas, and paraganglioma have been described in patients with MEN1.[1,2,2a] MEN1 is caused by mutations of the tumor suppressor *MEN1* gene, which encodes menin, which functions as a scaffold protein.[3,4] In MEN2, which is also called *Sipple syndrome*, medullary thyroid carcinoma (MTC) occurs in association with pheochromocytoma, and two main forms are recognized: MEN2A (now referred to as MEN2) and MEN2B (also referred to as MEN3). MEN2 and MEN3 are caused by specific mutations of the rearranged during transcription (*RET*) protooncogene, which encodes a receptor tyrosine kinase (RTK).[4a] MEN2, which is the most common form, is characterized by the development of MTC in association with pheochromocytoma and parathyroid tumors. Three variants of MEN2 are reported, including MEN2 with Hirschsprung disease, MEN2 with cutaneous lichen amyloidosis, and familial MTC only, in which MTC is the sole manifestation of the syndrome. However, in MEN3, parathyroid involvement is rare, and the occurrence of MTC and pheochromocytoma is found in association with a marfanoid habitus, mucosal neuromas, medullated corneal fibers, and intestinal autonomic ganglion dysfunction leading to megacolon. MEN4 is associated with mutations of the gene encoding the cyclin-dependent kinase inhibitor (CK1) p27 kip1 (*CDNK1B*), and patients may develop parathyroid adenomas, pituitary adenomas, duodenopancreatic neuroendocrine tumors, and tumors of the gonads, adrenal, kidneys, and thyroid.[5,6] All of these forms of MEN may be inherited as autosomal dominant syndromes or may occur sporadically (i.e., without a family history), although this distinction between sporadic and familial cases may sometimes be difficult.[1]

KEY POINTS

- Multiple endocrine neoplasia (MEN) syndromes (types 1–4, MEN1–4) are a group of heterogeneous disorders characterized by occurrence of specific tumors that may be inherited as autosomal dominant traits.

This chapter discusses the clinical aspects of the tumors arising in the context of MEN1 and reviews the molecular genetic basis of this syndrome.

KEY POINTS

- MEN1 is characterized by the occurrence of tumors of the parathyroid glands, pancreatic islets (e.g., gastrinomas and insulinomas), and anterior pituitary gland (e.g., prolactinomas and somatotropinomas), with some patients also developing adrenal and carcinoid tumors; in the absence of treatment, these endocrine tumors are associated with an earlier mortality in patients with MEN1.

HISTORICAL ASPECTS

Patients with MEN1 are characterized by the combined occurrence of tumors of the parathyroid glands, pancreatic islet cells, and anterior pituitary gland. The first occurrence of such multiple endocrine tumors was reported in 1903, in a patient with acromegaly whose autopsy revealed the presence of an anterior pituitary tumor and enlarged

TABLE 133.1 Multiple Endocrine Neoplasia Syndromes and Their Characteristic Tumors and Associated Genetic Abnormalities

Type (Chromosomal Location)	Tumors (Estimated Penetrance)	Gene; Most Frequently Mutated Codons
MEN1 (11q13)	Parathyroid adenoma (90%)	*MEN1*[c]
	Enteropancreatic tumor (30% to 70%)	83/84, 4-bp del (≈4%)
	Gastrinoma (40%)	119, 3-bp del (≈3%)
	Insulinoma (10%)	210–211, 4-bp del (≈8%)
	Nonfunctioning and PPoma (20%–55%)	418, 3-bp del (≈4%)
	Glucagonoma (<1%)	514–516, del or ins (≈7%)
	VIPoma (<1%)	Intron 4 ss (≈10%)
	Pituitary adenoma (30%–40%)	
	Prolactinoma (15%–20%)	
	Somatotropinoma (5%–10%)	
	Corticotropinoma (<5%)	
	Nonfunctioning (10%–15%)	
	Associated Tumors	
	Adrenal cortical tumor (20%–40%)	
	Pheochromocytoma (<1%)	
	Bronchopulmonary NET (4%–13%)	
	Thymic NET (2%–8%)	
	Gastric NET (10%)	
	Lipomas (30%)	
	Angiofibromas (85%)	
	Collagenomas (70%)	
	Meningiomas (8%)	
	Breast cancer[b]	
MEN2 (10 cen-10q11.2)		
MEN2A[a]	MTC (90%)	RET
	Pheochromocytoma (50%)	634, e.g., Cys→Arg (~85%)
	Parathyroid adenoma (20% to 30%)	
MEN2B (also known as MEN3)	MTC (>90%)	RET 918, Met→Thr (>95%)
	Pheochromocytoma	
	Associated abnormalities (40%–50%)	
	Mucosal neuromas	
	Marfanoid habitus	
	Medullated cornel nerve fibers	
	Megacolon	
MEN4 (12p13)	Parathyroid adenoma[d]	*CDKN1B*, no common mutations identified to date
	Pituitary adenoma (e.g., acromegaly, Cushing disease)[d]	
	Gastro-duodeno-pancreatic NETs (e.g., gastrinoma, nonfunctional pancreatic NET)[d]	
	Reproductive organ tumors[d] (e.g., testicular cancer, neuroendocrine cervical carcinoma)	
	Adrenal + renal tumors[d]	
	Bronchial carcinoid tumor[d]	
	Thyroid tumors[d]	

Autosomal dominant inheritance of MEN1 syndrome has been established.

[a] MEN2A also includes three variant disorders: familial-MTC only, MEN2A with cutaneous lichen amyloidosis, and MEN2A with Hirschsprung disease.

[b] An increased relative risk of breast cancer is reported (relative risk 2.8). The diagnosis of breast cancer in female MEN1 patients is also reported to occur at a younger age compared with the general population (i.e., median/mean age of diagnosis of 45–50 years in different series).

[c] *MEN1* mutation codon location reported according to the transcript encoding the 610–amino acid menin protein (NM_130799)

[d] Insufficient numbers reported to provide prevalence information.

del, Deletion; *ins,* insertion; *PPoma,* pancreatic polypeptide–secreting tumor; *VIPoma,* vasoactive intestinal polypeptide–secreting tumor; *MTC,* medullary thyroid cancer; *NET* neuroendocrine tumor; *RET,* rearranged during transcription; *ss,* splice site.

parathyroid glands.[7] Pancreatic islet cell tumors were subsequently observed in association with parathyroid and pituitary tumors, and a familial occurrence was suggested by the finding of these tumors in two sisters. Further case reports revealing the triad of parathyroid, pancreatic islet cell, and anterior pituitary tumors in individual patients, led to the recognition of a unifying disorder,[8] and a familial basis was demonstrated by documenting its occurrence in a father and daughter of one family and in a father and four daughters of another family. An autosomal dominant mode of inheritance was proposed and established by further family studies that demonstrated inheritance of the syndrome in five generations, with equal frequency in male and female subjects. Molecular genetic linkage studies mapped the *MEN1* locus to chromosome 11q13, and further positional cloning studies identified the *MEN1* gene in 1997[9,10] and revealed that it encoded a 610–amino acid ubiquitously expressed protein, designated *menin*.[9] Menin has been shown to be predominantly a nuclear protein that acts as a scaffold protein, interacting with a number of proteins involved in transcriptional regulation, genome stability, cell division, proliferation, and epigenetic regulation.[1,3,11] Elucidation of the crystal structure of menin has revealed that it contains a deep pocket that binds to the mixed lineage leukemia protein (MLL1) and transcription factor JunD, and that pharmacologic agents can inhibit these interactions.[12]

CLINICAL FINDINGS AND TREATMENT

The estimated prevalence of MEN1 is 1:30,000 of the population. The clinical manifestations of MEN1 are related to the sites of tumor development and to their products of secretion. In addition to the triad of parathyroid, pancreatic, and pituitary tumors (Fig. 133.1), which constitute the major components of MEN1, adrenal cortical tumors, carcinoid tumors (e.g., of the thymus, bronchi, and stomach), facial angiofibromas, collagenomas, meningiomas, and lipomas have also been described (see Table 133.1),[1,13] together with an increased risk of breast cancer in women with MEN1.[14] MEN1 is highly penetrant, such that virtually all patients develop clinical or biochemical evidence of tumor development by the age of 50 years. Clinical disease expression is unusual in early childhood (i.e., <5 years of age), but more than 20% of patients will have at least one clinical or biochemical manifestation by the age of 20 years.[13] Parathyroid tumors are the first clinical manifestation of MEN1 in 75% to 90% of patients.[13] The pancreatic tumors, which are neuroendocrine tumors (NETs) and occur in 40% to 70% of MEN1 patients, consist of gastrinomas, insulinomas, glucagonomas, vasoactive intestinal polypeptidomas (VIPomas), and nonfunctioning pancreatic NETs[4,15-18]; whereas anterior pituitary tumors, consisting of prolactinomas, somatotropinomas, corticotropinomas, and nonfunctioning adenomas, occur in 30% to 40% of patients.[19] The frequency of other endocrine tumors is variable, with 20% to 55% of MEN1 patients developing adrenal tumors[13,20] and less than 15% of patients manifesting thymic or bronchial carcinoid tumors.[21,22] Combinations of these tumors have been reported to differ in members of the same family and even between identical twins.[23] In children, presentations with pituitary adenomas (e.g., prolactinomas, Cushings disease), insulinomas, and nonfunctioning NETs are not infrequent, and some may occasionally present with thymic or adrenal malignancy. MEN1 is inherited as an autosomal dominant disorder, but nonfamilial (i.e., sporadic) forms account for 10% to 15% of patients with MEN1, with *de novo MEN1* mutations occurring in approximately 10% of MEN1 patients.[1]

A diagnosis of MEN1 may be established in an individual by one of three criteria (Fig. 133.2)[1]: on the basis of occurrence of two or more primary MEN1-associated endocrine tumors (i.e., parathyroid, enteropancreatic, and pituitary tumors); occurrence of one of the MEN1-associated tumors in a first-degree relative of a patient with a clinical diagnosis of MEN; and identification of a germline *MEN1* mutation in an individual who may be asymptomatic and has not yet developed serum biochemical or radiologic evidence of tumor development.

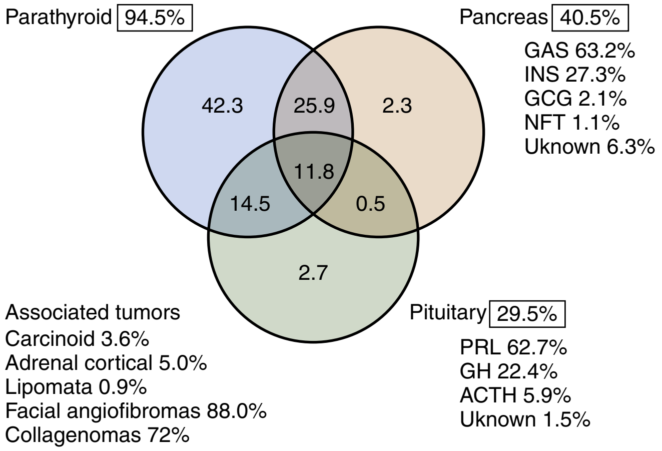

Fig. 133.1 Schematic representation of the distribution of 384 multiple endocrine neoplasia type 1 (MEN1) tumors in 220 patients with MEN1. The proportions of patients in whom parathyroid, pancreatic, or pituitary tumors occurred are shown in the respective boxes; for example, ~95% of patients had a parathyroid tumor. The Venn diagram indicates the proportions of patients with each combination of tumors; for example, ~35% (~25% + ~10%) of patients had both a parathyroid and a pancreatic tumor, whereas ~2% of patients had a pancreatic tumor only. In addition to the tumors reported in this series, a high frequency of facial angiofibromas (>80%) and collagenomas (>70%) have been reported in MEN1 patients in other series. The hormones secreted by each of these tumors are indicated: *ACTH,* adrenocorticotropic hormone; *GAS,* gastrin; *GCG,* glucagon; *GH,* growth hormone; *INS,* insulin; *NFT,* nonfunctioning tumor; *PRL,* prolactin. Parathyroid tumors represent the most common form of MEN1 tumors and occur in approximately 95% of patients, with pancreatic islet cell tumors occurring in approximately 40% and anterior pituitary tumors occurring in around 30%. However, use of radiologic surveillance methods has resulted in identification of nonfunctioning pancreatic NETs in 15%–55% of MEN1 patients, and thus these represent the most prevalent pancreatic NETs. (Modified from Trump D, Farren B, Wooding C, et al. Clinical studies of multiple endocrine neoplasia type 1 [MEN1]. *QJM.* 1996;89:653–669.)

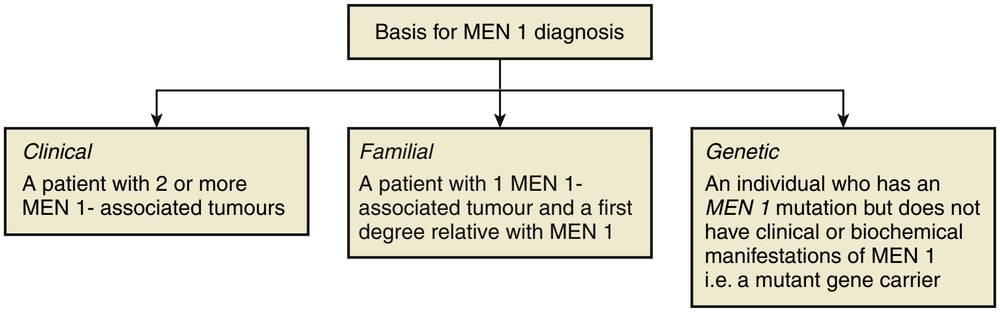
In the absence of treatment, endocrine tumors are associated with an earlier mortality in patients with MEN1[1]; for example, malignant pancreatic NETs and thymic carcinoid tumors are associated with a marked increase in risk for death (hazard ratio [HR] >3, $P < .005$). However, the prognosis of MEN1 patients with gastrinomas, which are associated with severe multiple peptic ulcers, has improved considerably following the introduction of acid-suppressive therapies, although 30% to 70% of individuals with MEN1 still die at a mean age of 50 to 60 years, of causes directly related to MEN1.[24] This earlier mortality, despite treatment, which for each type of MEN1-associated endocrine tumor is generally similar to that for the respective tumors occurring in non-MEN1 patients,[1] may be because of the occurrence of multiple synchronous or asynchronous tumors in the same or different tissues in MEN1 patients. For example, MEN1 patients often develop multiple submucosal duodenal gastrinomas, such that achieving biochemical remission is difficult without extensive surgical resection, and the cooccurrence of multiple synchronous pancreatic NETs may complicate the interpretation of imaging and biochemical investigations, as well as the planning of surgical intervention.



Basis for MEN 1 diagnosis
Clinical
A patient with 2 or more MEN 1- associated tumours
Familial
A patient with 1 MEN 1- associated tumour and a first degree relative with MEN 1
Genetic
An individual who has an *MEN 1* mutation but does not have clinical or biochemical manifestations of MEN 1 i.e. a mutant gene carrier

Fig. 133.2 Basis for a diagnosis of multiple endocrine neoplasia type 1 (*MEN1*) in individuals. A diagnosis of MEN1 based on clinical and familial criteria may be confounded by the occurrence of phenocopies. (Reproduced from Turner JJ, Christie PT, Pearce SH, et al. Diagnostic challenges due to phenocopies: lessons from Multiple Endocrine Neoplasia type 1 [MEN1]. *Hum Mutat.* 2010;31:E1089–E1101.)

Finally, it is important to recognize that there is an absence of high-quality evidence (i.e., randomized controlled trials) to guide the treatment of MEN1-associated tumors, and that the recommendations are typically based on the treatment of their sporadic counterparts or on limited case series of MEN1 patients, which may be prone to ascertainment and reporting biases.[1] It is therefore advised that decisions regarding treatment are made by a multidisciplinary team with relevant experience in the management of MEN1 that also takes into account the views of the patient. In particular, the potential risks and benefits of any intervention need to be balanced, with the aims of treatment being to minimize disease-associated morbidity and mortality, avoid iatrogenic harms, and preserve the patient's quality of life.[1]

KEY POINTS

- Malignant pancreatic neuroendocrine tumors and thymic carcinoid tumors are the leading causes of premature mortality. In the absence of treatment, multiple endocrine neoplasia type 1–associated tumors are associated with significant morbidity and an earlier mortality.

Parathyroid Tumors

Primary hyperparathyroidism occurs in approximately 95% of MEN1 patients and is the first manifestation of disease in 75% to 90% of patients.[1,13,13a] Patients may have asymptomatic hypercalcemia, nephrolithiasis, osteitis fibrosa cystica, vague symptoms associated with hypercalcemia (e.g., polyuria, polydipsia, constipation, or malaise), or occasionally peptic ulcers. Biochemical investigations reveal hypercalcemia, in association with raised or inappropriately normal circulating parathyroid hormone (PTH) concentrations.[1] The hypercalcemia is usually mild, and severe hypercalcemia resulting in crisis is rare, as is the occurrence of parathyroid carcinoma. Additional differences in the primary hyperparathyroidism of patients with MEN1, as opposed to those without MEN1, include an earlier age at onset (e.g., 15–25 years vs. 55 years), an equal male/female ratio (1:1 vs. 1:3), synchronous or asynchronous involvement of all four parathyroid glands, and a greater reduction in bone mineral density (BMD),[1] which particularly affects the lumbar spine, femoral neck, and distal radius, and is postulated to be attributed to the earlier age of disease onset and chronicity of disease. Primary hyperparathyroidism in patients with MEN1 is unusual before 10 years of age, although asymptomatic and symptomatic cases have been reported at as early as 4 and 8 years of age, respectively.[13]

Treatment. Surgical removal of the abnormally overactive parathyroid glands is the definitive treatment and is recommended for MEN1 patients with primary hyperparathyroidism who have symptomatic disease, severe hypercalcemia (i.e., corrected serum calcium >3.0 mmol/L), and/or those with evidence of end-organ damage (e.g., renal stones, hypercalciuria, or osteoporosis on BMD imaging (i.e., T score < –2.5). For those without a clear indication for surgery, regular clinical and biochemical monitoring, together with periodic reevaluation for end organ damage (e.g., renal ultrasound scan, dual-energy x-ray absorptiometry), is suggested.[1]

However, there is controversy regarding the timing (i.e., at an early or late stage[1]) and extent of parathyroidectomy (subtotal parathyroidectomy [SP; three and a half glands] or total parathyroidectomy [TP]) that should be undertaken, as all four (or more) parathyroid glands are typically affected, and preoperative imaging (e.g., neck ultrasound, Tc99m-sestamibi parathyroid scintigraphy, computed tomography [CT], magnetic resonance imaging [MRI], and (^{18}F)-fluorodeoxyglucose (FDG) positron emission tomography [PET]/CT) is reported to be of limited benefit in surgery-naïve MEN1 patients. For example, preoperative localization studies in MEN1 have been reported to: not alter the surgical approach in greater than 90% of MEN1 patients; be of only limited value in identifying ectopic parathyroid glands (correctly identified in only ~40% of patients); and only correctly identify the largest parathyroid in approximately 70% of cases, while failing to identify enlarged contralateral parathyroid glands in approximately 85% of these cases.[25] Thus, bilateral neck exploration is usually required, and the surgical approach needs to balance the likelihood of persistent or recurrent hyperparathyroidism with the risks of permanent hypoparathyroidism. In most centers, SP of at least three and a half glands is the recommended surgical approach. However, some other centers advocate TP with or without autotransplantation of fresh or cryopreserved parathyroid tissue (e.g., to the forearm), even though the risk of permanent hypoparathyroidism may be high and ranges from less than 15% to greater than 65%,[26,27] and recurrent hypercalcemia from the transplanted tissue is frequently observed, necessitating its surgical removal, which is not always successful. Moreover, an autotransplanted parathyroid gland has been reported to contain a metastatic neuroendocrine thymic carcinoma, thereby indicating further caution in adopting this approach. Concurrent bilateral transcervical thymectomy is also recommended at the time of surgery to remove parathyroid tumors that may be embedded within the thymus.[1] Such extensive parathyroidectomy is recommended, because lesser surgical approaches (i.e., removal of less than three glands) are associated with higher persistence and recurrence rates, of 15% to 65% at 15 years postsurgery. For example, a study of 99 MEN1 patients reported persistent hyperparathyroidism in approximately 70% of patients whose initial operation comprised removal of only one or two glands, compared with 20% in those in whom two and a half to three glands were removed, and only approximately 5% in those with removal of three and a half glands.[25] Persistent hypocalcemia following such extensive parathyroid surgery is treated with oral calcitriol

(1,25-dihydroxyvitamin D), although management of hypoparathyroidism can be challenging in some patients, even with the use of vitamin D analogs and calcium replacement.[1]

However, recent studies have reported more favorable short- to medium-term outcomes for MEN1 patients treated with less extensive surgical approaches (i.e., unilateral parathyroidectomy or minimally invasive parathyroidectomy).[28,29] For example, a study of 89 MEN1 patients treated for primary hyperparathyroidism with gland excision (GE) of one or two glands ($n = 28$), SP ($n = 23$), or TP with autotransplantation ($n = 38$) reported disease persistence and recurrence rates at a median follow-up of 112 months in the GE group of 15% and greater than 20%, respectively, which, although significantly higher than for the SP and TP groups, were associated with 0% of permanent hypoparathyroidism that was greater than 15% and greater than 30% in the SP and TP groups, respectively.[29] Thus, some centers advocate GE, which acknowledges the likely need for future surgery but avoids the immediate risks of permanent hypoparathyroidism in some patients (e.g., younger patients with apparent evidence of single or unilateral disease) who may benefit from a limited parathyroidectomy. Such individualization of the extent of parathyroid surgery in some MEN1 patients may be facilitated by the use of: preoperative parathyroid venous sampling, which has been reported to reduce the rates of permanent hypoparathyroidism and recurrent hyperparathyroidism; and of intraoperative monitoring of PTH by rapid assay that has been used to confirm the successful removal of hyperfunctioning parathyroid tissue, and the identification of ectopic and/or supernumerary hyperfunctioning parathyroid glands, located predominantly in the thymus but also at other locations in the mediastinum or carotid sheath.

These uncertainties in parathyroid surgery for MEN1 patients reflect the lack of high-quality evidence to guide clinical recommendations, and at present the timing and extent of surgery requires careful consideration of the surgical experience, availability of facilities for long-term regular serum calcium monitoring, accessibility of calcitriol (or other vitamin D analogs), and patient preferences.[1] Calcimimetics (e.g., Cinacalcet), which act via the calcium-sensing receptor, may also have a role to reduce or normalize serum calcium and circulating PTH levels in some MEN1 patients, in whom surgery has either failed or is contraindicated.

KEY POINTS

- Primary hyperparathyroidism occurs in >95% of multiple endocrine neoplasia type 1 patients and is the first manifestation of disease in the majority of patients. Most centers recommend subtotal parathyroidectomy of at least three and a half glands because typically there is synchronous or asynchronous involvement of all four parathyroid glands. Cinacalcet may be used for those in whom surgery has failed or is contraindicated.

Pancreatic Tumors

The incidence of clinically apparent pancreatic NETs in patients with MEN1 varies from 30% to 80% in different series, although microscopic islet tumors are found in almost all MEN1 patients. Malignant pancreatic NETs remain the leading cause of premature death in MEN1 patients.[15-17,30,31] MEN1-associated pancreatic NETs (Table 133.1) may produce excessive amounts of hormone (e.g., gastrin, insulin, glucagon, or vasoactive intestinal polypeptide [VIP]) and are associated with distinct clinical syndromes, although some (e.g., those secreting pancreatic polypeptide [PP]) may not be associated with clinical manifestations or may be nonsecretory (i.e., nonfunctioning) (see Fig. 133.1).[1] Indeed, nonfunctioning NETs are now reported to be the most common pancreatic NET in MEN1.[4,15-17,31,32] MEN1 patients may have more than one synchronous pancreatic NET, and it cannot be assumed that tumor visualization on imaging studies correlates with the site of hormone excess in functioning tumor syndromes (e.g., gastrinoma, insulinoma).[1,16] The goal of treatment of MEN1 pancreatic NETs is to reduce the morbidity and mortality associated with these tumors, which may be associated with hormone hypersecretion (e.g., gastrin, insulin) and/or their malignant behavior (i.e., development of metastases).[31] Surgery is generally recommended for functioning pancreatic NETs associated with localized disease (i.e., within the pancreas), as it offers a potentially curative approach.[1,4,17] For nonfunctioning pancreatic NETs, surgery is typically reserved for localized tumors greater than 2 cm, as the risk of metastasis and death is observed to increase significantly above this size.[1,4,15-17,33] Indeed, when evaluated as a single group, the risk of metastases in MEN1 duodenopancreatic NETs is associated with size greater than 2cm and age greater than 40 years, and surprisingly not with hypersecretion (or nonsecretion) of hormones.[34]

Gastrinoma. Zollinger and Ellison initially described two patients in whom non–β islet cell tumors of the pancreas were associated with recurrent peptic ulceration and marked gastric acid production, and gastrin was subsequently extracted from such tumors. The association of recurrent peptic ulceration, marked gastric acid production, and non–β islet cell tumors of the pancreas is referred to as the Zollinger–Ellison syndrome (ZES).[1] ZES patients may also suffer from esophageal symptoms (e.g., related to esophageal stricture, or Barrett's esophagus), as well as diarrhea and steatorrhea.

The diagnosis is established by demonstration of a raised fasting serum gastrin concentration in association with increased basal gastric acid secretion.[1] Occasionally, intravenous provocative tests with either secretin or calcium infusion are required to distinguish patients with ZES from other causes of hypergastrinemia, which include achlorhydria, antral G-cell hyperplasia, *Helicobacter pylori* infection, renal failure, hypercalcemia, and use of proton pump inhibitors (PPIs).[1] Investigations that may help to localize the gastrinomas include ultrasonography, endoscopic ultrasonography (EUS), CT, MRI, selective abdominal angiography, or somatostatin receptor scintigraphy (SRS).[1] In addition, the combined use of intraarterial calcium injections with hepatic venous gastrin sampling has been shown to regionalize the gastrinomas, while the selective arterial secretagogue injection test may also help localize the tumor.[1] However, MEN1-associated gastrinomas frequently occur with concomitant pancreatic NETs, most frequently nonfunctioning tumors, and this failure to distinguish between tumor types may have confounded earlier studies. Thus, it is likely that in many MEN1 patients with ZES, large (>2 cm) pancreatic tumors that were assumed to be gastrinoma were instead nonfunctioning NETs, and that the gastrinomas, which occurred within the duodenal wall, were unrecognized.[35] Moreover, in patients with MEN1, ZES does not appear to occur in the absence of primary hyperparathyroidism, and hypergastrinemia has also been reported to be associated with hypercalcemia. The successful treatment of the primary hyperparathyroidism with restoration of normocalcemia may ameliorate the clinical symptoms and biochemical abnormalities in approximately 20% of patients.[1] Thus, the diagnosis of ZES may be difficult in some MEN1 patients.

Gastrin-secreting tumors (gastrinomas) are reported to occur in 20% to 60% of MEN1 patients (see Fig. 133.1), and approximately 20% of patients with gastrinomas will have MEN1.[1,22] The majority of MEN1-associated gastrinomas occur as multiple small tumors (<0.5 cm in size) located within the duodenal mucosa and occur only rarely as macroscopic pancreatic tumors.[18,36] Despite their typical small size, local lymph node metastases appear to occur early in the disease, while hepatic metastases occur less frequently. For example, 70% to 80% of surgically treated patients have evidence of local lymph node metastases, while synchronous hepatic metastases are reported in approximately 10%.[37] Gastrinomas occur more often in male MEN1 patients great than 30 years of age, and past *H. pylori* infection is associated with an increased prevalence and severity of hypergastrinemia in MEN1 patients.[38] Gastrinomas are a major cause of morbidity and mortality in patients with MEN1, and before the advent of H2 receptor blockers and PPI therapy, recurrent severe multiple peptic ulcers (with associated perforation) and cachexia were major contributors to the high mortality. In addition, a recent study of 63 patients with MEN1-associated gastrinomas reported 5- and 10-year overall survival rates of approximately 80% and approximately 65%, respectively, with high gastrin levels (i.e., >20 times the upper limit of normal), a pancreatic NET greater than 2 cm, synchronous liver metastases, multiple concurrent NETs, and gastroduodenoscopy suspicious of gastric NET, each contributing to the reduced survival.[18]

KEY POINTS

- Gastrinomas occur in 20% to 60% of MEN1 patients, and when untreated are associated with the Zollinger–Ellison syndrome and increased mortality. Insulinomas occur in 10% to 30% of MEN1 patients, typically presenting at under 40 years of age, and are the first manifestation of disease in 10% of MEN1 patients.

KEY POINTS

- Clinically apparent nonfunctioning pancreatic neuroendocrine tumors occur in 15% to 55% of patients and are the leading cause of premature death in MEN1. The risk of malignancy is partially dependent on tumor size, and most centers recommend surgery for tumors over 2 cm, although some advocate lower thresholds.

Treatment. The aims of treatment are to control symptoms and/or sequelae associated with hypergastrinemia (e.g., ZES) and to reduce the mortality associated with the development of metastatic disease.[39] However, the inability to accurately predict disease course makes decisions regarding the optimal treatment challenging, with some centers recommending medical treatment and others favoring early surgical intervention.[36,39] Medical treatment of MEN1 patients with ZES is directed toward reducing basal acid output to less than 10 mmol/L, and this may be achieved by high-dose parietal cell H^+/K^+-adenosine triphosphatase (ATPase) inhibitors (i.e., PPI therapy including omeprazole or lansoprazole). Some patients may also require additional treatment with the histamine H2 receptor antagonists cimetidine or ranitidine.[1] The introduction of acid-suppressive therapies has markedly reduced the morbidity and associated mortality from the direct effects of hypergastrinemia, such that the overall prognosis of gastrinoma in MEN1 patients is now generally favorable, with 5-, 10-, and 20-year survival rates of approximately 80% to 95%, approximately 65% to 95%, and approximately 60% to 90%, respectively,[18,36] However, the effects of medical treatment on disease course (i.e., tumor growth, risk of metastases) and long-term consequences with continuous use for greater than 10 to 20 years are not known. The value of somatostatin analogues (SSAs), which have been used in a limited number of patients for the treatment of MEN1-associated gastrinoma, remains uncertain. The benefits of surgery for the majority of MEN1 patients with multiple duodenal gastrinomas are not established. For example, extensive duodenal resection aiming to remove all gastrinomas and thereby achieve persistent postoperative biochemical remission (i.e., eugastrinemia) is rarely possible, and duodenal-preserving procedures are associated with persistent or recurrent hypergastrinemia in 60% to 100% of patients.[1,17,35] However, some studies have reported improved remission rates of 75% to 100%, with short- to medium-term follow up,[35] following extensive surgical approaches including: duodenotomy with local removal of tumors in the duodenal wall, coupled with enucleation/resection of tumors in the pancreatic head and peripancreatic lymph node removal; partial pancreaticoduodenectomy; and pancreas-preserving duodenectomy.[1,35,36] Whipple pancreatoduodenectomy has been reported to achieve a greater than 65% cure rate but is associated with a higher operative mortality and long-term complications, which include weight loss, diabetes mellitus, and malabsorption, such that it is reserved for patients with large tumors, and total duodenopancreatectomy is very rarely performed because of the high risk of long-term sequelae (i.e., brittle insulin-dependent diabetes).[1] Laparoscopic surgery is not recommended, while total gastrectomy is rarely undertaken and only employed in very limited situations (e.g., a persistently noncompliant patient). Currently, most centers undertake nonsurgical management for the majority of MEN1 patients with duodenal gastrinomas, although some specialized centers with experience in preoperative and intraoperative imaging (e.g., transillumination of the duodenum) and regionalization advocate surgery for gastrinoma early in the disease course.[1] However, surgery is recommended for the rare patients (<1%) with a pancreatic gastrinoma greater than 2 cm, as it results in improved disease-related survival, and also for the minority of MEN1 gastrinoma patients who develop aggressive gastrinomas.[1,17,18] In summary, the role of surgery in the treatment of gastrinomas in patients with MEN1 is controversial, and this is partly because of an absence of randomized studies comparing medical and surgical approaches and the availability of a wide range of potential surgical techniques that have been evaluated only in the short to medium term.[17,18,35,40]

Treatment of disseminated gastrinomas is difficult, and chemotherapy with streptozotocin and 5-fluorouracil, capecitabine and temozolomide, cisplatin and etoposide, hormonal therapy with the SSAs octreotide or lanreotide, selected internal radiation therapy, radiofrequency ablation, peptide radioreceptor therapy (PRRT), hepatic artery embolization, administration of human leukocyte interferon, and removal of all resectable tumor, and hepatic transplantation have all been successful occasionally.[1]

Insulinoma. Insulinomas, β islet cell tumors that secrete insulin, occur in 10% to 30% (see Fig. 133.1) of MEN1 patients[1,37] and may occur in association with other pancreatic NETs (e.g., gastrinomas) in approximately 10% of patients. Insulinomas occur more often in patients with MEN1 who are younger than 40 years of age, whereas in patients without MEN1, insulinomas generally occur in those over 40 years.[1] Insulinomas may occur in childhood; in a study of 160 MEN1 patients presenting with manifestations before the age of 21 years, more than 10% of the cohort had insulinoma, with the earliest presentation at 5 years of age.[13] Indeed, insulinomas are the first manifestation of MEN1 in approximately 10% of patients, and approximately 5% of patients with insulinomas will have MEN1.[1,2,13] Patients typically present with hypoglycemic symptoms that develop after a fast or exertion and improve after glucose intake.[1] The most reliable test is a supervised 72-hour fast with biochemical investigations revealing increased plasma insulin, C-peptide, and proinsulin concentrations in association with hypoglycemia.[1] During this test, it is important to demonstrate an absence of sulfonylureas in the plasma and/or urine. The majority (65%–70%) of insulinomas in MEN1 occur as solitary pancreatic lesions, with most occurring in the body or tail, although multiple or multicentric tumors occur in 35%–40% of patients. However, patients diagnosed to have multifocal insulinomas have been reported to not have multiple insulin-staining tumors on histology, but instead to be likely have other pancreatic NET subtypes (e.g., nonfunctioning tumors).[37] Preoperative localization with EUS, CT scanning, MRI or celiac axis angiography, preoperative and perioperative percutaneous transhepatic portal venous sampling, selective intraarterial stimulation by calcium with hepatic venous sampling, and intraoperative direct pancreatic ultrasonography have been undertaken to improve the success rate of surgery.[1] SRS with ^{111}In-octreotide is associated with low sensitivity for insulinoma detection, although ^{68}Ga-DOTATATE PET/CT may improve detection rates. Scintigraphy based on glucagon-like peptide-1 has also been reported to be a highly sensitive modality for the detection of benign sporadic insulinomas, and its value in MEN1 patients with insulinoma has been demonstrated when used in conjunction with MRI.[41] The utility of FDG-PET/CT for insulinoma is typically limited to high-grade metastatic disease.

Treatment. Medical treatment, which consists of frequent carbohydrate meals and diazoxide or octreotide, is not always successful, and surgery is the treatment of choice in those with localized disease.[1,37] Surgical treatment, which ranges from enucleation of a single tumor to distal pancreatectomy or partial pancreatectomy, or excision of all the macroscopic pancreatic tumors with enucleation of nodules in the remaining pancreas, has been curative in many patients.[37] A recent retrospective study reported a 10-year hypoglycemia-free survival rate of greater than 90% following surgery for nonmetastatic disease.[37] Monitoring the insulin/glucose ratio during surgery has been reported to be of value in assessing successful removal of the insulinoma, as well as preventing intraoperative hypoglycemia and postoperative complications and infections. Insulinomas in MEN1 typically occur as benign tumors with highly favorable outcomes, although metastatic disease does occur in a minority of patients. Chemotherapy consisting of streptozotocin, 5-flurouracil, and doxorubicin, PPRT with ^{177}Lu-DOTATATE, or hepatic artery embolization have been used for metastatic disease.[1,4,17]

Glucagonoma. Glucagonomas, α islet cell glucagon-secreting pancreatic tumors, occur in less than 3% of patients with MEN1, although some nonfunctioning pancreatic NETs may immunostain for glucagon.[1] The characteristic clinical manifestations of a skin rash (necrolytic migratory erythema), weight loss, anemia, and stomatitis may be absent, and the presence of the tumor may have been detected in an asymptomatic patient with MEN1 undergoing pancreatic imaging or detected by glucose intolerance and hyperglucagonemia.[1]

Treatment. The tail of the pancreas is the most frequent site for glucagonomas, and surgical removal is the treatment of choice.[1,4] However, treatment may be difficult, because approximately 50% to 80% of patients have metastases at the time of diagnosis. Medical treatment with the SSAs octreotide and lanreotide or chemotherapy with streptozotocin and 5-fluorouracil or dimethyltriazeno-imidazole carboxamide has been successful in some patients, and hepatic artery embolization has been used to treat metastatic disease.[1,4]

Vasoactive Intestinal Polypeptidoma. Patients with VIPomas develop watery diarrhea, hypokalemia, and achlorhydria. This clinical syndrome has been referred to as Verner–Morrison syndrome, WDHA syndrome, or VIPoma syndrome. VIPomas have been reported in only a few patients with MEN1,[1] and the diagnosis is established by excluding laxative and diuretic abuse, confirming a stool volume in excess of 0.5 to 1.0 L/day during a fast, and documenting a markedly increased plasma VIP concentration.[1]

Treatment. Surgical management of VIPomas, which are mostly located in the tail of the pancreas, has been curative. However, in patients with unresectable tumor, treatment with SSAs, streptozotocin with 5-fluorouracil, corticosteroids, indomethacin, metoclopramide, and lithium carbonate has proved beneficial, and hepatic artery embolization has been useful for the treatment of metastases.[1]

Nonfunctioning Pancreatic Neuroendocrine Tumors. Nonfunctioning pancreatic NETs likely represent a heterogeneous group with distinct subtypes, with some nonfunctioning pancreatic NETs not secreting any hormones (also referred to as nonsecreting NETs) and therefore not associated with a clinical syndrome, and others associated with minor elevations (e.g., less than two times the upper limit of normal) of circulating pancreatic hormones (e.g., PP or glucagon) but without clinical features.[1] Thus, MEN1 patients with nonfunctioning pancreatic NETs may be asymptomatic, with the tumor detected during imaging tests, or they may present with symptoms related to local mass effects (i.e., pain and/or compression of adjacent structures) or metastatic disease (e.g., cachexia, jaundice, hepatomegaly). Currently, there are no reliable biomarkers for the detection of nonfunctioning pancreatic NETs, and several studies have reported a low diagnostic accuracy of PP, glucagon, and chromogranin A (CgA).[16,30,42,43] However, a recently developed test based on a multitranscript molecular signature for polymerase chain reaction–based blood analysis (referred to as the NETest) was reported in a study of patients with gastroenteropancreatic NETs to be a better predictor than CgA for progressive disease, tumor grade, and liver metastases.[44] A separate validation of the NETest is required in MEN1, because MEN1 patients often have multiple concomitant NETs that may be from different cellular origins.[16,30] The increasing sensitivity of radiologic surveillance methods has resulted in a greater identification of nonfunctioning pancreatic NETs. Thus, they are now the most prevalent pancreatic NET in MEN1 patients, with macroscopic tumors occurring in 15% to 55% of individuals,[4,16,17] although histopathological studies have reported that almost all MEN1 patients harbor nonfunctioning microadenomas.[17] Nonfunctioning pancreatic NETs, which are most frequently diagnosed in adult MEN1 patients, have also been identified in 5% to 40% of children and young adults aged 12 to 20 years.[13,45]

The identification of nonfunctioning pancreatic NETs is of particular clinical importance for several reasons. For example, malignant pancreatic NETs are now reported to be the most common cause of death in individuals with MEN1,[4,16,17] and have a worse prognosis than other functioning tumors, including insulinoma and gastrinoma. In addition, the absence of a clinical syndrome and specific biochemical abnormalities may result in a delayed diagnosis of nonfunctioning pancreatic NETs, unless a radiologic assessment is undertaken. However, the optimum screening method(s) for the detection of MEN1-associated pancreatic nonfunctioning NETs has not been established. A comparison of imaging modalities has demonstrated that EUS is likely to represent the most sensitive method for detecting small pancreatic tumors, while ^{68}Gallium-DOTA PET/CT is the most reliable method for detecting metastatic disease.[16,17] The use of EUS for screening is limited by its availability and patient acceptability, as well as the marked heterogeneity in sensitivity throughout the pancreas.[30] Furthermore, the value detecting small tumors (e.g., <1 cm) in asymptomatic individuals has yet to be fully evaluated. Based on the available evidence, as well as practical considerations and avoidance of ionizing radiation, MRI every 1 to 3 years is the preferred modality for nonfunctioning pancreatic NET surveillance in most centers, with EUS being reserved for additional characterization, as it allows the acquisition of tumor material via fine-needle aspirate for the analysis of tumor grade and/or additional molecular markers.[17,30]

Treatment. Management of asymptomatic nonfunctioning pancreatic NETs is controversial.[1,16,17] The goal of treatment is to reduce morbidity and mortality associated with metastatic disease while preserving pancreatic tissue and avoiding complications associated with surgery. Pancreatoduodenal surgery, which may be successful in tumor excision in approximately 80% of patients, may also result in complications that include diabetes mellitus, frequent steatorrhea, and early and late dumping syndromes. For example, in a study of 61 MEN1 patients who underwent surgery for nonfunctioning pancreatic NETs, approximately 35% were reported to develop major early complications, whereas approximately 25% developed endocrine or exocrine pancreatic insufficiency, with potential impacts on quality of life.[46] Other factors that should also be considered before undertaking surgery include the presence of occult metastatic disease (i.e., tumors not detected by imaging investigations) that may be present at the time of initial presentation, and that tumors may recur in remnant pancreatic tissue.[1]

Treatment recommendations are currently based on tumor size, as an increased rate of metastases is observed in patients with larger tumors.[15] For example, one study reported the presence of synchronous metastases in approximately 45% of patients with nonfunctioning NETs greater than 3 cm, approximately 20% of patients with NETs 2.1 to 3 cm, and less than 5% of patients with tumors less than 1 cm.[1] However, other studies have not confirmed this association, and tumor size is not universally correct at predicting metastatic risk, as a small percentage of patients with small tumors develop metastatic disease, thereby supporting the importance of World Health Organization (WHO) tumor-grading when considering management of these tumors. However, the majority of MEN1-associated nonfunctioning pancreatic NETs less than 2 cm seem to have an indolent behavior, with slow growth rates of 0.1 to 1.3 mm/year,[16,30,32,42,47] although some tumors will have faster growth rates, thereby suggesting that tumors can be stratified according to growth rates.[30,42,48] Biomarkers accurately predicting tumor behavior and/or disease course are currently unavailable. However, for tumors greater than 2 cm, a higher WHO tumor grade is reported to be associated with an increased risk of liver metastases (WHO G2 vs. G1 tumors = ~80% vs. ~25%).[49] Enhancer signatures that map gene regulatory networks have also been reported to be able to differentiate nonfunctioning pancreatic NETs into subtypes, based on their resemblance to islet α cells (defined by ARX expression) or β-cells (defined by PDX1 expression), with distant relapses being associated almost exclusively with ARX$^+$PDX$^-$ tumors.[50] This finding, which was observed in 61 MEN1 patients, indicated that tumor profiling may facilitate stratification of MEN1-associated pancreatic NETs and guide clinical follow-up.[50]

Currently, most centers advocate surgery for nonfunctioning pancreatic NETs greater than 2 cm (although some centers use a lower threshold of >1 cm) or tumors demonstrating rapid growth (e.g., doubling of size over a 3- to 6-month interval and exceeding 1 cm in diameter). Several studies have indicated that tumor size greater than 2 cm is associated with hepatic metastases and worse outcomes,[15,51] and surgery for nonfunctioning pancreatic NETs greater than 3 cm in MEN1 patients has been reported to be beneficial, as it reduced the occurrence of hepatic metastases or death to approximately 40% (i.e., six of 16 patients), compared with 80% (five of six patients) in the nonsurgery group.[32] However, such benefits of surgery for nonfunctioning pancreatic NETs 2 to 3 cm in size could not be established.[32] For smaller nonfunctioning pancreatic NETs (<2 cm) in MEN1 patients, a conservative (medical) approach is adopted by most centers, because studies have reported that approximately 70% of nonfunctioning pancreatic NETs less than 2 cm occurring in MEN1 patients remain stable over a median follow-up of 3 years[48]; approximately 60% (28 of 46) of MEN1 patients with nonfunctioning tumors less than 2 cm not undergoing surgery had stable disease for 10 years, while in the remaining approximately 40% who had an increase in size or number of tumors, only approximately 5% required surgery, and only one patient died from metastatic disease[47]; and progression-free survival (PFS) rates in MEN1 patients with nonfunctioning pancreatic NETs are not altered by surgery, as evidenced by similar PFS rates of approximately 65%, approximately 40%, and approximately 10% at 5, 10, and 15 years in the surgery (n = 27 patients) and nonsurgery (n = 33 patients) groups.[52] Medical therapies are therefore used to treat MEN1 patients with nonfunctioning pancreatic tumors less than 2 cm in size.

Medical therapies for small (i.e., <2 cm) nonfunctioning tumors include SSAs and use of long-acting octreotide, which has been reported to reduce or stabilize tumor load in approximately 10% and approximately 80% of MEN1 patients (n = 20), respectively; and lanreotide, which, when compared with active surveillance, has been reported in 42 MEN1 patients to be associated with improvements in objective tumor responses (lanreotide vs. active surveillance = ~15% [four of 23 patients] vs. 0%), stable disease (~65% [15 of 23 patients] vs. ~30% [6 of 19 patients]), and PFS over a median period of 6 years.[53] However, further studies are required to validate these findings and to determine whether SSA therapy reduces the risk of developing metastatic disease. For patients with advanced disease, treatments include locoregional and systemic approaches and are similar to those used for sporadic NETs.[1,4,17] However, the evidence base for the use of such treatments has typically arisen from the study of non-MEN1 patients, and extrapolation to the MEN1 population requires caution. For example, a study that demonstrated a significant benefit of SSA therapy in the treatment of metastatic enteropancreatic NETs excluded patients with MEN1; while studies demonstrating the efficacy of sunitinib, an RTK inhibitor, and everolimus, a mammalian target of rapamycin (mTOR) inhibitor in the treatment of advanced pancreatic NETs, included very few (n = 2), who were in the nontreatment arm, or unknown numbers of MEN1 patients, respectively. Additional treatments for advanced, metastatic disease include PRRT using ^{177}Lu-DOTATATE, systemic chemotherapy, and a variety of locoregional approaches (e.g., radiofrequency ablation, transarterial chemoembolization, and selective internal radiation therapy).[4,17]

Somatostatinoma. Pancreatic tumors secreting somatostatin are associated with the somatostatinoma syndrome, which is characterized by hyperglycemia, cholelithiasis, low acid output, steatorrhea, diarrhea, abdominal pain, anemia, and weight loss. Although approximately 5% of pancreatic islet cell tumors in MEN1 secrete somatostatin, the somatostatinoma syndrome has not been reported to date in MEN1.

GHRHoma. GHRHomas, or tumors that secrete growth hormone–releasing hormone (GHRH), have been reported in some patients with MEN1.[1] GHRHomas may be diagnosed by finding elevated serum concentrations of growth hormone and GHRH. In the context of MEN1, GHRHomas occur predominantly within the pancreas, although sporadic GHRHomas may arise in the lung or small intestine. Surgical removal is the treatment of choice for these tumors.

Pituitary Tumors

The incidence of pituitary tumors in patients with MEN1 varies from 15% to 50% in different series (see Table 133.1), and they may be the first presentation of MEN1 in 10% to 20% of patients.[1] Approximately 65% of MEN1-associated pituitary adenomas occur in female patients[19,54] and present in early adulthood, with a mean age of onset of 30 to 40 years, but they may occur earlier. For example, the youngest reported case of a MEN1 pituitary tumor was a prolactinoma in a 5-year-old boy, and in a study of 160 children presenting with manifestations of MEN1 before the age of 21 years, approximately 35% of the children had pituitary adenomas, with the majority arising between 15 and 20 years of age.[13] The majority of pituitary adenomas in MEN1 are microadenomas, with macroadenomas representing 25% to 35% of the tumors.[19,54] Pituitary tumors in MEN1 patients are reported to have a higher occurrence of invasive features but without a greater prevalence of pituitary carcinoma, and an increased prevalence of plurihormonal expression, when compared with their non-MEN1 counterparts, although no specific histological features are established to differentiate MEN1 from non-MEN1 pituitary tumors.[1]

Approximately 60% of the pituitary tumors in MEN1 patients are hormone-secreting, and the remaining approximately 40% are nonsecreting (nonfunctional). Among the hormone-secreting tumors, approximately 75% are prolactinomas, 5% to 15% are growth hormone (GH)-secreting tumors, approximately 5% are adrenocorticotrophic hormone (ACTH)-secreting tumors, less than 5% are gonadotroph-secreting tumors, and 5% to 10% are cosecreting tumors, for example, somatolactotrophinomas.[19,54] Approximately 75% of nonfunctioning pituitary adenomas, which may secrete glycoprotein subunits, are microadenomas, and the majority of these will remain stable for more than 5 years.[19,54] The clinical manifestations of each of the pituitary tumor types in patients with MEN1 are similar to those in patients with sporadic pituitary tumors and depend on the hormone secreted and the size of the pituitary tumor. Thus, patients may have symptoms related to hyperprolactinemia, acromegaly, or Cushing disease, while enlarging pituitary tumors may compress the optic chiasm or adjacent normal pituitary tissue resulting in visual disturbances, and/or hypopituitarism. The diagnosis and clinical investigation of MEN1 pituitary tumors is similar to that for sporadic pituitary tumors, including dynamic pituitary function testing and imaging to characterize the nature and extent of the tumor and determine any compromise on pituitary function.

KEY POINTS

- Pituitary tumors occur in 15% to 50% of multiple endocrine neoplasia type 1 patients and are the first presentation of disease in 10% to 20% of cases.

Treatment. Overall, the prognosis of pituitary tumors in patients with MEN1 is favorable, reflecting their typical benign features. Treatments of pituitary tumors in MEN1 patients are similar to those in patients without MEN1 and consist of appropriate medical therapy (e.g., bromocriptine or cabergoline for prolactinoma; or SSAs or GH receptor antagonists for somatotropinoma) or selective transsphenoidal adenomectomy if feasible, with radiotherapy reserved for residual unresectable tumor tissue.[1] Recent studies have reported that approximately 90% of MEN1 patients with prolactinomas respond well to dopamine agonist therapy,[19] and that the majority of asymptomatic nonfunctioning tumors managed conservatively remain stable (or demonstrate minimal growth) on serial imaging, with only a minority progressing and requiring surgical intervention.[19,54]

Associated Tumors

Carcinoid Tumors

Thymic Carcinoids. Thymic carcinoids occur in 2% to 8% of MEN1 patients and are associated with an aggressive disease course and an increased risk of death (HR = 4.29), such that they account for up to 20% of premature deaths in MEN1 patients.[1] The median age of diagnosis for thymic carcinoids in MEN1 patients is 40 to 45 years, and the median survival following diagnosis is approximately 9.5 years, with approximately 70% of patients dying as a direct result of the thymic tumor.[22,55] Earlier presentations of thymic carcinoids are reported and include a 16 year-old boy who died approximately 4 years following diagnosis with local and distant metastases.[13,22,55] Thymic carcinoids in European patients with MEN1 occur predominantly in men (male:female ratio = 20:1), with an increased prevalence in cigarette smokers; whereas in Japanese and Chinese MEN1 patients, thymic carcinoids have less marked gender differences (e.g., male:female ratio Japan = 2:1; China = 1:1). The majority of thymic carcinoids are nonsecretory, such that the features of carcinoid syndrome are absent, and the presentation is usually with clinical features resulting from the local effects of an anterior mediastinal mass (e.g., chest pain, vena caval obstruction), or from symptoms related to metastatic disease (e.g., to liver, lung, bone). However, the majority of patients are asymptomatic at diagnosis, with most tumors detected radiologically. Biochemical abnormalities (e.g., raised CgA or urinary 5-hydroxyindoleacetic acid) are insufficiently sensitive for tumor detection, and as such radiological surveillance is recommended, although the optimal screening methods have not been established, and there are also concerns regarding the repeated exposure to ionizing radiation that is associated with CT scans, which are considered to be more reliable for tumor detection (see later).[1]

The treatment of thymic carcinoids in MEN1 is dependent on the stage of presentation, as older age of presentation, larger tumor diameter, and presence of metastases are associated with worse outcome.[22,55] Complete surgical resection is the treatment of choice where possible, although recurrence rates following surgery are high. Adjuvant radiotherapy may be used where resection is considered incomplete. For patients with advanced disease, the potential treatment options are based on those used for sporadic thymic carcinoids and include chemotherapy (e.g., fluorouracil/temozolomide, etoposide/cisplatin), SSAs, radiotherapy, mTOR inhibitors (everolimus), and PRRT. Finally, it should be noted that, although transcervical thymectomy is recommended at the time of parathyroid surgery in MEN1 patients, this procedure does not reliably prevent thymic carcinoid development.

KEY POINTS

- Thymic carcinoid tumors occur in only 2% to 8% of multiple endocrine neoplasia type 1 patients but are associated with an aggressive disease course and account for 20% of premature deaths. Bronchopulmonary carcinoid tumors occur in 5% to 30% of patients, with equal sex distribution, and are often small (<1 cm) and multiple. Surgical resection is recommended, although in some settings tumor surveillance may be appropriate.

Bronchopulmonary Carcinoids. Bronchopulmonary carcinoid tumors occur in less than 5% to greater than 30% of MEN1 patients,[56,57] and it is important to distinguish these from alternative etiologies, including metastases from other tumors.[21,22,58] The median age of onset of bronchopulmonary carcinoids in MEN1 is 40 to 45 years,[56,57] with an approximately equal sex distribution and no reports of childhood presentations. Bronchopulmonary carcinoids are rarely hormonally-active, and patients may present with respiratory symptoms (e.g., cough, dyspnea), although increasingly they are diagnosed radiologically in asymptomatic patients and are frequently small (e.g., <1 cm), and may be multiple and/or bilateral.[57] Histologically, 50% to 75% of tumors have features of typical carcinoids, 25% to 30% are atypical carcinoids, approximately 5% are large cell neuroendocrine carcinomas (LCNECs), and approximately 5% are small cell neuroendocrine carcinomas (SCLCs).[22,56-58] The majority of bronchopulmonary NETs appear to have an indolent course and are not associated with increased mortality. For example, the 10-year survival was greater than 70% in one study of 42 MEN1 patients with bronchopulmonary NETs, and none of the deaths were directly related to the bronchopulmonary NET.[57] Another study of 51 MEN1 patients with bronchial NETs reported seven disease-related deaths, and three of these were associated with atypical carcinoids, three with SCLC, and one with LCNEC, thereby suggesting that patients with atypical carcinoids had a worse prognosis than those with typical carcinoids,[56] although this observation has not been confirmed in other studies.[57]

The diagnosis of bronchopulmonary NETs relies on imaging, together with histological confirmation undertaken with biopsy or at time of surgical resection. Thoracic imaging by FDG-PET/CT in MEN1 patients revealed that greater than 25% of patients had pulmonary nodules, and that these increased in size during follow-up in approximately 30% of patients with one or more FDG-avid lesions, with the tumor doubling time of the FDG-avid nodules being significantly less than that of non–FDG-avid nodules (24 months vs. 48 months, respectively).[58] Tumor growth rates have also been reported to be higher in males than females (tumor doubling time 2.5 vs. 5.5 years, respectively).[57] Histologic analysis is important, as it allows tumor characterization and grading (i.e., differentiating typical/atypical lesions) of the tumor and facilitates exclusion of other diagnoses (e.g., metastases from other sites). At present, surgical resection is the recommended treatment, although the increasing detection of multiple small nodules and evidence of slow growth rates indicate that tumor surveillance may be appropriate in some individuals. However, future studies are required to determine the optimal treatment of these tumors and to develop improved prognostic markers to guide decision-making.

Gastric Carcinoids. Type II gastric carcinoids (also referred to as enterochromaffin-like cell carcinoids (ECLomas) are observed in 15% to 70% of MEN1 patients with coexistent hypergastrinemia and are frequently detected incidentally at the time of upper gastrointestinal endoscopy. The tumors are usually small (e.g., <1.5 cm) and multiple, and SRS may demonstrate increased uptake in the stomach. Little is known about the malignant potential of ECLomas and where appropriate surgical resection may be appropriate, although treatment with SSAs such as octreotide or lanreotide has resulted in regression of these tumors.[1]

Adrenocortical Tumors. The incidence of adrenocortical tumors in patients with MEN1 is reported to be 20% to 55%, although a higher frequency of approximately 75% has been reported when sensitive imaging modalities (e.g., EUS) are used.[13,20] Most patients are asymptomatic, as the majority of these tumors are nonfunctioning, but manifestations of hormonal hypersecretion occur in less than 10% of patients, and among these primary hyperaldosteronism and ACTH-independent Cushing syndrome are the most common.[20] Occasionally, hyperandrogenemia may occur in association with adrenocortical carcinoma, and the occurrence of pheochromocytoma is rare (<2% of lesions).[20] Adrenal tumors are typically diagnosed in adulthood, with a mean age of 46 years (range: 2–78 years),[20] although severe presentations in childhood are reported and include a 3-year old boy with adrenocortical carcinoma manifesting as precocious puberty.[20] Some MEN1 kindreds are reported to have increased occurrence of adrenal tumors, including adrenal carcinoma, and in such families increased vigilance in screening for adrenal tumors is required. Biochemical investigation (e.g., plasma renin and aldosterone concentrations, low-dose dexamethasone suppression test, and plasma or urinary catecholamines, and/or metanephrines) should be undertaken in patients with symptoms or signs suggestive of functioning adrenal tumors or with tumors greater than 1 cm.[1] The incidence of adrenocortical carcinoma is approximately 1% in MEN1 patients, but this is higher, at 10% to 15%, in MEN1 patients with adrenal tumors greater than 1 cm,[20] and interval surveillance imaging at least annually is therefore recommended in these patients (see Table 133.2).

Treatment. Consensus has not been reached about the management of MEN1–associated nonfunctioning tumors, as the majority are benign.[1] However, the risk for malignancy is increased if the tumor has a diameter greater than 4 cm, although adrenocortical carcinomas have been identified in tumors less than 4 cm in MEN1 patients.[1,20] Surgery is recommended for adrenal tumors that are greater than 4 cm in diameter, have atypical or suspicious radiologic features (e.g., increased Hounsfield units on unenhanced CT) and are 1 to 4 cm in diameter, or show significant measurable growth over a 6-month interval.[1,20] The treatment of functioning (i.e., secreting) adrenal tumors in MEN1 patients is similar to that for tumors occurring in non-MEN1 patients.

Central Nervous System Tumors. Central nervous system tumors including ependymomas, schwannomas, and meningiomas have been reported in MEN1 patients (see Table 133.1). Meningiomas are found in less than 10% of MEN1 patients; the majority of these were not associated with symptoms, and approximately 60% did not enlarge.[1] The treatment of patients with MEN1-associated meningiomas is similar to of non-MEN1 patients.

Lipomas. Subcutaneous lipomas may occur in 15% to 35% of patients with MEN1,[1] and frequently they are multiple (see Table 133.1). In addition, visceral, pleural, or retroperitoneal lipomas may occur in patients with MEN1. Management is conservative. However, when surgically removed for cosmetic reasons, they typically do not recur.

Facial Angiofibromas and Collagenomas. Studies of patients with MEN1 have revealed that multiple facial angiofibromas occur in approximately 20% to 90%, and collagenomas in 0% to great than 70%, of patients (see Table 133.1).[1] MEN1 angiofibromas are clinically and histologically identical to those observed in patients with tuberous sclerosis, with the exception that, in patients with MEN1, angiofibromas are also present on the upper lip and vermilion border of the lip, which are areas not involved in tuberous sclerosis. These cutaneous findings, which occur with a higher frequency in patients with MEN1, may provide a useful means for possible presymptomatic diagnosis of MEN1 in the relatives of a patient with MEN1. Treatment for these cutaneous lesions is usually not required.

Thyroid Tumors. Thyroid adenomas, colloid goiters, and carcinomas have been reported to occur in more than 25% of patients with MEN1.[1] However, the prevalence of thyroid disorders in the general population is high, and it has been suggested that the association of thyroid abnormalities in patients with MEN1 may be incidental and not significant.[1] The treatment of thyroid tumors in MEN1 patients is similar to that for non-MEN1 patients.

Breast Cancer. Female MEN1 patients are reported to have an increased risk of breast cancer (relative risk 2.3–2.8).[14,59] The majority of breast tumors are of ductal type, with mixed hormone receptor (estrogen receptor [ER[, progesterone receptor and human epidermal growth factor receptor) status.[14,59,60] Some of these tumors have reduced menin expression and loss of heterozygosity (LOH) of the *MEN1* locus, in keeping with a tumor suppressor function, and this is supported by *in vitro* studies demonstrating that menin may exert an antiproliferative effect in

TABLE 133.2 **Suggested Biochemical and Radiologic Screening in Individuals at High Risk for Developing Multiple Endocrine Neoplasia Type 1**

Tumor	Age to Begin (Years)	Biochemical Test (Plasma or Serum) Annually	Imaging Test (Time Interval)
Parathyroid	8	Calcium, PTH	None
Pancreatic NETs			
Gastrinoma	20	Fasting gastrin	None
Insulinoma	5	Fasting glucose, insulin	None
Other pancreatic NET	<10	Chromogranin A; gastrointestinal hormone profile[a] (e.g., pancreatic polypeptide, glucagon, vasoactive intestinal peptide)	MRI, or EUS (annually)
Anterior pituitary	5	Prolactin, IGF-1	MRI (every 3 years)
Adrenal	<10	None unless symptoms or signs of functioning tumor and/or tumor >1 cm on imaging	MRI or CT (annually with pancreatic imaging)
Thymic and bronchial carcinoid	15	None	CT[b] or MRI (every 1–2 years)

[a] Chromogranin A, pancreatic polypeptide, and glucagon concentrations can be elevated with nonfunctioning pancreatic NETs, but they have low sensitivity and specificity, and their value is debatable.

[b] CT scanning has been suggested for the detection of thymic and or bronchial carcinoids, but there is a concern over the potential for high cumulative doses of ionizing radiation, such that some have advocated utilizing "low-dose" CT protocols or MRI.

CT, Computed tomography; *EUS,* endoscopic ultrasound; *MRI,* magnetic resonance imaging; *NET*, neuroendocrine tumor; *PTH*, parathyroid hormone; *IGF-1*, insulin-like growth factor-1.

(Modified from Thakker RV, Newey PJ, Walls GV, et al. Clinical practice guidelines for multiple endocrine neoplasia type 1 (MEN1). *J Clin Endocrinol Metab.* 2012;97: 2990–3011.)

normal mammary epithelium, although paradoxically it is reported to promote proliferation in sporadic ER-positive breast cancers.[60] The increase in breast cancer risk is not related to other known risk factors, and some centers now advocate breast screening in female MEN1 patients older than 40 years.[59]

Other Clinical Considerations

Gestational diabetes, hypertension, low birth weight, increased childhood mortality, and higher risk of venous thromboembolism (VTE) are reported to be associated with MEN1.[61-64] Thus, analysis of 96 pregnancies in 26 women with MEN1 revealed that maternal MEN1 was associated with increased prevalence of gestational diabetes, hypertensive disorders and low neonatal birth weight that resulted in admission to a neonatal unit (independent of maternal antenatal hypercalcemia), and that parathyroidectomy or medical management of hypercalcemia in women (n = 16) with confirmed hyperparathyroidism was only required in one and four pregnancies, respectively.[61,62] In addition, children born to a parent with MEN1 had an excess mortality by 15 years of age.[61] Patients did not have subfertility or infertility (except perhaps a subset of mothers with pituitary disease) or increased miscarriage rates.[63] Finally, MEN1 patients have been reported to have increased risk of VTE, as approximately 13% of 286 MEN1 patients had experienced a VTE event, which represents a lifetime incidence twice that of the general population, and approximately 80% of these events occurred in patients with pancreatic NETs, with only approximately 40% occurring in the perioperative period.[64]

MOLECULAR GENETICS

The *MEN1* Gene

The *MEN1* gene is located on chromosome 11q13 and consists of 10 exons that encode *menin,* a 610–amino acid protein[9,10] that regulates transcription, genome stability, cell division, and proliferation through direct associations with interacting protein partners or indirectly via the modulation of multiple cellular signaling pathways (Figs. 133.3 and Fig.133.4).[2a,3,4,11,65] Patients with MEN1 typically harbor a germline heterozygous *MEN1* mutation, which predisposes an individual to tumor development; however, tumorigenesis requires somatic inactivation of the wild-type *MEN1* allele, resulting in biallelic inactivation of the *MEN1* gene, consistent with Knudson's "two-hit" model of inherited tumorigenesis and a tumor suppressor function for menin in endocrine tissues. Somatic inactivation of the wild-type *MEN1* allele results from a large-scale deletion at the 11q13 locus, which manifests as LOH of the tumor DNA in greater than 90% of tumors, and in the remaining approximately 10% of tumors this inactivation may be caused by single nucleotide variants (SNVs) resulting in nonsense or missense amino acid substitutions, or small insertions or deletions (indels).[1,11]

The *MEN1* gene spans 7.7 kb of genomic DNA, and up to 19 different transcripts have been identified, of which 15 are predicted to result in protein products ranging from 146 to 652 amino acids. The main transcript of the *MEN1* gene is reported to be a 2.76-kb mRNA encoding a 610–amino acid isoform of menin, although the canonical transcript, which is 3.16 kb in length, elongates the reading frame by 15 nucleotides at the exon 2/intron 2 boundary and results in a protein isoform of 615 amino acids. *MEN1* transcripts and menin protein have been detected in all human tissues examined, with expression regulated at least in part by a 1400-bp region upstream of exon 2 that displays strong promoter activity, with additional mechanisms including an autoregulatory negative feedback loop, and microRNAs (e.g., miR24-1).[11] The *MEN1* gene and menin protein are highly evolutionary conserved in mammalian species (e.g., ~89% and ~97% DNA and protein identity, respectively, between human and mouse), while orthologs of menin are found in distant vertebrate (e.g., zebrafish) and invertebrate (e.g., *Drosophila*) species, although not in nematodes (e.g., *Caenorhabditis elegans*) or yeast (e.g., *Saccharomyces cerevisiae*). Recent analysis of population-level genetic data indicates that the *MEN1* coding region is under evolutionary constraint against genetic variation.[66]

KEY POINTS

- The *MEN1* gene encodes a 610–amino acid tumor suppressor protein, menin, which has tissue-specific and context-dependent roles in transcription regulation, genome stability, cell division, proliferation, and epigenetic regulation.

Fig. 133.3 **Schematic representation of the genomic organization of the *MEN1* gene, its encoded protein (menin), and regions that interact with other proteins. A,** The human *MEN1* gene consists of 10 exons that span more than 9 kb of genomic DNA and encodes a 610–amino-acid protein. The 1.83-kb coding region *(dark blue)* is organized into nine exons (exons 2 to 10) and eight introns (indicated by a *line* but not to scale). The sizes of the exons *(boxes)* range from 41 to 1297 bp, and that of the introns range from 80 to 1564 bp. The start (ATG) and stop (TGA) codons in exons 2 and 10, respectively, are indicated. Exon 1, the 5′ part of exon 2, and the 3′ part of exon 10 are untranslated *(light blue).* The promoter region I is located within a few 100 bp upstream of exon 2. The sites of nine germline mutations which have been reported to occur with a frequency >1.5% are represented by red bars with the affected codon number(s) shown. These germline mutations, which collectively represented approximately 20% of all reported mutations include: c.249_252delGTCT (codons 83–84); c.292C>T (codon 98); c.358_360delAAG (codon 120); c.628_631delACAG (codon 210-211); c.784-9G>A (intron 4); c.1243C>T (codon 415); c.1378C>T (codon 460); c.1546delC (codon 516); and c.1546_1547insC (codon 516).** Indicates the two different recurrent germline mutations affecting codon 516. The respective frequency of these mutations is dependent on the populations studied and varies by geographical region. The frequent occurrence of the same germline mutations in apparently unrelated kindreds may indicate the presence of founder mutations or regions of genomic DNA more prone to mutation. Codons reported to be affected by more than four different germline mutations are represented by black bars with respective codon numbers. The locations of these mutations are reported with reference to the transcript encoding the 610–amino acid menin protein (i.e., NM_130799), while it is important to note that the majority of contemporary variant databases report such *MEN1* variants according to the longer transcript encoding the 615–amino acid protein (i.e., NM_000244.3). **B,** Menin has three nuclear localization signals (NLSs) at codons 479–497 (NLS1), 546–572 (NLSa), and 588–608 (NLS2) indicated by *dark blue bars* and five putative guanosine triphosphatase (GTPase) sites (G1–G5) indicated by *dark blue.* **C,** Menin regions that have been implicated in the binding to different interacting proteins are indicated by *light blue boxes.* Illustrative examples of some key interactions are shown. *Recent crystal structure studies indicate that MLL1 and JunD utilize the same binding pocket of menin; the individual domains required for the JunD/menin interaction have been characterized, whereas those for the MLL1/menin interaction remain to be elucidated. (Modified and updated from Lemos MC, Thakker RV. Multiple endocrine neoplasia type 1 [MEN1]: Analysis of 1336 mutations reported in the first decade following identification of the gene. *Hum Mutat.* 2008;29:22–32.)

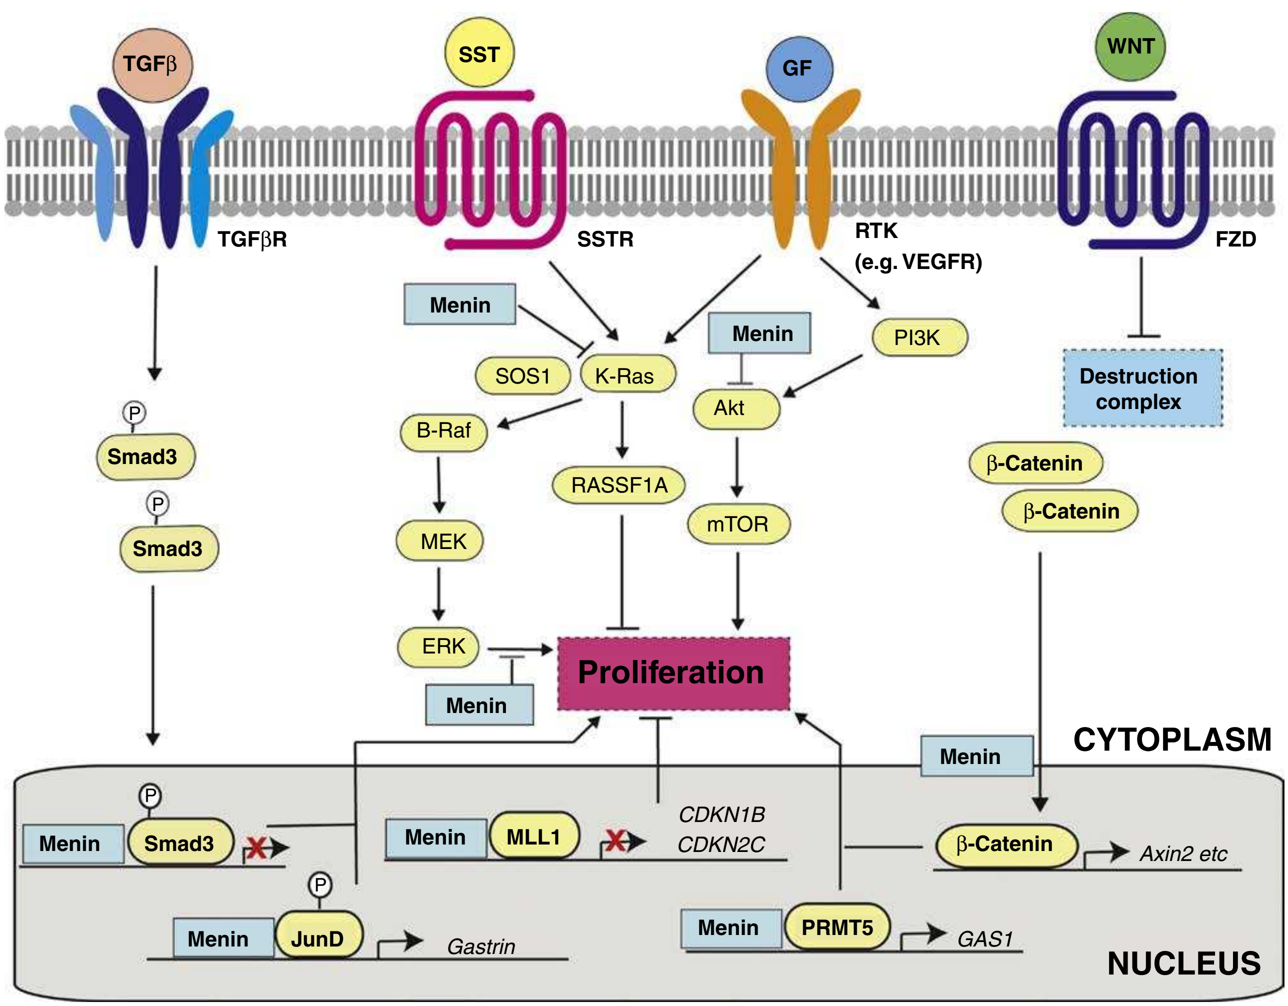

Fig. 133.4 Roles of menin in cell proliferation. Loss of menin expression *(blue boxes)* in endocrine tissues may result in increased cell proliferation by multiple pathways. In the nucleus, loss of menin results in disruption of its interaction with transcription factors JUND and PRMT5, which lifts the transcriptional repression of target genes including *Gastrin* and *GAS1*, respectively; binding to MLL1, MLL2, and SMAD3 (a TGFβ signaling component) to promote transcription of target genes; and ability to regulate the WNT pathway, as β-catenin is no longer prevented from entering the nucleus by menin, thereby enabling transcription of WNT pathway target genes. Interactions with additional transcription factors and chromatin-modifying protein complexes may further modulate oncogenic signaling pathways. In the cytoplasm, loss of menin reduces its inhibitory actions on the mTOR pathway by binding to AKT (downstream of PI3K, part of the RTK signaling pathway) and preventing its translocation to the plasma membrane; and KRAS-induced proliferation (by possible inhibition of ERK-dependent phosphorylation [P] and prevention of the interaction between SOS1 and KRAS). All pathways affect proliferation, which involves both nuclear and cytoplasmic mechanisms (shown in the cytoplasm only). Examples of ligands and their respective receptors are shown. *FZD*, Frizzled; *GF*, growth factor; *TGFβR*, transforming growth factor β receptor; *RTK*, receptor tyrosine kinase; *SST*, somatostatin; *SSTR*, somatostatin receptor. (Modified from Frost M, Lines KE, Thakker RV. Current and emerging therapies for PNETs in patients with or without MEN1. *Nat Rev Endocrinol* (2018); 14;216–227.)

MEN1 Germline Mutations

To date, more than 1200 germline mutations of the *MEN1* gene (see Fig. 133.3) have been reported in patients with MEN1, or those with associated tumors, and amongst these greater than 600 different mutations are reported.[47] The majority of pathogenic variants (~70%) are predicted to result in a loss of function through premature truncation of the menin protein (i.e., frameshift indels (35%–45%), nonsense SNVs (~15%–20%), or splice site variants (~10%), whereas the remainder result from missense SNVs (20%–25%), in-frame indels (~5%), or gross deletions of all or part of the *MEN1* gene (1%–2.5%).[11,67] The mechanisms leading to large-scale deletions are poorly understood, although a study of a patient with an entire *MEN1* gene deletion noted *Alu* repetitive elements flanking the respective breakpoints, indicating that an *Alu/Alu*-mediated rearrangement may have been responsible for the deletion.[68] Deletions may occur in the noncoding regions of the *MEN1* gene, as illustrated by a study of identical twins that identified a 596-bp deletion involving the 5′ untranslated region (UTR).[23] The majority (~90%) of *MEN1* mutations are inherited from a parent, but approximately 10% occur *de novo*, and studies using next-generation sequencing (NGS) have also identified individuals who are mosaic for *MEN1* mutations.[69]

The mutations affecting the *MEN1* coding region occur throughout the length of the gene, with no obvious clustering, although several variants are reported multiple times in apparently independent kindreds. In addition, at least 11 codons (45, 69, 70, 139, 156, 183, 220, 253, 418, 436, 516) are reported to be affected by more than four different *MEN1* pathogenic variants, indicating that specific regions of the *MEN1* gene may be more prone to mutation, and it is notable that some of these mutations occur within repetitive DNA sequences, consistent with a replication-slippage model of mutagenesis.[11]

A consistent genotype-phenotype correlation has not been observed in MEN1, and studies of several large MEN1 families each harboring the same *MEN1* mutation have shown that members of the respective families develop a different range of tumors.[1,2,11] However, a correlation between *MEN1* mutations affecting the menin checkpoint kinase 1 interaction domain (i.e., codons 428–610) and a higher frequency of aggressive pancreatic NETs and death is reported, while those involving the JunD-interacting domains are reported to be associated with an increased risk of premature death, although these studies require validation. Some kindreds with *MEN1* mutations do not appear to manifest the full clinical phenotype; for example, kindreds harboring the Burin (or "prolactinoma") *MEN1* variant (i.e., Tyr312Ter) are reported to have a high frequency of prolactinoma but a low incidence of gastrinoma; whereas an absence of GH-secreting pituitary adenomas is observed in a large Tasmanian kindred with a splice site variant (c.444-CC>G), thereby indicating that additional genetic factors may influence MEN1 clinical expression. A minority of families with *MEN1* mutations are reported to only manifest parathyroid tumors, referred to as familial isolated hyperparathyroidism (FIHP). A higher prevalence of missense variants are reported in FIHP kindreds compared with MEN1 (~40% vs. ~25%, $P < .01$), with several of these FIHP-associated missense mutations reported to retain menin protein stability and biological activity, potentially consistent with a milder phenotype.[11] However, some FIHP kindreds harbor protein-truncating mutations (e.g., nonsense, frameshift), indicating that genetic modifying influences are also likely to be present. Other studies have reported decreases in the strength of intrafamilial correlation for pituitary, adrenal, and thymic NETs with genetic dilution, thereby further supporting the role of likely genetic modifiers.[56,70]

Between 5% and 25% of patients with a clinical diagnosis of MEN1 do not harbor mutations in the *MEN1* coding region, and a minority of these individuals may have mutations in the promoter or UTRs, or alternatively represent phenocopies with mutations in other genes (see later). However, the possibility that *MEN1* mutations may not have been detected by use of conventional methods should be considered, as a study using whole-genome sequencing (WGS) has reported identifying *MEN1* mutations in greater than 20% of such patients ($n = 14$).[71] Recent studies indicate that patients with a clinical diagnosis of MEN1 (i.e., at least two MEN1 manifestations), but negative *MEN1* genetic testing, have a different clinical course to those with *MEN1* mutations, including a later age of first tumor diagnosis, a higher prevalence of single-gland parathyroid disease, the rare occurrence of three MEN1 manifestations, and a greater life expectancy,[72,73] which all suggest that a substantial proportion of such patients may have the cooccurrence of two sporadic tumors rather than a hereditary MEN1 syndrome.

MEN1 Germline Coding Variants

Five common (allele frequency [AF] >0.5%) germline coding variants are observed in the *MEN1* gene, including three synonymous and two nonsynonymous variants that result in p.Thr546Ala and p.Arg176Gln in the canonical transcript. However, a wide spectrum of rare coding variants (AF <0.5%) are observed in the background population, and greater than 200 nonsynonymous *MEN1* SNVs are reported in the GnomAD dataset (http://gnomAD.broadinstitute/org/), with the majority of these being unlikely to be of clinical significance, although their presence may confound interpretation of genetic test results.[66,74]

MEN1 Somatic Mutations

The role of the *MEN1* gene in sporadic endocrine tumorigenesis has been investigated, and somatic biallelic inactivation of the *MEN1* gene is reported at varying frequencies in other endocrine tumors. For example, somatic *MEN1* mutations are reported in 20% to 35% of sporadic parathyroid tumors, approximately 45% of nonfunctioning pancreatic NETs, 40% of gastrinomas, 0% to 15% of insulinomas, 15% to 20% of bronchopulmonary carcinoids, 3% to 5% of anterior pituitary adenomas, less than 3% of small intestinal NETs, and less than 3% of adrenocortical tumors. These somatic mutations occur throughout the coding region and comprise protein-truncating (i.e., nonsense, frameshift) and missense variants. Currently, identifying somatic *MEN1* mutations in tumor tissue has little clinical utility, but in the future it may help for prognostication, for example, the presence of somatic *MEN1* mutations in pancreatic NETs and absence of chromosomal instability gene mutations (e.g., *DAXX*, *ATRX*), have been reported to be associated with favorable outcomes[75] or stratification for personalized treatment approaches, for example, as reported for selpercatinib in *RET*-altered thyroid cancers.[76]

MEN1 Phenocopies and Mutations in Other Genes

Phenocopies are reported in 5% to 10% of MEN1 kindreds and may occur in different clinical settings. For example, phenocopies have been reported in the context of familial MEN1, in which a member of the kindred has a clinical manifestation of MEN1 (e.g., pituitary adenoma or primary hyperparathyroidism) but is subsequently found not to harbor the familial *MEN1* mutation (i.e., likely representing a coincidental sporadic occurrence of the tumor). Patients with a clinical diagnosis of MEN1 (i.e., with two or more MEN1-associated tumors) may also represent phenocopies, whereby they do not manifest a *MEN1* mutation, but instead have a mutation in another gene, more typically associated with a different disease.[1] Such genes include *CDC73*, which encodes the tumor suppressor parafibromin, mutations of which are associated with the hyperparathyroidism-jaw tumor syndrome,[71,77] *CASR*, which encodes the calcium-sensing receptor, mutations of which are associated with familial hypocalciuric hypercalcemia,[71] and *AIP* (also located at chromosome 11q13), which encodes the aryl hydrocarbon interacting protein, mutations of which are associated with familial isolated pituitary adenoma. Less than 5% of patients with a clinical diagnosis of MEN1 who do not harbor a mutation in the *MEN1* gene may instead harbor mutations in *CDKN1B*, located on chromosome 12p13, which encodes the cyclin-dependent kinase inhibitor p27$^{\mathrm{kip}}$ and results in the associated disorder MEN4.[5,6] To date, fewer than 50 MEN4 patients (from <20 kindreds) have been reported, such that the clinical phenotype and its associated penetrance are not fully characterized.[6] Patients with MEN4 are reported to predominantly express parathyroid and pituitary tumors in association with pancreatic, gastrointestinal, bronchial, and cervical NETs, nonfunctional adrenal tumors, papillary thyroid cancer, lipoma, and breast cancer.[6] Primary hyperparathyroidism occurs in approximately 80% of MEN4 cases, but at a later age than in MEN1 (e.g., typically after age 40 years, but as young as 15 years). Pituitary adenomas, which include GH- and ACTH-secreting adenomas, prolactinomas, and nonfunctioning adenomas, are reported in 30% to 40% of MEN4 patients, and duodenal-pancreatic NETs in 5% to 30% of MEN4 cases.[6] The investigation and treatment of these tumors are similar to those described for MEN1. The germline *CDKN1B* mutations observed in MEN4 include protein-truncating (i.e., nonsense, frameshift, splice site) and missense variants, with the majority resulting in reduced levels of $p27^{kip}$ protein, or altered protein function, consistent with a tumor suppressor function. Germline missense *CDKN1B* variants have also been reported in patients with apparently sporadic parathyroid adenomas, although the relative high background frequency of rare nonsynonymous variants in the Cyclin Dependent Kinase Inhibitor (CDKI) genes suggests that some of these variants represent benign alleles.[66] The $p27^{kip}$ protein is involved in cell cycle regulation, and particularly in controlling the G1/S-phase checkpoint by binding to cyclin E/cdk2, thereby inhibiting cell cycle progression. Downregulation of $p27^{kip}$ is observed in several cancers (e.g., stomach, breast, colon), while somatic *CDKN1B* mutations are observed in a small percentage of small intestinal NETs, in keeping with a tumor suppressor function.

Thus, the possibility of a phenocopy or alternate genetic diagnosis should be considered in patients presenting with typical or atypical manifestations of MEN1 in whom a *MEN1* mutation is not found, although it is recommended that all kindred members in families with a known *MEN1* mutation undergo genetic testing, irrespective of the presence or absence of clinical features.[1]

MEN1 Mutational Analysis in Clinical Practice

MEN1 mutational analysis is helpful in clinical practice in several ways, including: (1) confirmation of the clinical diagnosis; (2) identification of family members who harbor the *MEN1* mutation and require screening for tumor detection and early/appropriate treatment; (3) identification of family members who do not harbor the familial germline *MEN1* mutation and can therefore be reassured and alleviated of the anxiety burden of developing future tumors; and (4) facilitation of preconception genetic counseling and, in some settings, preimplantation genetic diagnosis (PGD) (Table 133.3).

TABLE 133.3 Suggested Approach for Multiple Endocrine Neoplasia Type 1 Mutation Analysis in a Clinical Setting

Value in Clinical Setting

- Aid in confirming the diagnosis
- Identify mutation carriers in a family for screening and development of tumors, thereby facilitating early treatment
- Identify the 50% of family members who do not harbor the *MEN1* mutation, thereby alleviating the anxiety and burden of disease from them and their progeny
- Facilitate preconception genetic counseling (and the potential for preimplantation genetic diagnosis)

Who should be tested?

In an index case

- Meeting the clinical criteria for multiple endocrine neoplasia type 1 (i.e., two or more MEN1-associated tumors or a diagnosis of familial MEN1)
- Suspicious (i.e., multiple parathyroid adenomas before 40 years of age; recurrent hyperparathyroidism; gastrinoma or multiple pancreatic neuroendocrine tumors at any age) or atypical for MEN1 (i.e., development of two nonclassical MEN1-associated tumors, e.g., parathyroid and adrenal tumor)

A first-degree relative of family member with known MEN1 mutation

- Asymptomatic first-degree relative
- First-degree relative with familial MEN1 (i.e., one MEN1-associated tumor)

When should testing be undertaken?

- As early as possible (e.g., <5 years of age for asymptomatic individuals)

Where should testing be performed?

- In an accredited department/laboratory undertaking DNA testing of *MEN1* gene

(Modified from Thakker RV, Newey PJ, Walls GV, et al. Clinical practice guidelines for multiple endocrine neoplasia type 1 (MEN1). *J Clin Endocrinol Metab.* 2012;97: 2990–3011.)

Current guidelines[1] recommend that *MEN1* mutational analysis should be undertaken in: (1) an index case with two or more of the major MEN1-associated endocrine tumors (i.e., parathyroid, pancreatic, or pituitary tumors); (2) all first-degree relatives of a known *MEN1* mutation carrier, irrespective of whether they are symptomatic or manifest associated clinical features; (3) patients with suspicious or atypical MEN1, which includes individuals with parathyroid adenomas occurring before 30 years of age or multigland parathyroid disease, gastrinoma, or multiple pancreatic NETs at any age, or individuals who have two or more MEN1-associated tumors that are not part of the classical triad of parathyroid, pancreatic islet, and anterior pituitary tumors (e.g., parathyroid tumor plus adrenal tumor) (see Table 133.3).[1] Several studies have evaluated these recommendations in different clinical settings and confirmed that tumor multiplicity, a family history of MEN1, and/or young age of tumor onset are the strongest predictive indicators for the individual to have an *MEN1* mutation. Thus, one study of 200 patients with endocrine tumors has reported that *MEN1* mutations were present in greater than 70% of individuals with two or more of the major MEN1-associated tumors and a family history of relevant tumors; approximately 60% of patients with at least one of the major endocrine tumors and a first-degree relative with one of the major tumors; and only approximately 5% of patients with sporadic (i.e., nonfamilial) MEN1-associated tumors, although all of these patients had an onset of disease before the age of 30 years, and/or multiple tumors, thereby highlighting the importance of genetic testing in younger patients. Another study of 292 patients reported identification of *MEN1* mutations in 80% of index cases who presented with three MEN1-related tumors, and this increased to greater than 90% if there was a history of a relative with an associated MEN1 tumor; but only 15% of patients who presented with a single MEN1-associated tumor, and this decreased to 0% if family history of endocrine neoplasia was absent. Furthermore, the strongest predictors for the presence of an *MEN1* mutation from a study of 365 patients with sporadic endocrine tumors (i.e., patients without a clinical diagnosis of MEN1, or known family history of MEN1), were reported to be recurrent or multigland primary hyperparathyroidism; nonrecurrent primary hyperparathyroidism with an additional risk factor, such as relevant family history or young age of onset; and occurrence of NETs of the gastrointestine, pancreas, bronchi, or thymus.[78] In addition, a study of 205 patients with primary hyperparathyroidism and an associated family history of primary hyperparathyroidism, which identified a *MEN1* mutation in approximately 45% of cases, found that multigland disease, male sex, and age less than 45 years were each independent predictors for the presence of a germline *MEN1* mutation (odds ratios of 14, ~1.5, and ~8, respectively).[78] However, patients with acromegaly and coexistent primary hyperparathyroidism[79] or patients presenting with pituitary adenomas and pheochromocytoma/paraganglioma (i.e., "atypical" MEN1) have been reported to have a low occurrence (0%–5%) of germline *MEN1* mutations.[80]

Once a genetic diagnosis of MEN1 has been established in an index case, predictive testing should be offered to first-degree relatives, and current guidelines recommend that this should be undertaken at the earliest opportunity.[1] Delays in diagnosis of MEN1 are common, and a median lag time of approximately 3.5 years has been reported between index case diagnosis and that of subsequent family members, leading to higher rates of metastatic disease in family members.[81,82] The delay in diagnosis may be because of multiple reasons, which include the relevant information not being available to the patient (or doctors) because they may be unaware of relevant family history because of medical information not being shared between family members (and/or medical teams); geographical or social separation of family members; relatives dying prematurely of causes unrelated to the disorder; or incomplete or variable penetrance of manifestations.[74] There are also potential ethical issues to consider for predictive testing, and therefore individuals should receive appropriate genetic counseling, especially as many MEN1 patients are fearful of disease occurrence, both for themselves and their relatives, and this may be compounded by investigations and regular surveillance screening.[83]

Predictive testing in young children, which requires parental/guardian consent, is important because MEN1-associated tumors may develop at an early age, and the current guidelines therefore recommend that genetic testing of asymptomatic children should be undertaken in the first decade of life, and ideally before 5 years of age. Preconception genetic counseling can also be provided to individuals at risk of transmitting MEN1 to their future offspring, and advances in genetic testing combined with *in vitro* fertilization now facilitate PGD, in which direct sequencing of DNA from a small number of cells removed from the early blastocyst facilitates implantation of embryos without the *MEN1* mutation.[74]

Genetic testing for MEN1 should be undertaken in accredited genetic diagnostic laboratories and include DNA sequence analysis of all exonic and splice site regions of the *MEN1* gene, and, in those without *MEN1* mutations, multiplex ligation-dependent probe amplification (MLPA) should be considered to detect partial or whole gene deletions. The identified DNA sequence variants (i.e., SNVs, indels) should then be assessed for variant pathogenicity using validated methods; many centers adopt the American College of Medical Genetics and Genomics (ACMG) guidelines.[84] These ACMG guidelines consider multiple variant- and gene-specific factors in categorizing variants into benign or pathogenic categories, but this may not be able to achieve a definitive classification (i.e., benign/likely benign or pathogenic/likely pathogenic), but instead yield a "variant of uncertain significance" status.[84] This situation mostly arises for rare missense variants for which there is either insufficient or conflicting evidence to support a definitive classification.[66,74] A recent report that places additional weight on phenotype data to improve the accuracy of genetic test reporting for MEN1 has recommended a MEN1-specific adjustment to the ACMG criteria.[85] Other approaches aimed at improving *MEN1* variant interpretation include *in silico* and/or bioinformatic analysis modeling; for example, thermodynamic analysis of protein structure was used to evaluate the impact of 338 missense *MEN1* variants, and this facilitated discrimination between pathogenic and benign variants.[86] Finally, if initial genetic testing by DNA sequence analysis and MLPA has failed to identify a *MEN1* mutation in a patient for whom there is a strong clinical suspicion for MEN1, then *MEN1* mosaicism and repeat testing should be considered using a different method such as NGS, for example, WGS with a greater depth of DNA sequencing, which has been reported to successfully identify *MEN1* mutations in greater than 20% of cases (three of 14).[69,71]

SURVEILLANCE OF INDIVIDUALS AT RISK OF MULTIPLE ENDOCRINE NEOPLASIA TYPE 1 TUMORS

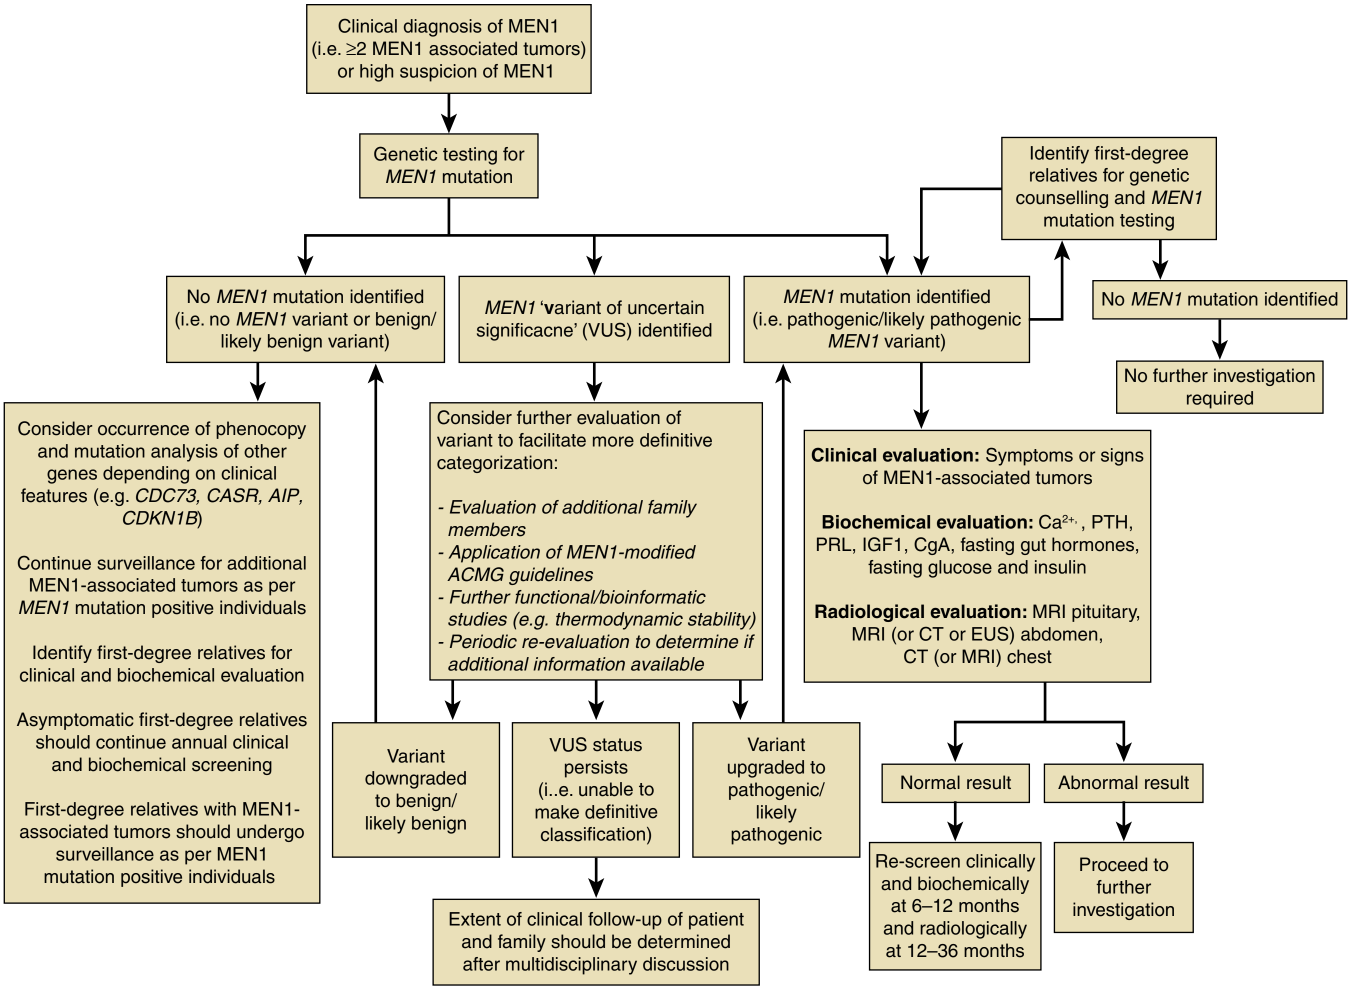
Current guidelines recommend that all individuals at high risk of MEN1 (i.e., *MEN1* mutation carriers) undergo periodic clinical, biochemical, and radiologic screening to facilitate the early detection and treatment of tumors, with the aim of reducing their associated morbidity and mortality (Table 133.2, Fig. 133.5), although high-quality evidence to support this approach remains to be established.[1] However, most clinicians implement such surveillance protocols, although there are debates about the extent and frequency of screening, as well as the age at which it should commence. These controversies reflect many factors, including the variable clinical expression and age-related penetrance of MEN1-associated tumors; the lack of genotype-phenotype correlations; the observations that some manifestations cluster at higher frequency in some individual kindreds[70]; a possible genetic anticipation for clinical manifestations[87]; a lack of high-quality evidence to guide treatment decisions; the possibility of iatrogenic harms from screening methods; and the psychological burdens associated with frequent investigation.[16,83] The current guidelines for surveillance suggest that individuals at higher risk for MEN1 (i.e., *MEN1* mutation carriers) undergo clinical and biochemical screening at least once per annum and also have baseline pituitary and abdominal imaging (e.g., MRI or CT scans), which should be repeated at 1- to 3-year intervals (Table 133.2). A similar schedule is likely to be appropriate for MEN4. Screening should be repeated annually, because the disease may not manifest in some individuals until the eighth decade. Screening should commence in early childhood, because the disease has developed in some individuals by 5 years of age, with imaging for pancreatic and pituitary lesions from around 10 years of age. Some centers consider that radiological screening in asymptomatic *MEN1* mutation carriers for pancreatic NETs should be delayed until 16 years of age, although children with nonfunctioning NETs great than 2 cm have been identified at as young as 12 years.[45] Screening for thymic carcinoids is likely to require cross-sectional imaging with CT every 1 to 2 years, thereby resulting in high cumulative doses of ionizing radiation, and the risks of this need to be appraised and discussed with the patients, a minority of whom will develop thymic carcinoids with a potentially rapid and aggressive course. MRI and "low-dose" CT have been suggested as alternative approaches, but their suitability for screening thymic carcinoids is not established. Screening for breast cancer in women with MEN1 from age 40 years has also been proposed, although it should be noted that this is undertaken for all women aged 50 to 71 years in some countries. Further studies are required to validate these screening approaches, and it may be appropriate to individualize clinical follow-up based on the availability of local resources and patient-specific factors (e.g., age, comorbidities, family history of early-onset malignant disease).

KEY POINTS

- Inheritance of a germline *MEN1* mutation predisposes an individual to developing a tumor that arises after a somatic mutation, and genetic testing combined with periodic clinical, biochemical, and radiological screening has facilitated earlier detection and treatment of MEN1-associated tumors.

FUNCTION OF THE MULTIPLE ENDOCRINE NEOPLASIA TYPE 1 PROTEIN, MENIN, AND FUTURE TARGETED TREATMENTS

Menin is a 67-kDa ubiquitously expressed nuclear protein that can also be found in the cytoplasm of dividing cells, where it localizes to the mitotic spindle and spindle poles in early mitosis. Menin is reported to interact or associate with greater than 75 proteins and to function as a scaffold protein, which is a type of protein that simultaneously interacts (or binds) with two or more member proteins of a signaling pathway, thereby tethering them into larger regulatory complexes that enhance the efficiency and fidelity of the pathways.[3,4,88,89] Furthermore, analysis of the crystal structure of menin has revealed that it adopts a "curved left hand" structure, with a deep pocket within



Clinical diagnosis of MEN1 (i.e. ≥2 MEN1 associated tumors) or high suspicion of MEN1
Genetic testing for MEN1 mutation
Identify first-degree relatives for genetic counselling and MEN1 mutation testing
No MEN1 mutation identified (i.e. no MEN1 variant or benign/ likely benign variant)
MEN1 'variant of uncertain significacne' (VUS) identified
MEN1 mutation identified (i.e. pathogenic/likely pathogenic MEN1 variant)
No MEN1 mutation identified
No further investigation required
Consider occurrence of phenocopy and mutation analysis of other genes depending on clinical features (e.g. CDC73, CASR, AIP, CDKN1B)
Continue surveillance for additional MEN1-associated tumors as per MEN1 mutation positive individuals
Identify first-degree relatives for clinical and biochemical evaluation
Asymptomatic first-degree relatives should continue annual clinical and biochemical screening
First-degree relatives with MEN1-associated tumors should undergo surveillance as per MEN1 mutation positive individuals
Consider further evaluation of variant to facilitate more definitive categorization:
- Evaluation of additional family members
- Application of MEN1-modified ACMG guidelines
- Further functional/bioinformatic studies (e.g. thermodynamic stability)
- Periodic re-evaluation to determine if additional information available
Clinical evaluation: Symptoms or signs of MEN1-associated tumors
Biochemical evaluation: Ca2+, PTH, PRL, IGF1, CgA, fasting gut hormones, fasting glucose and insulin
Radiological evaluation: MRI pituitary, MRI (or CT or EUS) abdomen, CT (or MRI) chest
Variant downgraded to benign/ likely benign
VUS status persists (i..e. unable to make definitive classification)
Variant upgraded to pathogenic/ likely pathogenic
Normal result
Abnormal result
Re-screen clinically and biochemically at 6–12 months and radiologically at 12–36 months
Proceed to further investigation
Extent of clinical follow-up of patient and family should be determined after multidisciplinary discussion

Fig. 133.5 **An approach to screening in multiple endocrine neoplasia type 1 (*MEN1*).** Index cases, or individuals in whom there is a high suspicion of clinical MEN1 (e.g., multigland parathyroid disease, parathyroid + adrenal tumor), should be offered genetic counseling and *MEN1* mutation testing. Mutation testing should also be offered to those with familial MEN1 (i.e., individuals with one MEN1-associated tumor and a first-degree relative with a known *MEN1* mutation). The identification of a germline *MEN1* mutation should prompt entry into a periodic clinical, biochemical, and radiologic screening program. At the same time, first-degree relatives should be identified and offered genetic counseling and *MEN1* mutation testing. Individuals who have inherited the *MEN1* mutation should enter periodic screening, even if asymptomatic. First-degree relatives who have not inherited the *MEN1* mutation require no further follow-up and may be alleviated of the anxiety associated with the development of MEN1-associated tumors. Identification of a variant of uncertain significance (VUS) represents a clinical challenge, whose resolution to establish it as a pathogenic/likely pathogenic variant or benign/likely benign variant requires further evaluation that may include assessment of the strength of the clinical phenotype in the patient; evaluation of additional family members for relevant clinical features to determine if the variant cosegregates with affected individuals; and/or additional bioinformatic analyses. The management of patients in whom the VUS cannot be established to be pathogenic/likely pathogenic or benign/likely benign requires careful consideration that should involve the multidisciplinary team, patients, and family members. For index cases in whom a *MEN1* mutation, which includes testing for partial or whole gene deletions *(asterisk),* is not identified, additional genetic testing may be required, depending on the specific clinical features. This may include examination for mutations in genes associated with familial parathyroid syndromes, including *CDC73* associated with the hyperparathyroidism-jaw tumor syndrome syndrome and *CASR* associated with familial hypocalciuric hypercalcemia; or *CDKN1B* and *AIP*, which are rarely identified in those with clinical MEN1. Up to 10% of kindreds with clinical MEN1 may harbor phenocopies, emphasizing the importance of accurate genetic evaluation. For MEN1 kindreds in whom no *MEN1* mutation is identified, a pragmatic approach is to offer clinical, biochemical, and radiologic screening to those with clinical manifestations of disease and to offer annual clinical and biochemical screening to asymptomatic first-degree relatives. *ACMG*, American College of Medical Genetics and Genomics; *Ca*2+, calcium; *PTH,* parathyroid hormone; PRL, prolactin; IGF-1, insulin-like growth factor-1; *CgA*, chromogranin A; *MRI,* magnetic resonance imaging; *CT,* computer tomography; *EUS,* endoscopic ultrasound. (Modified from Thakker RV, Newey PJ, Walls GV, et al. Clinical practice guidelines for multiple endocrine neoplasia type 1 [MEN1]. *J Clin Endocrinol Metab.* 2012;97:2990–3011.)

the central "palm" region that acts as a binding site for several interacting partners, such as the transcription factor JunD and the histone methyltransferase MLL1.[3,12] Thus, menin, by its direct interactions with transcription factors or membership of epigenetic regulatory complexes, has central roles in transcription of genes involved in cell proliferation.[3,4] Menin is also reported to be involved in additional cellular functions, including regulation of genome stability, DNA repair, cell division, cell signaling, and cell motility, that are cell-type and tissue-specific and enable it to modulate the activity of several canonical signaling pathways, which are implicated in endocrine and nonendocrine tumorigenesis (Fig. 133.4).[4,89] For example, menin has been reported to act as both a negative and positive regulator of Wnt/β-catenin signaling.[4,89] Thus, in embryonic fibroblasts and insulinoma cells from *Men1* knockout mice, menin acts as a negative regulator of Wnt signaling, facilitating export of β-catenin out of the nucleus, such that menin depletion results in nuclear accumulation of β-catenin and Wnt signaling activation.[4] Similar observations (i.e., Wnt activation following menin loss) are reported in human and murine pancreatic NETs and provide the rationale for evaluating small-molecule Wnt inhibitors in preclinical MEN1 studies.[88] In contrast, menin is also reported to augment Wnt signaling in pancreatic endocrine cells, via a direct interaction with β-catenin, revealing apparent paradoxical activities.[4] Menin is reported to have similarly complex and tissue-specific roles in regulating the K-RAS signaling pathways in the pancreas.[4,90] K-RAS activation is generally considered to be an oncogenic signaling pathway that is associated with cellular proliferation, as observed in pancreatic ductal adenocarcinoma, which arises from pancreatic exocrine cells.[90] However, in pancreatic endocrine cells K-RAS activation is associated with suppression of proliferation, which is mediated by a menin-dependent activation of the Ras effector RASSF1A pathway, with simultaneous suppression of the proproliferative RAF/MAPK cascade.[90] In this setting, menin loss results in a shift in balance of these opposing pathways, leading to preferential activation of RAF/MAPK signaling, thereby releasing the "brake" on proliferation.[90] Additional signaling pathways modulated by menin include TGFβ, BMP, AKT, Hedgehog, and MYC (Fig 133.4).[4]

Men1 mouse models generated as conventional and conditional "knockout" murine models have also been used to study these tumorigenic pathways *in vivo* and also in preclinical studies.[89,91-93] *Men1* mouse models have been used to investigate novel therapies for MEN1-associated NETs, including SSAs, epigenetic modifying agents, *Men1* gene therapy, and Wnt antagonists, as well as to evaluate the potential for drug repurposing.[4,89] The efficacy of SSAs has been assessed in different models. For example, pasireotide, a pan-SSTR agonist targeting SSTR1, 2, 3, and 5, was demonstrated to have antiproliferative and proapoptotic activity against pancreatic NETs and pituitary adenomas in conventional and conditional (Pdx-1-Cre) *Men1* models,[89,94] while both pasireotide and lanreotide had chemoprophylactic activity in *Men1* models that reduced tumor development.[94,95] The epigenetic modifying agent JQ1, a member of the bromo and extra terminal domain family of proteins that bind to acetylated histone residues, has been demonstrated to have antiproliferative, antisecretory, and proapoptotic activity in NET cell lines *in vitro,* and also *in vivo* on pancreatic NETs that developed in β cell–specific *Men1* knockout mice.[93,96] Proof-of-concept for *Men1* gene replacement therapy has been established for the treatment of MEN1-associated tumors. The administration of a replication-incompetent adenoviral vector expressing murine *Men1* cDNA directly into pituitary tumors of female conventional *Men1*$^{+/-}$ mice resulted in restoration of menin expression and decreased tumor proliferation[97]; and use of an adeno-associated virus and phage vector displaying octreotide to deliver a tumor necrosis factor transgene to pancreatic NETs in *Pdx1-Cre-Men1* mice resulted in decreased tumor volume and improved survival.[98] Drugs targeting the WNT and KRAS pathways have also been assessed, and a small-molecule β-catenin antagonist (PKF115-584) was shown to reduce proliferation of pancreatic NETs in *RIP-Cre-Men1* mice and decrease excess insulin secretion[88]; whereas MEK1/2 inhibitors targeting KRAS signaling via the RAF/MEK/ERK pathway were demonstrated to have antiproliferative activity and result in synthetic lethality in pancreatic islets from *Ins2-Cre-Men1*$^{+/-}$ and *Ins2-Cre-Men1*$^{-/-}$ mice, respectively.[90] Finally, *Men1* models have been used to investigate repurposing of drugs used for other ailments and diseases. For example, the combination of aspirin and enalapril was reported to reduce the size and number of pancreatic NETs in conventional *Men1*$^{+/-}$ mice, indicating a potential chemo-preventive effect,[99] while the autophagy inhibitor hydroxychloroquine accelerated apoptosis in pancreatic NETs in conventional *Men1*$^{+/-}$ mice.[100]

KEY POINTS

- Menin, which acts as a scaffold protein, is involved in proliferative pathways that represent targeted approaches for future treatments, and use of *MEN1* mouse knockout models that develop the same endocrine tumors observed in patients has facilitated *in vivo* evaluations of several potential novel treatments that include gene therapy and epigenetic modifying drugs.

CONCLUSION

Combined clinical, genetic, and laboratory investigations of MEN1 have resulted in an increased understanding of this autosomal dominant disorder, which has improved patient management and treatment. Germline genetic testing facilitates the identification of mutant *MEN1* gene carriers, who are at high risk for developing this disorder and are likely to benefit from interval biochemical and radiologic surveillance, which aims for earlier detection and treatment of endocrine tumors. Application of the techniques of molecular biology has facilitated important insights into the function of the *MEN1* gene and its encoded protein, menin, which has context-specific pleotropic activities involved in the regulation of transcription, genome stability, cell division, and the epigenome. These advances have provided new avenues for exploring future targeted treatments for the different endocrine tumors that occur in patients with this disorder.

KEY POINTS

- Medullary thyroid carcinoma (MTC) presents sporadically in 75% of cases. In 25% of cases, MTC shows autosomal dominant inheritance as part of the multiple endocrine neoplasia type 2 (MEN2) and 3 (MEN3) syndromes.
- MEN2 and MEN3 syndromes are associated with mutations in the *RET* protooncogene. Affected patients may also develop pheochromocytomas and primary hyperparathyroidism, in addition to other clinical features.
- All patients who develop MTC, including apparently sporadic cases, require germline *RET* mutation analysis.
- Genotype-phenotype correlations have allowed familial cases to be stratified according to the level of risk associated with the specific *RET* variant. Guidelines published by the American Thyroid Association guide clinical management and help to determine the age at which prophylactic thyroidectomy should be performed in asymptomatic *RET* mutation carriers.
- MTC is characterized by early spread to local lymph nodes, and nodal disease is evident in up to 50% of patients at diagnosis. Surgery remains the mainstay of therapy; total thyroidectomy with comprehensive clearance of central lymph nodes is performed as a minimum in index cases.
- Treatment of persistent and metastatic disease has evolved, with targeted kinase therapy demonstrating effective control in patients harboring *RET* germline or somatic variants.

PREVALENCE AND EPIDEMIOLOGY

Multiple endocrine neoplasia type 2 (formerly MEN2A) refers to the occurrence of *medullary thyroid carcinoma* (MTC) in association with pheochromocytoma in 50% of cases, and in association with hyperparathyroidism in 20% to 30% of cases.[1] *Multiple endocrine neoplasia type 3* (formerly MEN2B) consists of MTC in conjunction with pheochromocytoma and several additional features, including mucosal neuromas, ganglioneuromatoses of the gastrointestinal tract, and a marfanoid habitus (Fig. 134.1B). Parathyroid disease is very rare in MEN3. *Familial medullary thyroid carcinoma* (FMTC) describes the autosomal dominant inheritance of MTC alone and was previously a freestanding disease but is now considered a variant of MEN2. Clinical presentation is usually delayed, and prognosis is more favorable, compared with MEN2 and MEN3.[2]

Rare kindreds have been described with the combination of MEN2 and a pruritic skin lesion over the upper back with a lichenoid appearance (Fig. 134.1A). This cutaneous lichen amyloidosis (CLA) may be preceded by pruritus alone for several years.[3]

Although 25% of cases of MTC occur in well-defined familial endocrine syndromes with autosomal dominant inheritance, 75% of MTC cases are sporadic. MTC may also present with ectopic hormonal

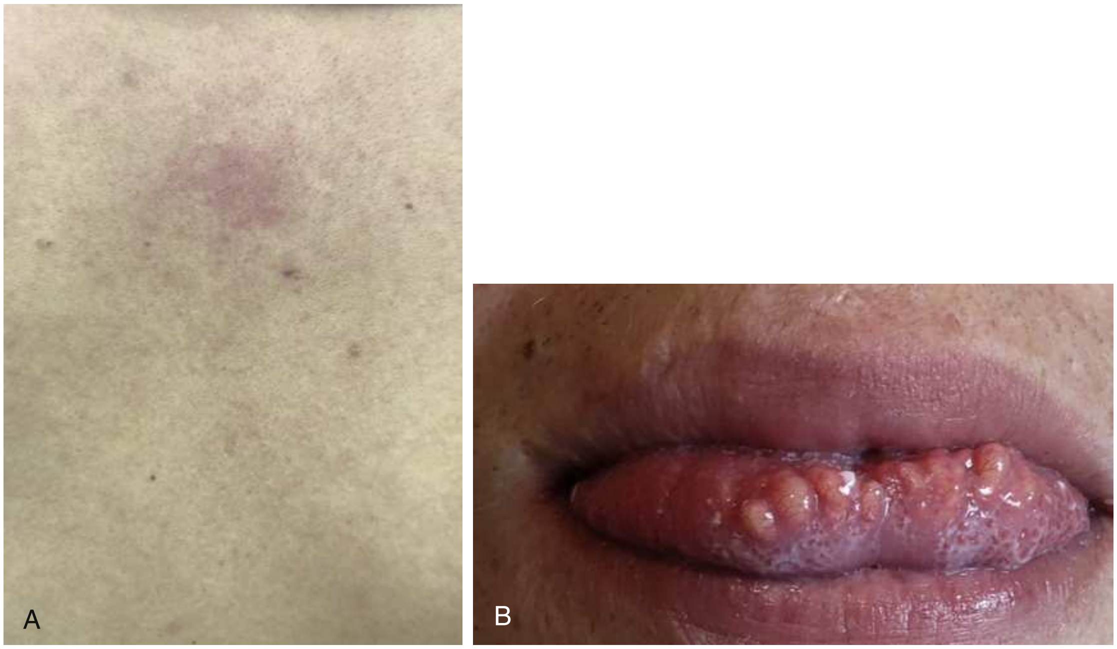

Fig. 134.1 Clinical Images in Multiple Endocrine Neoplasia Type 2 (MEN2) and Multiple Endocrine Neoplasia Type 3 (MEN3). **A**, Cutaneous lichen amyloidosis in a MEN2 patient. **B**, Mucosal neuromas in a MEN3 patient.

syndromes such as ectopic adrenocorticotropic hormone (ACTH; discussed later). Although MTC accounts for only 5% to 10% of all thyroid cancers, its management can be very challenging, and early diagnosis is essential for good outcomes.

The overall prevalence of MEN2 is approximately 1:80,000.[4] The penetrance is approximately 70% at 70 years of age.[5] It has been reported that 90% of MEN2 carriers will eventually show evidence of MTC.6 This contrasts with multiple endocrine neoplasia type 1 (MEN1), in which penetrance is 94% by 50 years of age.[7] For further detailed discussion of pheochromocytoma, see Chapter 110. For primary hyperparathyroidism, see Chapter 63. MEN1 is discussed in Chapter 148.

MOLECULAR PATHOGENESIS: *RET* PROTOONCOGENE

The causative gene for the MEN2 syndromes was identified in 1993.[8,9] The gene is the rearranged during transfection (*RET*) protooncogene located on chromosome 10q11.2.[10]

The *RET* protooncogene encodes a tyrosine kinase cell surface receptor. Point mutations in *RET* segregating with the disease phenotype were identified in MEN2 and FMTC in 1993.[9] Germline variants of *RET* at two specific codons were subsequently identified in MEN3, at a different site.[11] Genetic screening has revolutionized the management of MEN2 families.

The International *RET* Mutation Consortium performed an extensive study of 477 MEN2 families around the world and established important genotype-phenotype correlations.[12] *RET* mutations have been characterized in approximately 98% of MEN2 families overall. In MEN2, approximately 97% of families will have an identifiable *RET* germline variant, and in MEN3, approximately 98% of families are mutation-positive. *RET* variants are summarized in Table 134.1.

RET Structure and Function

RET consists of 21 exons spanning a minimum of 30 kb of genomic DNA, encoding a cell surface receptor. RET consists of an extracellular domain (exons 1–10), a transmembrane domain (exon 11), and an intracellular domain (exon 12 and onward) (Fig. 134.2).

The RET protein is membrane-bound, with its intracellular portion having tyrosine kinase activity. The extracellular domain extends for the initial 635 amino acids and includes an area of cadherin homology and a conserved cysteine-rich region immediately adjacent to the transmembrane domain. The cysteine-rich domain is typical of the transforming growth factor beta superfamily.[13] The protein is glycosylated to produce receptors with molecular weights of 150 and 170 kD. The 170-kD form is present in the cell membrane, whereas the 150-kD form is an immature form present in the cell cytoplasm.[14] Phosphorylation of RET tyrosine residues results in activation of several intracellular second messenger systems and signaling pathways. These include phospholipase Cγ/protein kinase C, c-Jun N-terminal kinases, products of the protooncogene Src-related kinases, and nuclear factor κB. Other downstream targets include the RAS/RAF/ERK (extracellular regulated kinase) and phosphatidyl-inositol-3-kinase/AKT pathways. Through these signaling cascades, *RET* appears to have a central role in cellular proliferation, differentiation, and migration.[15-17] Interestingly, in addition to its role in endocrine neoplasia, aberrant *RET* signaling has been associated with other distinct phenotypes. Hirschsprung disease has been described together with MEN2 in subjects with codon 609, 611, 618, and 620 variants,[18] and CLA with the codon 634 variant.[19]

RET Ligands

There are four known RET ligands: glial cell line–derived neurotrophic factor (GDNF)[20], neurturin,[21] artemin,[22] and persephin.[23] The link between *RET* and GDNF was suggested by studying mice that were deficient in GDNF expression. These mice were very similar to *RET* knockout mice, with absent or limited development of the kidney and an absence of enteric neurons in the colon and small intestine.[24] Interestingly, genitourinary abnormalities are not a feature of MEN2, despite the fact that *RET* is expressed in human fetal kidney during development. The three other ligands have sequences related to GDNF. RET activation by ligand occurs via membrane-bound

TABLE 134.1 Genotype-Phenotype Correlations and Risk Levels for Medullary Thyroid Carcinoma Behavior

Rare mutations based on very few families with genetic variants of unknown significance are not included.

ATA, American Thyroid Association; *MEN*, multiple endocrine neoplasia; *MTC*, medullary thyroid carcinoma.

(From Wells SA Jr, Asa SL, Dralle H, et al. Revised American Thyroid Association guidelines for the management of medullary thyroid carcinoma. *Thyroid*. 2015;25:567–610.)

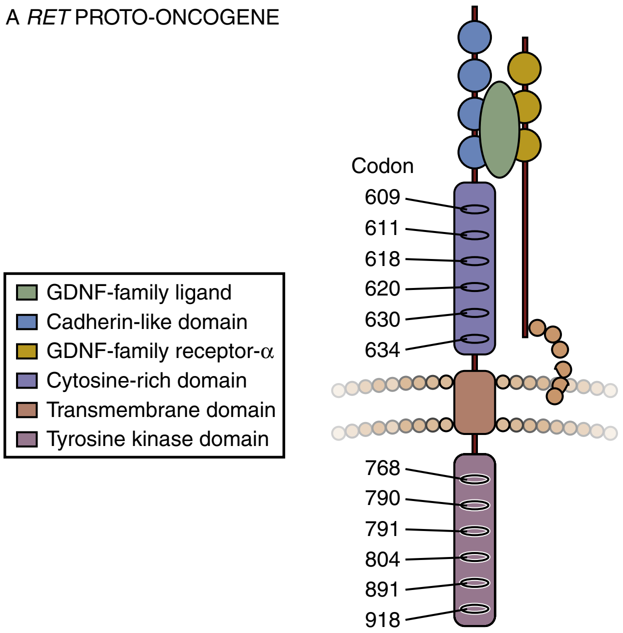

Fig. 134.2 Structure of the *RET* Protooncogene. *GDNF*, glial cell line–derived neurotrophic factor. (From Cote GJ, Gagel RF. Lessons learned from the management of a rare genetic cancer. *N Engl J Med*. 2003;349:1566–1568.)

proteins that function as the ligand-binding domain of a ligand/receptor complex. GDNF-family ligands bind to specific GDNF-family receptor proteins, all of which form receptor complexes and signal through RET. Additional proteins, GDNF-family receptor alpha (GFRα) or GDNF-family receptor alpha 1 (GFRα-1), were found to be essential for the high-affinity binding of GDNF to RET and for its consequent functional effects.[25] A single molecule of GDNF binds two GFRα-1 molecules that interact with two molecules of RET and lead to activation of RET tyrosine kinase. Similarly, neurturin, persephin, and artemin require the binding of different GFRαs (GFRα1–4) as coreceptors before downstream receptor activation occurs. It was suggested that MEN2 families with no identifiable *RET* variants may have *GDNF* variants, but so far no such variants have been described in MEN2. However, somatic *GDNF* variants have been found in sporadic pheochromocytomas.[26]

KEY POINTS

- Multiple endocrine neoplasia type 2 is a hereditary syndrome referring to the occurrence of medullary thyroid carcinoma (MTC) in association with pheochromocytoma (50% of cases) and hyperparathyroidism (20%–30% of cases). Multiple endocrine neoplasia type 3 refers to a hereditary syndrome involving MTC in conjunction with pheochromocytoma, together with several additional features including mucosal neuromas, ganglioneuromatoses of the gastrointestinal tract, and marfanoid habitus.

Functional Effects of *RET* Variants

Although the genotypes do overlap, in general, different codons are affected in either MEN2 or MEN3. These mutations in different regions of the *RET* protooncogene increase the transforming activity of the kinase by distinct mechanisms. In MEN2, the extracellular cysteine-rich or transmembrane domains are predominantly affected. Such mutations lead to a loss of cysteine residues. As a result, two RET molecules may undergo ligand-independent dimerization, with resultant constitutive activation of tyrosine kinase activity.[27] A variant in codon 634, usually a cysteine-to-arginine substitution (C634R), occurs in 85% of cases of MEN2.[17] In contrast, MEN3 usually is caused by a mutation in the intracellular tyrosine kinase domain. Codon 918 is involved in 95% of cases, in a methionine-to-threonine substitution (M918T).[17] This alters the kinase specificity, with alternative substrate phosphorylation and altered downstream signaling. The rarer intracellular RET mutations in codons 768 and 804 have been shown to produce “gain of function” of the receptor, although the precise mechanism by which tumor formation occurs is not clear.[28]

KEY POINTS

- *RET* mutations are found in nearly all multiple endocrine neoplasia type 2 (MEN2) and multiple endocrine neoplasia type 3 (MEN3) kindreds. In MEN2, codon 634 is involved in >85% of cases, and in MEN3 codon 918 is involved >95% cases.

HISTOLOGY

C-Cells

Calcitonin-secreting C-cells of the thyroid gland arise from pharyngeal endoderm, and their development is significantly influenced by the neural crest cells.[29,30] Located mainly in the upper and middle thirds of the thyroid gland, C-cells are members of the amine-precursor uptake and decarboxylation family and express a variety of neuroendocrine markers, including calcitonin, chromogranin A, neuron-specific enolase, and serotonin.[31] Calcitonin is a highly sensitive tumor marker for monitoring of MTC. Carcinoembryonic antigen (CEA) is another C-cell marker used in clinical practice. C-cells usually display an endocrine phenotype, but may revert to a neuronal phenotype following malignant transformation, at which point they predominantly express alternately spliced calcitonin gene-related peptide (CGRP).[31] The biological role of C-cells is not precisely clear. Calcitonin may be important for calcium homeostasis *in utero*, and C-cells may contribute to thyroid follicular microenvironment. Pharmacologically, calcitonin inhibits calcium resorption from bone, opposing the effect of parathyroid hormone. It has been used therapeutically for treatment of hypercalcemia and osteoporosis.

C-Cell Hyperplasia

C-cell hyperplasia (CCH) is the pathologic description of an increase in C-cell numbers that can precede malignancy. Criteria for the diagnosis of CCH are variable in the literature, although consensus suggests that there should be more than 50 C-cells per field at 100× magnification.[32] C-cells may increase in number with age, and CCH is a common finding in normal thyroid glands at autopsy. CCH is no longer considered to be a specific marker of familial MTC. Multifocal CCH is regarded as a precursor lesion to hereditary MTC. Its progression to microscopic MTC is variable and may take many years.[33]

CLINICAL RELEVANCE OF GERMLINE *RET* VARIANTS IN MULTIPLE ENDOCRINE NEOPLASIA TYPE 2 AND MULTIPLE ENDOCRINE NEOPLASIA TYPE 3

Multiple Endocrine Neoplasia Type 2 and Familial Medullary Thyroid Carcinoma

Extensive studies of MEN2 families from around the world have now clarified that nearly all will have a germline *RET* mutation, usually in the cysteine-encoding codons 609, 611, 618, 620, or 634. The codon 634 variant in exon 10 predominates, usually with an arginine substitution, although other substitutions, such as by tyrosine or glutamine, are described.[34] In the subcategory FMTC, 88% of families have a germline mutation in one of the listed cysteine codons or, more rarely, in intracellular codons, including 768, 790, and 791. *RET* mutations in the intracellular exons 13, 14, and 15 are less common in MEN2, although they will be detected by routine sequencing of these exons. Isolated cases of kindreds with germline mutations in other exons, namely exons 1, 5, and 8 have also been reported.[17,35]

Multiple Endocrine Neoplasia Type 3

In 95% of MEN3 families, the germline RET variant at codon 918 in exon 16 occurs, causing a mutation of methionine to threonine (M918T).[36] This mutation is in the tyrosine kinase domain and is specific to MEN3.[11] Of note, this *RET* codon 918 variant is also found in the tumor tissue in some sporadic MTCs. The majority of germline *RET* codon 918 variants occur *de novo*, where MEN3 patients have no family history of the disease, and the pathogenic variant is mostly paternal in origin.[37] However, they still have a 50% chance of passing this variant on to their offspring. Rarer tyrosine kinase domain mutations occur in codons 883 and 891, and the MEN3 phenotype has also been reported when a germline codon 804 variant is coupled with a second germline *RET* mutation (see Table 134.1).[38]

SPECIFIC GENOTYPE-PHENOTYPE CORRELATIONS

There has been much interest in the prediction of phenotypic behavior from genotype analysis. As published by the International *RET* Consortium, the presence of any *RET* codon 634 variant correlates significantly with the presence of both pheochromocytoma and hyperparathyroidism. One study suggested more aggressive behavior of MTC with the common arginine substitution at codon 634 (C634R), compared with the C634Y variant.[39] The C634R variant has not been associated with FMTC. FMTC was reclassified as a variant of MEN2 to avoid failure to identify pheochromocytoma, which can occur later in life.[34] The occurrence of different phenotypes in different families with the same germline *RET* variant suggests a role for more complex gene interactions. The rarer phenotypes associated with MEN2 include Hirschsprung disease with *RET* codon 609, 618, and 620 variants,[18] and CLA with codon 634 mutations.[19] The codon 918 mutation in exon 16 is MEN3-specific.[17] The rarer codon 883 MEN3 variant in exon 15 appears to be associated with less aggressive MTC than does the codon 918 variant.[40]

KEY POINTS

- There is a strong genotype-phenotype correlation in multiple endocrine neoplasia type 2. Each mutated codon is correlated with a specific phenotype.

CLINICAL PRESENTATION

Medullary Thyroid Carcinoma

MTC is the initial manifestation in the majority of cases of MEN2 and occurs in over 95% of these patients. MTCs are usually multifocal and have spread to adjacent cervical lymph nodes in approximately 40% of “index” patients at the time of diagnosis, making cure difficult. Patients with MTC may present with a palpable thyroid lump or with the symptoms of calcitonin excess—usually diarrhea and flushing. Diarrhea does not usually occur until the calcitonin level is very high (at least 10-fold above the upper limit of the normal range). Unfortunately, by the time the diarrhea has occurred, regional lymph node spread is likely, together with distant metastases. Aggressive tumors spread early to bone, lung, and/or liver, and may lose expression of the calcitonin gene, switching to production of CGRP. Fortunately, only a minority of MTC patients (5%–10%) display an aggressive course, whereas many show an indolent course, surviving for decades in the presence of disease. A clinical presentation with MTC (i.e., by palpable neck lump or elevated calcitonin), as opposed to a preclinical diagnosis by prospective screening, is associated with higher rates of residual or recurrent disease. Nonsecretory MTCs are rare (0.83% in one MTC cohort), but absence of raised calcitonin and CEA lead to their diagnosis at a later clinical stage.[41]

Familial cases of MTC will have different presentations, depending on the specific *RET* variant, as described earlier. MEN3 presents with aggressive MTC at a young age. It accounts for 5% of familial MTC cases overall. Early recognition is crucial but challenging, as *de novo* germline mutations account for greater than 50% of MEN3 cases, and thus the parents of an affected child may not provide phenotypic clues.[42] Patients may present in early childhood with diarrhea from very high calcitonin levels or with other features of MEN3 syndrome.[1] Affected individuals may have a marfanoid habitus, thickened corneal nerves, musculoskeletal abnormalities, and intestinal ganglioneuromatosis. Interestingly, some patients with MEN2 also show corneal nerve thickening. Mucosal neuromas in MEN3 can occur on the tongue, in the lips, and on the eyelids, giving a distinctive facial phenotype (see Fig. 134.1B). Gastrointestinal symptoms are universal and varied. Neuromas in the gastrointestinal tract can cause abdominal pain, gaseous distension, and even pseudoobstruction. Hirschsprung disease can have a similar presentation in children and is as a result of inactivating mutations in the extracellular domain of RET, as distinct from the activating mutations of the tyrosine kinase domain seen in MEN3 patients.[1] *RET* variants are found in 20% of sporadic and 50% of familial Hirschsprung disease cases.[43] *RET* mutation carriers may develop simultaneous Hirschsprung disease and MEN2, or either syndrome in isolation. The mechanism by which *RET* mutations are simultaneously activating (to cause MEN2) and inactivating (to cause Hirschsprung disease) is complex and fascinating.[44]

CLA is seen in approximately 10% of MEN2 families and may precede the onset of MTC, with skin lesions seen in the interscapular region of the back (see Fig. 134.1A). Pruritus leads to scratching and amyloid deposition in the skin.[45]

KEY POINTS

- Medullary thyroid carcinoma (MTC) is the most common manifestation of multiple endocrine neoplasia type 2 and multiple endocrine neoplasia type 3. Presentation with MTC, as opposed to preclinical presentation through screening, is associated with higher rates of residual and recurrent disease. Pheochromocytomas are often bilateral and usually follow a benign course. Hyperparathyroidism is multiglandular and is frequently asymptomatic.

Pheochromocytoma

Pheochromocytoma occurs in approximately 50% of MEN2 patients, although it is less common in those with moderate risk variants. Pheochromocytoma is occasionally the initial manifestation of MEN2 and typically presents at an older age (>35 years) or concurrently. The exception is MEN3, in which pheochromocytoma may occur at an early age.[38] Knowledge of the hereditary pheochromocytoma and paraganglioma syndromes has increased in the last decade and is discussed in detail in Chapter 110. Sporadic pheochromocytomas present later than those associated with MEN2. Pheochromocytoma in MEN2 is usually benign and develops on a background of adrenal medullary hyperplasia. A unilateral pheochromocytoma may be followed by pheochromocytoma in the contralateral gland some years later.[46] Bilateral adrenal pheochromocytomas are seen in 63% of cases overall; coexistent paragangliomas are rare.[47] Metastatic pheochromocytoma is rare (<2.9%) in MEN2, despite the fact that capsular invasion is commonly seen.[47] The hormonal profiles of MEN2 and MEN3 pheochromocytomas are similar, and epinephrine secretion generally predominates, leading to elevated plasma and urinary epinephrine and metanephrines. This pattern of secretion may relate to regulation of adrenomedullary phenylethanolamine N-methyltransferase by RET. By contrast, norepinephrine and normetanephrine metabolite secretion predominate in both sporadic and von Hippel-Lindau disease–associated pheochromocytomas.[48,49]

Hyperparathyroidism

Hyperparathyroidism is usually asymptomatic and occurs in only 20% of MEN2 patients, and is absent in MEN3 patients. It is a much less challenging disease in MEN2 than in MEN1. Hyperparathyroidism is usually multiglandular and rarely occurs at an early age. Recurrence after initial surgery is unusual. It is often diagnosed at the time of MTC surgery, where parathyroid glands may have an appearance similar to nodular hyperplasia. Enlarged parathyroid glands are concurrently removed along with the thyroid gland, even if the patient is asymptomatic and normocalcemic.[50-52]

SCREENING IN MULTIPLE ENDOCRINE NEOPLASIA TYPE 2 AND MULTIPLE ENDOCRINE NEOPLASIA TYPE 3

The purpose of biochemical and genetic screening in MEN2 and 3 families is to detect MTC well before it becomes clinically apparent, as, once clinically evident, it may have spread to the lymph nodes. Early detection of pheochromocytoma is important to reduce the risk for catecholamine-induced hypertensive crises.

Biochemical Screening

Medullary Thyroid Carcinoma. Historically, stimulation with pentagastrin, a calcitonin secretagogue, was used to screen members of MEN2 families biochemically for CCH or MTC. However, the advent of genetic screening has rendered the test largely redundant.

Calcitonin values are generally higher in males (normal range [NR] <10 pg/mL) than in females (NR <5 pg/mL), and ranges are more varied in children. Reference ranges vary in different laboratories, and there can be variation even in the same patient. Chemiluminescent immunometric assays are preferred, and clinicians should use the same laboratory for serial measurement in a particular patient.

Pentagastrin is not available in the United States, and calcium may be used as an alternative calcitonin secretagogue if needed. One such rare indication may be when parents are reluctant to allow prophylactic thyroidectomy in a *RET* mutation–positive child with normal basal calcitonin. A stimulated calcitonin level significantly above normal may help to reinforce the need for timely thyroidectomy.

Pheochromocytoma. Annual measurement of fractionated metanephrines in plasma, rather than urine, is now the method of choice for biochemical pheochromocytoma screening in MEN2. The age at which this should commence will depend on the *RET* variant in the family. Screening generally should commence by 11 years of age for patients with MEN3 and those with codon 634 or 630 variants (American Thyroid Association [ATA] "high" and "highest" risk categories) with MEN2, and by 16 years of age for patients with all other *RET* variants in the ATA "moderate" risk category.[38] In addition, preoperative screening for pheochromocytoma should occur in all MTC patients, with baseline plasma metanephrines demonstrating the highest sensitivity.

Hyperparathyroidism. Biochemical screening for hyperparathyroidism is straightforward, in that serum calcium (albumin-corrected or ionized), and usually serum parathyroid hormone, are measured annually from the time that calcitonin testing is implemented.

Genetic Screening

RET variants are clustered tightly, and the analysis can be confined to specific exons. This compares favorably with genetic analysis in MEN1, where the variants are scattered. Once a pathogenic variant is identified, other family members are screened with a straightforward analysis for that specific variant. Various techniques have been used, and direct polymerase chain reaction–based sequencing is currently commonly performed by most laboratories, although next-generation sequencing is becoming more widespread. Testing should ideally be performed on two different blood samples collected on separate occasions to avoid risk of sample error. *RET* variant–negative members of known MEN2 families (i.e., where a pathogenic *RET* variant has been identified in the family) can be reassured that their risk for developing MTC is no greater than for the general population. Genetic screening must therefore be comprehensive and include sequencing of exons 5, 8, 10, 11, 13, 14, 15, and 16.[35,53]

MANAGEMENT IMPLICATIONS OF GENETIC RESULTS

Timing and Benefits of Prophylactic Thyroidectomy

The advent of genetic screening has allowed prophylactic thyroidectomy to be performed earlier than it would be by traditional biochemical screening. The specific mutated *RET* codon may be correlated with the degree of aggressiveness of the MTC. The three-level risk stratification system developed at the Seventh International Workshop on Multiple Endocrine Neoplasia in 1999[53] was revised in the guidelines published by the ATA in 2015 to include three levels of risk (see Tables 134.1 and 134.2).[38] The highest risk group includes all MEN3-associated mutation carriers harboring the M918T variant. Such patients should have thyroidectomy within the first year of life, because metastases within the first year of life have been described. The second group is the "high risk" category, which includes patients with *RET* codon C634 and A833F variants, where thyroidectomy before 5 years of age is recommended depending on basal calcitonin level. MTC with the codon 634 variant has been reported as early as age 2 years, although cases of MTC are generally rare before the age of 5 years in MEN2 and FMTC. Thyroidectomy at this age is technically possible without significant morbidity. The final cohort has combined category A and B into a moderate risk category that includes mutations at a number of *RET* codons, and surgery should be considered, but the timing is not always clear. Patient/parent preference and calcitonin levels can be used to help guide timing (see Table 134.2). It should be noted that a single case of metastatic MTC in a 6-year-old patient was reported in a family with the codon 804 *RET* variant.[54] Recent data suggesting that p.V804M may be a low-penetrance variant[55] makes this timing and recommendation even more challenging, as discussed later. Fig. 134.1 describes the earliest reported age at onset of MTC for each of the known *RET* variants. Early prophylactic surgery has also alleviated the need for ongoing biochemical stimulation testing being performed in a child.

Calcitonin measurement may assist timing prophylactic thyroidectomy in combination with baseline genetic status. If baseline calcitonin is elevated, then thyroidectomy should be performed immediately, regardless of the *RET* variant found. Histology in this setting is likely to show MTC rather than CCH, with the associated risk for lymph node spread.[56] In one series, all patients with a preoperative basal calcitonin level less than 30 ng/L were cured with prophylactic thyroidectomy.[57] In summary, an ideal protocol for timing includes following early genetic testing and risk stratification, depending on the specific *RET* variant in combination with calcitonin measurement.

KEY POINTS

- Prophylactic thyroidectomy is recommended at specific ages, depending on *RET* genotype. Each codon mutation is divided into three risk categories. Calcitonin measurement may assist in determining optimal timing of thyroidectomy for patients harboring codons in the high or moderate risk category.

Strategy and Extent of Thyroidectomy

In young children with MEN2, the MTC that occurs is usually small; lymph node metastases are rare if the tumor is less than 10 mm, and some groups have reported nodal disease being uncommon under 11 years of age.[38] Hence, although there has been a general consensus regarding the timing of prophylactic thyroidectomy based on risk stratification, the extent of central lymph node dissection at prophylactic thyroidectomy is controversial. Most advocate thyroid surgery with central node dissection for MEN3. The practice of routine central-node clearance is most important in asymptomatic gene

TABLE 134.2 American Thyroid Association Risk Level and Prophylactic Thyroidectomy Testing and Therapy

American Thyroid Association Risk Level	Age of First Investigation	Age of Prophylactic Surgery	Surgical Comments
Highest	Soon after birth, calcitonin levels are high in first few months of life and limited value in timing thyroidectomy	Within the first few months of the first year of life	Central neck dissection considered if parathyroid glands can be identified and left *in situ* or autotransplanted
High	From 3 years of age physical examination, cervical US, and serum calcitonin	Before 5 years of age	Central neck dissection if serum calcitonin >40 pg/mL
Moderate	From 5 years of age physical examination, cervical US, and serum calcitonin	Timing should be based on elevated calcitonin glevel if parental concern recommend surgery at 5 years	

ATA, American Thyroid Association; *US,* ultrasound.

(From Wells SA Jr, Asa SL, Dralle H, et al. Revised American Thyroid Association guidelines for the management of medullary thyroid carcinoma. *Thyroid.* 2015;25:567–610.)

carriers with the higher-risk variants but can be modified for lower-risk variants with normal preoperative calcitonin. ATA guidelines suggest that, if basal calcitonin is less than 40 pg/mL preoperatively, a central neck dissection could be avoided.[38] Considering the need for lateral lymph node dissection is also challenging. Basal calcitonin has not been shown to predict the need for prophylactic lateral lymph node dissection.[58]

THE ROLE OF SOMATIC MUTATIONS

Sporadic Medullary Thyroid Carcinoma

Somatic mutations of *RET* are observed in around 60% of sporadic MTC cases. The most common somatic *RET* mutation is the M918T variant.[59] The reported prevalence of this mutation may vary based on geographic differences in population studies or perhaps methodologic differences. Other somatic mutations reported in sporadic MTC include codon 883 in exon 15 and codon 634 in exon 11. The somatic *RET* codon 918 variant is associated with a poorer prognosis in sporadic MTC, with several series correlating the mutation with distant metastases and tumor recurrence.[60-62] Dual *RET* mutations have been correlated with poorer outcome.[63] Somatic mutations of the protooncogene *RAS* (predominantly *HRAS* and *KRAS*) occur in a proportion of sporadic MTCs, nearly exclusively those tumors that are *RET* mutation–negative, suggesting that *RAS* mutations provide an alternative pathogenic pathway in sporadic MTC. In contrast to *RET* mutations, there is no evidence that harboring a *RAS* mutation predicts poorer outcome.[64] *RAS* mutations in sporadic MTC may even procure a positive outcome, as these tumors demonstrate a less aggressive phenotype.[65]

Low-Penetrance Phenotypes

With the advent of large, population-based genetic databases, it has become apparent that some RET variants formerly thought of as rare are in fact more common in the community than expected.

These variants thus have a lower penetrance for MEN2, and this is particularly obvious for *RET* p.Val804Met.[55] Using the ExAC database, the penetrance of p.Val804Met has been estimated at 46%, which was corroborated by a German cohort where only 51% of patients with this variant developed MTC.[66] One theory for the low penetrance for this particular *RET* variant is the modification by coinheritance of other *RET* variants in *cis*. Ongoing research is needed when considering deferring prophylactic thyroidectomy and replacing it with close clinical surveillance for carriers of p.Val804Met.

Hereditary Medullary Thyroid Carcinoma

Somatic *RET* mutations have also been described in hereditary MTC. The somatic codon 918 *RET* variant has been reported, albeit rarely, in association with germline *RET* mutations in exons 10 or 11.[67] This important observation negated the theory that the codon 918 somatic *RET* variant could be used as a specific marker of sporadic disease. Others have observed the somatic codon 918 *RET* variant occurring in patients with a germline codon 768 *RET* variant.[68] Microdissection techniques have shown that somatic *RET* mutations may be found in some regions of an MTC tumor but not in others.[12] It has been suggested that the presence of a somatic mutation in addition to the germline *RET* mutation provides a "second hit" that may explain the more aggressive behavior of some familial cases of MTC.

Whole-exome studies have identified a novel germline *ESR2* frameshift mutation that predispose patients to CCH and MTC. Smith et al. demonstrated the mechanism of upregulation of RET activity through constitutional activation of ESR2.[69] A possible link between germline *MET* variants and MTC has also been reported.[70]

GERMLINE SCREENING

Sporadic Medullary Thyroid Carcinoma

It is now recommended that all new cases of sporadic MTC should have germline screening for *RET* variants. Unsuspected familial cases are uncovered in approximately 6% of such patients, despite an apparently negative family history.[71] This was confirmed in a series of apparently sporadic cases of MTC, in which 7.3% of subjects were found to possess a germline mutation. Lower-risk *RET* mutations in the noncysteine codons were most commonly discovered, including codons 804, 891, and 768, although cysteine codon variants were also found. Genetic screening of first-degree relatives should be undertaken if a germline *RET* mutation is identified in a subject with MTC.

Given that more than 97% of MEN2 families have identifiable *RET* mutations, a negative germline *RET* mutation test provides a high degree of certainty that a particular individual has sporadic MTC. This is assuming that the genetic analysis is comprehensive. It is important to include exons 13, 14, and 15, because mutations in these exons are most likely to manifest late, with a lower prevalence of pheochromocytoma, and are more likely to escape detection as familial.

Whole-gene expression profiling of both hereditary and sporadic MTC showed no distinct differences between each group, suggesting a homogenous nature of MTC.[72] *NTRK3* dysregulation was disproportionally observed in in MEN3 over MEN2 samples, which may be a component of its clinical aggressiveness.

NATURAL PROGRESSION AND BEHAVIOR OF MULTIPLE ENDOCRINE NEOPLASIA TYPE 2 AND MULTIPLE ENDOCRINE NEOPLASIA TYPE 3

Staging of Medullary Thyroid Carcinoma

Once the initial diagnosis of MTC has been made, either through the presentation of thyroid nodule or screening of familial presentations, both biochemical testing and imaging should be performed to stage the extent of disease, as this may alter the goals of management and the prognosis. Once surgery has been performed, certain histological features may also be useful in determining prognosis of MTC.

KEY POINTS

- Calcitonin is a sensitive tumor marker for medullary thyroid carcinoma (MTC) and can be used in staging. Structural imaging (ultrasound scanning and magnetic resonance imaging), together with functional imaging, are both advantageous in MTC staging. (18F)-dihydroxyphenylalanine positron emission tomography (PET) demonstrates the highest sensitivity of the PET tracers for MTC.

Biochemical Markers. Calcitonin is a sensitive tumor marker for MTC. Rarely, other non–C-cell tumors may secrete calcitonin, including carcinoid tumors and small cell lung carcinomas. Calcitonin elevation is useful in confirming early diagnosis of MTC, and monitoring can indicate persistent or recurrent disease. Levels above 100 ng/mL confirm diagnosis, with the level corresponding with the volume of disease. Lower levels (10–40 ng/mL) may be found in nonmalignant conditions, such as autoimmune thyroiditis, chronic renal failure, chronic pulmonary disease, trauma, pregnancy, hypercalcemia, hypergastrinemia, pheochromocytoma, mastocytosis, and sepsis.[73] A metaanalysis in 2020 looked at 16 studies with 72,368 participants who had had a calcitonin level assessed during investigation of thyroid nodule. Results showed a calculated sensitivity of 100% (range within studies of 83%–100%) and specificity of 97.2% (range within studies of 94%–100%) with a threshold of 10 pg/mL.[74] However, 15 of the 16 studies lacked long-term follow-up of calcitonin participants, likely causing bias towards use of calcitonin in nodule diagnosis. Calcitonin levels may be measured within fine-needle aspirate biopsy washout to determine the risk of MTC.[75] The preoperative calcitonin level can also determine the risk of metastatic disease, with lymph node metastases very unlikely if below 53 ng/mL but likely if greater than 500 ng/mL.[73,75] Calcitonin levels above 1000 ng/mL are highly suggestive of distant metastases. The level of calcitonin may guide surgical management of localized disease, with calcitonin levels greater than 200 ng/mL suggesting a need for contralateral lateral neck dissection in addition to total thyroidectomy, bilateral central neck dissection, and ipsilateral central neck dissection.[38] Postoperative levels less than 10 ng/mL are suggestive of "biochemical remission." Nonsecretory MTC can evidently not be biochemically staged with calcitonin.[41] CEA, along with other less used markers including neuron-specific enolase, chromogranin A, and procalcitonin, have also been useful in staging the extent of MTC, particularly in those with calcitonin-negative disease.

Structural Imaging. Structural imaging of MTC should include imaging for MTC, phaeochromocytoma, and hyperparathyroidism. The current staging for MTC is via the eighth edition of the American Joint Committee on Cancer staging system. Unlike differentiated thyroid carcinoma, age is not considered in staging. Stage I denotes T1 tumor, which is less than 2 cm and confined to the thyroid, without nodal or metastatic spread. Stage II denotes a T2 tumor, between 2 and 4 cm, or a T3 tumor greater than 4 cm but confined to the thyroid, without nodal or distant metastatic spread. Stage III is any size tumor with local nodal spread, without distant metastases. Stage IV is where the cancer has grown to nearby tissues of the neck (IVA), or tumor has grown to invade local structures (IVB), or there is distant metastases (IVC).

MTC is most often detected with sonographic examination, with an often calcified hypoechoic, sometimes cystic, nodule, which can also be seen on computed tomography (CT) and magnetic resonance imaging (MRI).[76] The size of the primary tumor correlates with the likelihood of nodal metastases, with tumors less than 1 cm predicting 20% to 30% nodal metastases and tumors greater than 4 cm predicting 90% nodal metastases.[77]

The intensity of search for metastases will be guided by the calcitonin levels. There is a paucity of systematic studies assessing various radiographic imaging protocols. One study compared ultrasonography, spiral CT scan, MRI of the liver and whole body, and (^{18}F)-fluorodeoxyglucose (FDG) positron emission tomography (PET) in a group of 55 patients with MTC and persistently elevated calcitonin.[78] They found neck ultrasound to be the most sensitive tool in detecting lymph node metastases. Liver metastases are best seen in dynamic contrast-enhanced MRI, appearing as hyperechoic. In a study comparing MRI liver to functional imaging ^{18}F-DOPA-PET/CT, MRI was superior and more precise in detecting liver lesions.[79] Lung metastases are best seen on CT or FDG-PET. Bone scan complemented MRI in the detection of axial skeletal metastases but was superior in assessing peripheral skeletal lesions.

Functional Imaging. A variety of nuclear imaging methods have been used in an attempt to take advantage of the specific expression of hormonal receptors or transporters by endocrine tumors to allow disease localization. Unfortunately, no single method is sufficiently sensitive or specific for definitive diagnosis. Radionuclide agents that have been previously investigated include ^{201}T1-chloride, ^{131}I-metaiodobenzylguanidine (MIBG), ^{99m}Tc pentavalent-dimercapto-succinic acid, ^{131}I anti-CEA or anticalcitonin antibodies or fragments, labeled somatostatin receptors, and technetium-99m-sestamibi (^{99m}Tc-sestamibi).[80]

In recent years, the utility of PET imaging has been increasingly studied in MTC, initially using FDG and (^{18}F)-dihydroxyphenylalanine (DOPA) and more recently the somatostatin analogs ^{68}Ga-DOTATATE and ^{68}Ga-DOTATOC. FDG-PET has been widely used in oncology, and its combination with CT imaging has enhanced diagnostic accuracy. Initial results using FDG as a tracer in MTC suggested disappointingly low sensitivities; however, small studies suggest that FDG-PET positivity may be more useful for identifying metastatic deposits in patients who have shorter calcitonin doubling times, and perhaps more aggressive disease.[78] A retrospective series of 29 patients with MTC found calcitonin doubling time to be shorter in PET-positive patients (n = 14) than those who were FDG-PET–negative (n = 15), and ten of the 11 PET-positive patients for whom clinical data were available had either died from metastatic disease or experienced disease progression, compared with 11 of the 12 PET-negative patients for whom data were available, who remained free from clinical disease.[81] Another recent study suggested that FDG-PET was useful in the small subset of study patients who had shorter CEA doubling times.[82]

DOPA is a positron-emitting analog of dopamine that has shown particular promise in imaging the sympathetic nervous system (e.g., pheochromocytomas). It may have greater sensitivity than FDG as a PET tracer in MTC: a metaanalysis of eight studies reported a pooled detection rate of 66% per patient and 71% per lesion, increasing to 86% in those patients with calcitonin levels great than or equal to 1000 ng/L or doubling times less than24 months.[83] There is interest in whether DOPA- and FDG-PET/CT studies may be complementary.[82] A retrospective study of 47 patients with recurrent MTC found FDG-PET positivity to be associated with progressive disease and reduced survival, while DOPA-PET showed greater sensitivity in detecting lesions, correlating with calcitonin and CEA levels as an indicator of tumor burden.[84]

The radiolabelled somatostatin analog ^{68}Ga-DOTATATE has a broader role in diagnosis and staging of neuroendocrine tumors, and small studies have examined its role in MTC. One small retrospective study compared ^{68}Ga-DOTATATE and FDG-PET/CT in 18 patients with recurrent MTC, reporting a similar sensitivity of 72.2% for ^{68}Ga-DOTATATE and 77.8% for FDG; however, FDG-PET/CT identified a greater number of lesions, particularly in the liver.[85] Another retrospective study of 18 patients with MTC and elevated serum calcitonin levels compared DOPA, FDG, and two different ^{68}Ga-somatostatin analogs, DOTANOC (14 patients) and DOTATOC (four patients), as PET/CT tracers. It reported a sensitivity of 72.2% for DOPA, significantly greater than 16.7% for FDG, and 33.3% for ^{68}Ga-somatostatin analogs, with the latter two sensitivities not being significantly different. Imaging was negative for all tracers in five patients who had calcitonin doubling times greater than 24 months (i.e., indolent disease).[86] This study is the only multicenter trial comparison trial looking at all three tracers. Somatostatin receptor–PET was studied in a metaanalysis and showed a detection rate per patient-based analysis of 63.5%.[87] The detection rate rose to 83% in those with serum calcitonin greater than 500 ng/L, although faster doubling time did not correlate with improved diagnostic performance, as seen using DOPA-PET. Most studies have small numbers and variable diagnostic performance, and overall these analogs seem inferior to DOPA-PET, but may complement the role of FDG-PET.

A metaanalysis of different PET radiopharmaceuticals in 2020 included 14 trials with 306 patients using five different PET radiopharmaceuticals (FDG, DOPA, ^{68}Ga-somatotatin analogs, (3-)-methyl-6-(F) fluoro-DOPA, and C-methionine) for the detection of MTC.[88] Of these, DOPA-PET had the best performance for detection of metastatic MTC on both patient- and lesion-based analysis (odds ratios 2.44 and 5.74, respectively), and was found to be superior to FDG-PET.

Histological Grading. The diagnosis of MTC is confirmed with surgical pathology, with characteristic features including solid and nesting growth patterns, along with amyloid deposits. Some variants may mimic papillary thyroid cancer (PTC), and immunohistochemistry for calcitonin is required for confirmation.[38] A number of histological, clinical, and genetic features were interrogated in 76 patients in a retrospective cohort in an attempt to create a histological grading system that could predict prognosis.[89] The clinical features of age and MEN2, as well as histological features of Ki-67 proliferative index, mitotic count, and coagulative necrosis, were predictive of prognosis. This grading system used three histological features and divided MTC into low-grade (82%), intermediate-grade (12%), and high-grade (7%). Overall survival for each grade was 193, 146, and 45 months respectively, and the difference was highly significant even after correction for age and MEN2 syndrome (P = .0001). A second study looking at 144 patients with MTC also found that tumor necrosis and high mitotic rate (as determined by greater than five mitoses per ten high-powered fields) correlated with disease-specific survival, whereas tumor necrosis only correlated with local recurrence–free survival and distant metastasis–free survival. These appeared to outperform calcitonin level and stage.[90]

Future Directions for Staging. Liquid biopsy is the detection of mutations in circulating plasma cell-free DNA and is emerging as a less invasive tool in diagnoses and treatment outcome in many cancers. Cote et al. demonstrated they could detect the *RET* codon 918 variant in patient plasma with high specificity and low sensitivity, and that it correlated with worse overall survival (OS).[91] MicroRNAs are small noncoding RNAs that function in RNA silencing and posttranscriptional regulation of gene expression. They promote chemoresistance, can predict prognoses, and may assist in staging in the future. MicroRNA expression profiling has demonstrated that miR-375 expression is a negative prognostic marker for MTC,[92] and miR-153-3p has been shown to be a RET-regulated tumor suppressor microRNA in MTC.[93] These assays remain largely in research settings for now but will likely infiltrate clinical practice in the near future.

Hereditary Versus Sporadic Medullary Thyroid Carcinoma

Hereditary MTC is characterized by the early onset of bilateral and multifocal disease. Sporadic MTC may present as a palpable thyroid mass or a nodule on ultrasound, and lymph node involvement is commonly present at diagnosis. Local lymph node spread occurs early in the course of the disease in both hereditary and sporadic forms and can be present with tumors as small as 1 cm in diameter.

A study by Raue and colleagues evaluating prognostic factors in MTC found that the stage of disease at diagnosis, age, sex, and type of disease (sporadic vs. hereditary) were relevant prognostic factors in a univariate analysis, with better prognosis for young female patients with familial disease diagnosed at an early stage.[94] The difference in the survival rate of patients with hereditary disease versus those with the sporadic form disappeared in multivariate proportional hazards analysis, but the prognostic information provided by age and sex was still significant. The overall adjusted survival rate was 86.7% at 5 years and 64.2% at 10 years. These rates are comparable to those quoted by other studies.[95,96] Another study found only the stage of disease and presence of extrathyroidal growth at presentation with MTC to be independent predictors of clinical behavior and life expectancy. In this study, increased age at diagnosis was found to be associated with a reduction in OS; however, when adjusted for the baseline mortality rate of the general population on multivariate analysis, this effect was lost.[96] Disease-free survival and OS were no different in hereditary versus sporadic MTC in the analysis by Abraham and colleagues, but there was a significant reduction in the rates of local MTC recurrence in the hereditary group compared with the sporadic MTC patients.[97]

A retrospective analysis of MEN2 kindreds with the codon 634 mutation looked at whether the presence of pheochromocytomas in these patients was associated with a more aggressive MTC. Those who had MTC without pheochromocytoma did not differ significantly from those who had MTC and pheochromocytoma in terms of the stage of MTC or survival.[46]

Paraneoplastic Features of Medullary Thyroid Carcinoma

Although MTC presents with the presence of a thyroid mass or distant particularly liver metastases, systemic symptoms may occur as a result of secretion of hormones from the tumors, particularly with increased tumor load with metastatic disease. High levels of calcitonin can cause flushing, particularly of the face, and refractory diarrhea. In some patients this may be the presenting symptom, and measurement of calcitonin should be performed as part of initial investigation. Diarrhea is caused by a combination of hypersecretion and increased gastrointestinal mobility.[38] Management is based upon reducing MTC burden, both surgically and with systemic therapies, including tyrosine kinase inhibitors (TKIs; discussed later). Nutritional status should be monitored, with avoidance of alcohol and increased intake of high-fiber foods. Antimotility agents (loperamide and codeine) have limited benefit, as do somatostatin analogs,[98,99] even in combination with interferon alpha.[100] There are reports of the anticholinergic agent glycopyrrolate assisting in resistant cases.[101] The serotonin-3 receptor antagonist ondansetron was reported in a nonrandomized series to relieve diarrhea in six patients with metastatic small bowel neuroendocrine tumors, and anecdotally can improve MTC-associated diarrhea.[102] Local therapy to large liver metastases may also improve diarrhea.[103]

Ectopic Cushing syndrome is an uncommon but debilitating paraneoplastic manifestation of MTC and accounts for 1% to 3% of Cushing syndrome cases and 2.2% to 7.5% of all ectopic ACTH cases.[104] It features in only 0.7% of cases of MTC but is known particularly for its association with MEN2-related MTC.[105,106] Patients will often have metastatic disease, with significant morbidity secondary to the Cushing's, including weight gain, abdominal striae, lethargy, diabetes, and myopathy. Histological confirmation may be challenging, as immunohistochemistry staining for ACTH is not always positive because of reduced stored granules and increased secretion of the hormone from the tumors.[107] Investigations include confirmation of cortisol excess, ACTH elevation, and localizing studies including MRI pituitary and[68] Ga-DOTATATE PET. Patients who develop Cushing syndrome have significantly increased mortality, accounting for 50% contribution to overall mortality in MTC with Cushing syndrome. Again, the mainstay of treatment includes reducing tumor burden surgically but also includes antiadrenal therapies, including medical therapy (ketoconazole, mitotane, and metyrapone) or surgical intervention with bilateral adrenalectomy, which can anecdotally significantly improve quality of life. TKIs can offer disease control in difficult cases. Vandetanib has been shown to control ACTH secretion and symptoms of Cushing syndrome,[108-110] although clinicians must be mindful of amplifying adverse effects (AEs), as ketoconazole, mitotane, and vandetanib all cause QTc prolongation. A case report of sorafenib resolving hypercortisolism has also been published.[111]

KEY POINTS

- Paraneoplastic features of medullary thyroid carcinoma are often attributed to high levels of calcitonin causing refractory diarrhea. Ectopic Cushing syndrome is a rare but debilitating complication. Bilateral adrenalectomy or treatment with the tyrosine kinase inhibitor vandetanib can improve quality of life.

Pheochromocytoma

Pheochromocytomas related to MEN2 tend to be bilateral and of adrenal origin, best visualized on CT or MRI structurally and by functional imaging using ^{68}Ga-DOTATATE PET/CT scan, which has replaced the role of MIBG scan.[112] Structural imaging often reveals areas of calcification and/or necrosis, with avid enhancement on dynamic contrast-enhanced MRI. Pheochromocytomas almost always have a precontrast CT density of at least 10 Hounsfield units, although low-density areas can occur, with intratumoral fat or necrosis.[76]

Hyperparathyroidism

Imaging of hyperparathyroidism may be via structurally via ultrasound, with a hypoechoic oval shape, and asymmetric hypervascularity. ^{99m}Tc-sestamibi uptake scan can show parathyroid adenomas, assisting with perioperative staging.[76]

MANAGEMENT OF MEDULLARY THYROID CARCINOMA

Localized Medullary Thyroid Carcinoma

Complete surgical removal of all neoplastic tissue offers the only potential for cure, and alternative forms of treatment using radiotherapy or chemotherapy provide little benefit. As mentioned earlier, whenever a patient is assessed for thyroid surgery, fractionated metanephrines should be measured before undergoing general anesthesia to exclude unrecognized pheochromocytoma. Serum calcium and parathyroid hormone levels should ideally also be measured preoperatively. Clinical guidelines for surgical decision-making include those published by the ATA in 2015.[38] Overall, 40% to 50% of MTC patients will have lymph node involvement at presentation. Patients with MEN3 and sporadic MTC have a higher rate of extrathyroidal spread than do those with MEN2. The primary neck operation should include total thyroidectomy and removal of all lymph nodes in the paratracheal central neck compartment (level VI), bounded by the hyoid bone, sternal notch, and internal jugular veins. Lymph nodes in the upper mediastinum and lateral neck regions (levels II to V) should be removed if clinically or radiologically abnormal, and some authors advocate prophylactic lateral neck dissection if lymph node metastases are present in the adjacent central compartment. In individuals with advanced local or extensive distant disease, less aggressive neck surgery may be considered, with the goal of obtaining local disease control and symptom palliation with less morbidity to speech, swallowing, and parathyroid function.[38]

Recurrent Medullary Thyroid Carcinoma

Persistent elevation of serum calcitonin and CEA are useful markers for the presence of residual or recurrent MTC. The most common sites of distant metastases from MTC are the liver, lung, bone, and brain. Regional spread in the neck and chest is very common and can occur early.

Localization of recurrence is often very difficult, particularly when calcitonin levels are only modestly elevated. One commonly faces the problem of failure of detection of metastatic disease, even when its presence is suggested by persistently elevated serum calcitonin or CEA. The biological behavior of MTC varies between subjects. In addition to being tumor markers, the doubling times of calcitonin and CEA are prognostic factors for progressive disease and poor survival.[113,114] These doubling times may be used to guide the frequency and intensity of serial imaging in most patients. One study compared calcitonin and CEA doubling times in 55 patients with MTC to disease progression as measured by Response Evaluation Criteria in Solid Tumors (RECIST). The authors found the doubling times of the two markers to be strongly correlated in 80% of patients, reporting progressive disease in 94% of patients who showed doubling times of less than 24 months and stable disease in 86% of those with doubling times of greater than 24 months.[115] A subsequent metaanalysis by Meijer and coworkers of 10 retrospective studies confirmed calcitonin and CEA doubling times to be significant indicators for both clinical disease recurrence and survival, reporting a higher hazard ratio (HR) for recurrence in those patients with a calcitonin doubling time of less than 12 months (HR 5.33) compared with those with a doubling time of less than 24 months (HR 2.93). In this study, the 5-year and 10-year survival rates for patients with a calcitonin doubling time of less than 1 year was 36% and 18%, respectively, compared with 98% and 95%, respectively, for those with a calcitonin doubling time of greater than 1 year; the corresponding CEA analysis found 5-year and 10-year survival rates of 43% and 21%, respectively, for a doubling time of less than 1 year, and 100% at both time points for a doubling time of greater than 1 year.[114] Of note, calcitonin and CEA markers can fluctuate significantly in the short term, so caution in assessing trends is required.[116] In both hereditary and sporadic MTC, the calcitonin level may accelerate and decelerate over time, reflecting the unpredictability of MTC disease.[117]

Selective Venous Catheterization. Historically, selective venous catheterization was regarded as a sensitive tool for the localization of residual disease and early detection of distant metastases in MTC.[118] However, in light of newer imaging modalities, it now has limited practical utility.

Structural and Functional Imaging. The large number of imaging modalities used to investigate persistently elevated calcitonin reflects the inadequacies of each modality. Reports in the literature are limited by the lack of use of a gold standard of histologic confirmation. In considering restaging with structural and functional imaging, refer to the description discussed in primary staging section earlier.

Persistent and Metastatic Medullary Thyroid Carcinoma

Local Therapies

Reoperation. Elevated levels of calcitonin persist after primary operation in many patients with MTC. Failure of normalization of calcitonin is more likely in subjects with a higher preoperative calcitonin level and in those in whom nodal metastases were confirmed at surgery.[119] Because of the lack of a highly sensitive and specific diagnostic tool to detect micrometastases postoperatively, one is often confronted with the unique situation of whether to reoperate without definite localization and, if so, to what extent. There have been no clinical trials performed to date in which patients have been randomized to observation or reoperation.[38]

Radiotherapy. Routine adjuvant neck irradiation postsurgery confers little demonstrated benefit and may be associated with significant morbidity.[38] A retrospective study by Brierley and colleagues in 73 patients demonstrated no overall difference in the local or regional relapse-free rate between those who received external irradiation and those who did not.[120] A systematic review in 2019 suggested that the risk of locoregional relapse was minimized in patients at high risk, including those with extrathyroidal extension and nodal involvement, but of concern is the potential for tissue damage complicating future surgery.[121] Radiotherapy may have a role in controlling local disease, which is an important quality-of-life endpoint in MTC.[38] If used, it appears that 60 Gy given within the first 2 months of surgery was most effective.[121]

Systemic Therapy

Somatostatin Analogues. Therapy with different formulations of somatostatin analogues does not demonstrate antitumor activity in MTC, in contrast to various neuroendocrine tumors. No significant decrease in the size of metastases has been found with the use of these somatostatin analogues in patients with advanced MTC.[122] However, such agents have a role in symptomatic control of symptoms of hormonal excess.[123]

Multikinase Inhibitors. Recent decades have seen an increased understanding of the role of receptor tyrosine kinases in a number of human malignancies, including the role of oncogenic RET in MTC, as discussed in this chapter. These cell surface transmembrane proteins, activated by hormones, growth factors, or, in disease states, genetic mutation, induce intracellular signaling pathways to modulate cellular activities, including proliferation, migration, and invasion. Inhibition of these cascades in neoplastic tissue has formed the basis of research into targeted molecular therapies. Most of the agents developed to date lack specificity for a single kinase and are best described as multikinase inhibitors (MKIs). Earlier studies of MKIs demonstrated modest benefit, but more targeted TKIs with greater specificity are proving useful.[38,124] The constitutive expression of the active RET receptor tyrosine kinase in MTC offers an enticing therapeutic target. The MKIs that have been assessed to date in phase III clinical trials are listed in Table 134.3, and phase I/II/III trial data are discussed in the following section.

Axitinib, a selective inhibitor of vascular endothelial growth factor receptor (VEGFR) 1, 2, and 3, but not RET, was evaluated in a phase II study of advanced thyroid cancer patients, including 11 patients with MTC. The small study suggested modest clinical efficacy: two patients demonstrated a partial response, and three patients demonstrated stable disease.[125] In a later study, a cohort of 13 MTC patients who received compassionate access showed median progression-free survival (PFS) of 9.4 months (95% confidence interval [CI]: 4.8–13.9).[126] Motesanib, an oral agent that targets VEGFR1, 2, and 3, platelet-derived growth factor receptor (PDGFR), and c-KIT (stem cell factor receptor), as well as wild type RET *in vitro*, was studied in 91 patients with locally advanced or metastatic MTC, of whom just 2% demonstrated a partial response and 48% demonstrated stable disease beyond 24 weeks.[127] Vandetanib, an oral inhibitor of RET, VEGFR, and epidermal growth factor receptor signaling, has been assessed in two phase II trials with patients with advanced hereditary MTC, at doses of 300 mg/day (n = 30) and 100 mg/day (n = 19).[128,129] Disease control was achieved in 73% and 68% of patients, respectively, and a phase III study in patients with advanced hereditary or sporadic disease has subsequently been reported, as discussed later.[130] The MKI sunitinib, targeting VEGFR1 and 2, PDGFR, c-KIT, Fms-related tyrosine kinase (FLT3), and RET, was assessed in a phase II study of advanced iodine-refractory differentiated thyroid carcinoma and metastatic MTC. The MTC cohort included seven patients, of whom six were able to be evaluated for clinical response, and three achieved an objective partial response by RECIST.[131] Twenty-six MTC patients received sunitinib as first-line antiangiogenic therapy in another phase II trial and showed an objective response rate (ORR) of 38.5% (95% CI: 22.6–56.4) with median PFS 16.5 months.[132] Of note, this study also had considerable AEs, with 14.1% of all patients (combined PTC, anaplastic thyroid cancer, and MTC) having a cardiac event and frequent grade III AEs.

Sorafenib, an orally available MKI that targets VEGFR2 and 3, RAF kinases C-RAF and B-RAF, PDGFR, c-KIT, FLT3, and RET, has had limited success in MTC treatment. In a phase II study that included 16 patients with advanced sporadic MTC, one individual achieved a partial response, 14 demonstrated stable disease, and one individual was not evaluable by RECIST and demonstrated clinical progression; *post hoc* analysis of the 10 patients who had demonstrated progressive disease before study entry included one partial response and four patients with stable disease beyond 15 months on study drug.[133] A subsequent study evaluating sorafenib in advanced thyroid carcinoma of any histopathologic type reported a partial response at 12 months in 25% of MTC patients.[134] Ito et al. showed an ORR of 25% and disease control rate of 75% in eight MTC patients.[135] Cabozantinib, an oral inhibitor of MET (also known as *hepatocyte growth factor receptor,* a receptor

TABLE 134.3 Phase III Trials and US Food and Drug Administration-Approved Tyrosine Kinase Inhibitors in Medullary Thyroid Carcinoma

Tyrosine Kinase Inhibitor	Target	Phase	Population	Result	Common Adverse Events
Cabozantinib[142]	VEGFR, c-Kit, ERT, MET, RET	III	Progressive metastatic disease	PFS 11.2 months, OS 44.3 months[a143]	[b]Diarrhea, PPE, weight loss, anorexia, nausea, fatigue, dysgeusia, hair color changes, HTN, constipation, hemorrhage
Vandetinib[130]	VEGFR, c-Kit, RET, EGFR, RET	III	Stable metastatic disease	PFS 30.5 months	[b]Diarrhea, rash, nausea, hypertension, fatigue, headache, anorexia, acne, asthenia, vomiting, back pain, dry skin, insomnia, abdominal pain, dermatitis acneiform
Selpercatinib[124]	RET	II	Stable or progressive metastatic disease	69% objective response at 1 year, 86% response ongoing	Hypertension, increased alanine aminotransferase and aspartate aminotransferase, hyponatremia, and diarrhea

[a]Not significant.

[b]AEs were observed in >25% of patients treated with vandetanib or cabozantinib. In patients treated with selpercatinib, even the most frequent AE was only found in 21% of cases.

FDA, US Food and Drug Administration; *AE*, adverse event; *TKI*, tyrosine kinase inhibitor; *MTC*, medullary thyroid carcinoma; *PPE*, palmar-plantar erythrodysethesia; HTN, hypertension; PFS, progression-free survival; OS, overall survival.

RECIST or Response Evaluation Criteria in Solid Tumours is a very standard description for measuring response see: https://www.cancer.gov/publications/dictionaries/cancer-terms/def/recist.

tyrosine kinase involved in invasive growth, metastasis, and angiogenesis[136]), VEGFR2, and RET kinase, was suggested to demonstrate clinical benefit in the MTC subset of a phase I study of advanced solid malignancies: a partial response was observed in 29% of the 37 patients with MTC, and 41% achieved stable disease of at least 6 months. Lenvatinib, another antiangiogenic MKI that inhibits VEGFR1 to 3, FGFR1 to 4, PDGFRα, RET, and v-kit Hardy–Zuckerman 4 feline sarcoma viral oncogene homolog (KIT), is approved for radioiodine-refractory differentiated thyroid cancer and was assessed in a phase II study of MTC patients.137 In the cohort of 59 patients, ORR was 36% (95% CI: 24–49), with all partial responses. Median PFS was 9 months (95% CI: 7–not evaluable).

The combination of sorafenib and tipifarnib (a farnesyltransferase inhibitor that inactivates RAS and other farnesylated proteins) has been reported in a phase I study of advanced thyroid malignancy. Of the 13 patients with MTC, 38% had a partial response (duration ranging from 9+ to 34+ months), and 31% had stable disease of at least 6 months.[138] There is also evidence that the mammalian target of rapamycin (mTOR) pathway is activated in MTC tissue,[139] and *in vitro* data suggest that dual blockade of RET and mTOR kinase activities results in suppression of MTC cell growth.[45] Everolimus, an mTOR inhibitor, has been shown to be antiproliferative to MTC cells *in vitro*,[140] and a small ($n = 7$) phase II trial demonstrated clinical efficacy, with 71% showing stable disease.[141]

Two phase III studies of MKIs in MTC have been reported, with the resultant approval of vandetanib and cabozantinib by the US Food and Drug Administration (FDA) for use in progressive metastatic disease in adults. The vandetanib study included 331 patients with sporadic or hereditary advanced MTC and reported prolonged PFS with vandetanib compared with placebo (HR 0.46, 95% CI: 0.31–0.69); predicted median PFS was 30.5 months with vandetanib and 19.3 months with placebo.[130] Cabozantinib was assessed in 330 patients with progressive, locally advanced, or metastatic MTC: median PFS with cabozantinib was 11.2 months, compared with 4.0 months with placebo (HR 0.28, 95% CI: 0.19–0.40).[142] OS was assessed in 2017 and showed a statistically nonsignificant increase in OS of 26.6 versus 21.1 months in patients treated with cabozantinib versus placebo (HR 0.8595%, 95% CI: 0.64–1.12; $P = 0.24$).143 The above MKIs are all associated with AEs, including diarrhea, hypertension, fatigue, and skin rashes, often necessitating dose reductions or interruptions. Vandetanib and cabozantinib are also associated with prolonged QT intervals, palmar-plantar erythrodysesthesia, and mucositis.

The development of the specific RET kinase inhibitors LOXO292 (selpercatinib) and BLU667 (pralsetinib) has created a new paradigm in systemic therapy for metastatic MTC. These more specific RET kinase inhibitors have shown not only a better disease control rate, albeit in phase I/II trials, but also fewer and less severe AEs.[144] Among 49 response-evaluable MTC patients, pralsetinib demonstrated an ORR of 47% (95% CI: 33–62).[145] In a phase I/II trial, selpercatinib demonstrated a 1-year PFS rate of 82% (95% CI: 62–82) in patients who had been previously treated with vandetanib and cabozatinib.[124] Those who had not been previously treated had an even higher 1-year PFS rate of 92% (95% CI: 82–97). AEs included hypertension (21%), transaminase rise (9%–11%), hyponatremia (8%), and diarrhea (6%). However, in contrast to the other TKIs mentioned previously, adverse events were far less debilitating, and withdrawal from drug only occurred in 2% of patients. In May 2020, the FDA has approved selpercatinib for *RET*-fusion radioiodine-refractory differentiated thyroid cancer and for patients 12 years and over with *RET*-mutant MTC.

Resistance to TKIs, particularly vandetanib, in patients harboring the *RET* codon 804 variant is well described.[146] Selpercatinib has been reported to overcome both hereditary and acquired V804M resistance, but a recent report showed the development of solvent-front mutations leading to acquired resistance in two MTC patients receiving selpercatinib.[147]

There is much interest in whether tumor genotype may determine response to drug in an individual. Patients on vandetanib harboring the M918T mutation exhibited a higher response rate.[130] Analysis of the cabozantinib study found the presence of any *RET* mutation to be associated with a longer median PFS on drug compared with wild-type *RET* (60 weeks vs. 25 weeks, $P = 0.0001$), and, in addition, found mutation M918T to show the longest median PFS on cabozantinib treatment compared with any other mutation (61 weeks vs. 36 weeks, $P = .009$). The small number of patients found to harbor a *RAS* gene mutation showed similar treatment responses to *RET*-mutated patients when treated with cabozantinib.[148] Lenvatinib disease response rates showed no difference between *RET* variants.137

KEY POINTS

- Traditional treatment, including chemotherapy and radiation, has been surpassed by targeted treatment with tyrosine kinase inhibitors. Multikinase inhibitors have shown increased progression-free survival in phase III trials, but adverse effects can impair quality of life. Early trials of more targeted RET kinase inhibitors have shown promising overall response rates and appear to be better tolerated.

Radionuclide Therapy. Radioactive iodine (^{131}I) has not demonstrated efficacy in treatment of MTC.[149] This is attributed to the fact that MTC arises from parafollicular C-cells of the thyroid gland, which do not concentrate iodine. There has been limited experience with therapeutic ^{131}I-MIBG in MTC. A recently reported retrospective series of ^{131}I-MIBG therapy in 13 patients with metastatic MTC described a partial response in four individuals and stable disease in four individuals.[150] Randomized, prospective data are lacking. Other attempts to deliver targeted radioactivity are under ongoing investigation. One approach has been to administer monoclonal antibodies coupled with radioisotopes as pretargeted radioimmunotherapy. A recent phase II study reported disease stabilization and prolonged survival with two-part radioimmunotherapy against CEA in patients with rapidly progressing metastatic MTC, although hematologic toxicity was observed.[151] Other groups have used yttrium-90–labeled somatostatin analogues for targeted radiotherapy, with modest success. A phase II trial evaluating ^{90}Y-DOTATOC reported a partial response in 29% of the 13 patients.[152] Forty-three somatostatin receptor–positive metastatic MTC patients were treated with ^{177}Lu–DOTATATE peptide receptor radionucleotide therapy (PRRT), and 61% were responders based on molecular imaging (^{68}Ga–DOTATATE) with prognostic variables relating to size of lesion (<2 cm) and lower FDG uptake (maximum standardized uptake value <5). Some 62% were responders on anatomical imaging using RECIST criteria, demonstrating that PRRT has the utility as a therapeutic tool in metastatic MTC.[153]

Chemotherapy. Conventional cytotoxic chemotherapy has been of limited value and is not recommended as first-line therapy for patients with persistent MTC.[38] Doxorubicin has been the most widely used single chemotherapeutic agent in the treatment of MTC, and therefore is the one associated with most reported responses. Dacarbazine is the most widely used agent in combination therapy. Petursson reported a patient with metastatic MTC who demonstrated a complete response with combination chemotherapy of dacarbazine and 5-fluorouracil.[154] Combined chemotherapy has been tried in patients with advanced

MTC using cyclophosphamide, vincristine, and dacarbazine; this yielded only moderate antitumor activity.[155] Small studies have investigated selective arterial chemoembolization to treat hepatic metastases, with some tumor response and symptom palliation.[156,157]

MANAGEMENT OF PHEOCHROMOCYTOMA

Early identification of pheochromocytoma is important to prevent the associated morbidity and the risks associated with unsuspected pheochromocytoma in pregnancy or with intercurrent surgery. When pheochromocytoma is confirmed, the patient will require alpha blockade, likely plus beta blockade, as discussed in Chapter 110. Molecular imaging modalities such as ^{68}Ga–DOTATATE localize pheochromocytomas at a smaller size than in the past,[112] and surgical techniques have also advanced. Confirmed pheochromocytomas should be removed before thyroidectomy for MTC.[38] Laparoscopic adrenalectomy, ideally with the posterior retroperitoneal approach, is now the operation of choice, where available.[158] There is interest in cortical-sparing adrenalectomy, particularly when bilateral adrenalectomy is required and when patient compliance with steroid replacement is likely to be problematic. However, the cortical-sparing approach may be associated with higher recurrence rates, and there is a lack of long-term studies.[159]

MANAGEMENT OF HYPERPARATHYROIDISM

The surgical approach to hyperparathyroidism is less aggressive than in MEN1 owing to the different behavior of the parathyroid disease in the two conditions. Total parathyroidectomy is not recommended, and recurrences are uncommon. However, an open neck exploration is preferred to minimally invasive surgery.[51,52] Preoperative localization studies are only recommended in patients who have had previous neck surgery. Only enlarged parathyroid glands should be removed, and forearm parathyroid autografting is recommended at the initial parathyroid surgery. This is because the risk for MTC recurrence is such that further neck operations are likely to be needed in the future, resulting in parathyroid removal or devascularization.[38] Normal parathyroid glands may also be resected or devascularized at the time of initial thyroidectomy for MTC. Parathyroid "normal" tissue should be transplanted into the sternomastoid muscle in the neck in the case of MEN3 or FMTC patients, in whom there is a low risk for hyperparathyroidism. Devascularized parathyroid glands from patients with the codon 634 mutation or a strong family history of hyperparathyroidism should be autografted into the forearm, where portions of the graft can be removed if hyperparathyroidism develops.[38]

CONCLUSION

Therapeutic modalities for advanced MTC have improved over the past decade. Cure is still only possible with early diagnosis followed by surgery. Genetic screening for *RET* variants has revolutionized the management of familial MTC and MEN2 by enabling prophylactic thyroidectomy or early diagnosis of established disease. The more common sporadic disease remains a much greater challenge. Phase II clinical trials of the more selective RET kinase inhibitors have demonstrated efficacy, with tolerable side effects, and may offer a better prognosis and quality of life for patients with advanced MTC.

INTRODUCTION

In 1907, Siegfried Oberndorfer selected the term *karzinoide* (“carcinoma-like”) to refer to the group of neoplasms he discovered within the small intestine that simultaneously shared the histological appearance of adenocarcinoma but yet had no apparent ability to invade or metastasize. This latter observation would prove false, but Oberndorfer’s name for the pathologic entity would be maintained and later used to name the syndrome for which these tumors would become best known.[1]

Neuroendocrine tumors (NETs) have since been found in a variety of sites. They are most common in the small and large intestine, pancreas, lungs, and bronchi, and less common in the thyroid, parathyroid, pituitary gland, adrenal glands, breast, ovary, and thymus. NETs produce and secrete a variety of peptide hormones and bioactive amines. Many of these factors can be measured in blood or urine, and some aid in diagnosis, prognostication, and disease surveillance. When hypersecreted, these factors can produce clinical symptoms and physiologic derangements that adversely affect a patient’s quality of life or even prove to be life-threatening. Tumors manifesting with such symptoms are termed “functional.” Nonfunctional tumors may secrete factors that do not result in a clinical syndrome.[2] The hormonal syndromes produced by these tumors are distinct but rare and typically require multimodal therapy for palliation or cure.

This chapter will briefly cover the epidemiology and pathogenesis of well-differentiated NETs of the gastrointestinal and aerodigestive tracts but focuses more specifically on the diagnosis and management of the clinical syndromes produced by these unique tumors. Ectopic hormone syndromes and other NETs (e.g., pheochromocytoma) are covered elsewhere in this text and will not be discussed here.

EPIDEMIOLOGY

Neuroendocrine neoplasms (NENs) are rare but increasing in incidence, affecting 6.98 per 100,000 individuals according to the Surveillance Epidemiology End Results (SEER) database. The rise is seen across all NET primary sites and disease stages. Lung NETs have the highest incidence, followed by ileal/jejunal, rectal, and pancreas. The rising incidence is likely multifactorial and related not only to a true increase in incidence and growing recognition of the disease, but also greater use of cross-sectional imaging and endoscopy that may detect these tumors during the course of surveillance and diagnosis of other conditions. Patients are typically 65 years old or greater at diagnosis, with women only slightly more commonly affected (52.7%).[3]

The heterogeneity of primary tumor sites, functional status, and propensity for metastasis requires careful communication with subtly different terminology. NEN is a generic term used to encompass all NETs, regardless of grade, differentiation, or metastatic potential. A group of well-differentiated NENs with metastatic potential are termed NETs. The term “neuroendocrine carcinoma” (NEC) specifically refers to the group of poorly differentiated NETs with Ki-67 greater than 20%.

Despite their infamy, NET syndromes are only seen in a fraction of patients. The most common is carcinoid syndrome (most frequently found in patients with jejunal/ileal NETs), followed by those caused by hormones hypersecreted by pancreas/duodenum NETs. The proportion of patients affected by these clinical presentations is difficult to ascertain. It ranges widely in the literature, as most series are single-institution and retrospective, but is often estimated at 25% to 30% in gastroenteropancreatic (GEP) NETs[4] and less than 10% of lung NETs.[5] A 2017 study using the SEER-Medicare database estimated that 19% of NEN patients suffered from carcinoid syndrome

TABLE 135.1 **Pathologic Classification of Gastroenteropancreatic Neuroendocrine Tumors**

Terminology	Differentiation	Grade	Mitotic Rate (mitoses/mm^2)	Ki-67 Index (%)
NET G1	Well-differentiated	Low	<2	<3
NET G2	Well-differentiated	Intermediate	2–20	3–20
NET G3	Well-differentiated	High	>20	>20
NEC G3	Poorly differentiated	High	>20	>20

at diagnosis. These patients were more likely to have regional or distant metastases, grade 1 or 2 tumors, and primary sites either in the jejunum/ileum or cecum.[6] In pancreatic NENs, an analysis of SEER data revealed that the majority were not classified as functional (90.8%). Of the functional neoplasms, gastrinomas are most common, followed by insulinomas, glucagonomas, and vasoactive intestinal peptide (VIP) tumors.[7]

KEY POINTS

- The terminology of neuroendocrine neoplasms (NENs) varies by metastatic potential, grade, and differentiation. Neuroendocrine tumors (NETs) are well-differentiated NENs with metastatic potential, and a Ki-67 ≤20%. The term “neuroendocrine carcinoma” should only be applied to poorly differentiated NETs with Ki-67 >20%. NENs are further defined by their function, or lack thereof.

ETIOLOGY

NETs arise from secretory cells of the diffuse neuroendocrine system. Gastrointestinal NETs derive from enterocytes, goblet cells, Paneth cells, or endocrine omnipotent stem cells at the base of the crypts of Lieberkühn, with differences in transcription and signaling driving ultimate neoplastic differentiation.[8] Pancreas NETs (PNETs) originate from the islets of Langerhans, as well as from embryonal cells within the duct/acinar system.[2,9]

The majority of NETs are sporadic and not related to an inherited genetic factor. Neither GEP nor lung NETs are associated with significant behavioral or environmental factors (i.e., smoking). Genetic predisposition accounts for less than 10% of GEP NETs, with multiple endocrine neoplasia type I (MEN1) the most common of the inherited cancer syndromes.[10] MEN1 is inherited in an autosomal dominant fashion. Patients develop multigland hyperparathyroidism (95%–100%), PNETs (80%–100%), and pituitary adenomas (54%–65%). Most MEN1-associated PNETs are nonfunctional (70%). Gastrinomas and insulinomas are the most common functional tumors in hereditary syndromes, as in sporadic disease. Less common familial NET syndromes include neurofibromatosis-1, tuberous sclerosis, Cowden syndrome, von Hippel Lindau,[4] and inositol polyphosphate multikinase.[11]

PATHOLOGIC CLASSIFICATION AND PROGNOSIS

Gastrointestinal NENs are classified as either well-differentiated NETs or poorly differentiated NECs, depending on the extent to which the tumor cells resemble their nonneoplastic counterparts. Well-differentiated tumors have uniform, “organoid” cellular arrangements, whereas poorly differentiated tumors have a more diffuse sheet-like architecture, with irregular nuclei and scant cytoplasmic granularity.[12]

Gastrointestinal NETs are also described by their grade, which is determined by the cellular proliferation rate (Table 135.1). It is most common to define a GEP NET’s grade via Ki-67, an immunohistochemical (IHC) method that reports the percentage of neoplastic cells that stain for the proliferation antigen, although calculation of the mitotic rate (mitoses per 2 mm^2)[13] is also acceptable. Low-grade (G1) NETs are defined by a Ki-67 index of less than 3%, intermediate-grade (G2) 3% to 20%, and high-grade (G3) greater than 20%.[14] Ki-67 IHC is highly reproducible, and concordance between biopsy and surgical specimens is greater than 90%.[15]

Clinical behavior can be predicted by a tumor’s cellular differentiation and grade. Well-differentiated, low-grade (G1 and G2) tumors behave indolently and tend to be slower to metastasize. Low- (G1) and intermediate- (G2) grade GEP NETs are associated with a median overall survival (OS) of 16 and 8 years, respectively. Examined by primary site (but not controlled for grade or stage), appendiceal NETs have the most favorable OS, estimated at greater than 30 years, followed by rectal NET, with a median OS of 24.6 years. PNETs have the shortest median OS of GEP NETs, at only 3.6 years. Stage is also predictive of prognosis, but also depends on the primary site. Localized small intestine NETs have a median OS of 14 years. This is reduced to 8.6 years in advanced cases. Pancreas NETs diagnosed when still localized have a median OS of approximately 20 years. Survival decreases to approximately 5 years in advanced disease.[3]

Historically, shorter OS was reported for patients with functional tumors.[16-18] This observation is likely related to two factors—the disproportionate effect carcinoid heart disease had on NET-related mortality, and methodological errors in the retrospective studies performed. The pathophysiology of carcinoid heart disease is incompletely understood but is thought to relate to chronically elevated levels of circulating serotonin causing fibrous endocardial thickening of heart valves (typically right-sided), heart failure, and death.[19] In the 1990s, carcinoid heart disease accounted for approximately 50% of NET-related deaths, but aggressive surgical management has improved disease-related survival, and these patients now have an OS that approximates that of nonsyndromic patients.[20] The second factor relating to this observation was that many studies failed to control for hepatic tumor burden when determining factors associated with shorter OS in NET patients. Carcinoid syndrome is associated with high metastatic tumor burdens, and a significant portion of these patients will ultimately die of liver failure. Correction of this factor eliminated the survival disadvantage seen in patients with elevated levels of serotonin and urinary 5-hydroxyindoleacetic acid (u5-HIAA).[21,22]

Poorly differentiated, high-grade NEC have a poor prognosis and progress rapidly, and are therefore managed differently than well-differentiated, lower-grade NETs.[23] In this group, median OS is a mere 10 months.[3] Sorbye et al. analyzed a large group of NECs and found that survival outcomes and response to platinum-based chemotherapy were associated with Ki-67 index. NECs with Ki-67 less than 55% had low response rates to platinum-based chemotherapy, but significantly longer OS (14 months vs. 10 months with Ki-67 index >55%).[24] Bridging these two categories of GEP NENs are the newly described well-differentiated G3 GEP NETs, which seem to have a better prognosis than poorly differentiated G3 NEC. In one series of 31 GEP NETs, median disease-specific survival was 55 months for well-differentiated G3 NET compared with 11 months for G3 NEC.[25]

Lung NETs have retained the term "carcinoid" and are categorized as typical or atypical carcinoids, based on their grade and histologic appearance. Typical lung carcinoids have fewer than 2 mitoses/mm^2 and lack necrosis, whereas atypical lung carcinoids have two or more mitoses/mm^2 or have focal necrosis. The use of Ki-67 to differentiate these entities is controversial, and not currently recommended.[26] Typical lung carcinoids behave similarly to G1 GEP NETs, whereas atypical lung carcinoids more closely approximate G2 GEP NETs. Small and large cell lung cancers, classified morphologically, are analogous to poorly differentiated G3 NECs. Typical lung carcinoids are associated with a median OS of approximately 20 years, whereas patients with high-grade lung carcinomas demonstrate a median OS of 1 to 2 years.[3] Lung NETs do not have an equivalent well-differentiated, high-grade entity.

KEY POINTS

- All neuroendocrine neoplasms should be described by the location of the primary tumor, cellular differentiation and grade, and function, as each of these factors contributes to management decisions and discussions of prognosis. Functional tumors are not necessarily associated with poor prognosis. Rather, it is the underlying tumor burden and physiologic sequelae of hypersecreted hormones and bioactive amines that affect outcome.

DIAGNOSTIC APPROACH AND CLINICAL PRESENTATION

Whether functional or nonfunctional, a high index of suspicion is required to correctly diagnose a NET. The symptoms produced by hypersecreting NETs may not manifest at once, can vary in severity, and also mimic symptoms of common diseases like inflammatory bowel disease, diabetes, or dermatitis. Patients with nonfunctional tumors may suffer from vague abdominal pain or inflammatory bowel disease–like symptoms, allowing the tumor to go undetected for many years. These difficulties support the recommendation that patients diagnosed with NET are best served at high-volume NET centers with specialized multidisciplinary teams familiar with the nuances of diagnosing, staging, and treating these unique tumors.

Laboratory Tests and Biomarkers

Nonspecific biochemical testing is most useful to monitor response to therapy or detect disease progression and recurrence. Current biomarkers lack the sensitivity and specificity to be used as screening tools and are more appropriately obtained to confirm or rule out a diagnosis when pretest probability is high.[27] Historically, guidelines from both the North American and European Neuroendocrine Tumor Societies have recommended measuring chromogranin A (CgA) and 24-hour u5-HIAA for extrapancreatic NET,[28,29] although more recent guidelines have deemphasized their use and utility.[30] In PNETs, institutional practices vary. Some initially order a broad spectrum of tests and then narrow their scope once the secretory behavior of the tumor is ascertained, whereas others order only those labs that will confirm the diagnosis of a specific functional syndrome (e.g., gastrin in a patient with symptoms of Zollinger–Ellison syndrome). Most data used to guide practice are retrospective and can be difficult to interpret or apply broadly. The lack of consensus emphasizes the importance of specialized, multidisciplinary care delivered by practitioners well-versed in the limitations of each biomarker, as well as their utility when applied consistently.

CgA may be a useful aid to assess the completeness of surgical cytoreduction, or to indicate disease recurrence and progression, as its levels can correlate with tumor burden. It is widely distributed in neuroendocrine tissues, present in normal islet cells, and also cosecreted with serotonin. Its sensitivity and specificity range between 67% and 93% and 85% and 96%, respectively. Caution must be used when interpreting results, as the levels can be falsely elevated by proton pump inhibitors, or in patients with atrophic gastritis, renal or hepatic failure, or cardiac dysfunction.[31]

5-HIAA is a metabolite of serotonin with high sensitivity (>95%) but low specificity for GEP NET. It is measured in a 24-hour urine collection or via plasma assays. Levels do not correlate with either tumor burden or symptom severity,[20] so its utility is limited to diagnosis, rather than surveillance. As with CgA, its levels can be falsely elevated by a number of substances—medications (acetaminophen, monoamine oxidase inhibitors, 5-fluorouracil), caffeine, wine, or tryptophan-rich foods (mockernuts, cheese, pineapple, tomato).[31]

Patients with a suspected functional NET in the duodenum or pancreas may require a more intensive laboratory workup to confirm a diagnosis, with selection of tests guided by symptoms. In most cases, demonstration of elevated circulating levels of the hormone responsible for the symptoms is sufficient. When these tests are equivocal, diagnosis of insulinomas or gastrinomas can be pursued with provocative testing. Patients with a suspected insulinoma may undergo a monitored 48-hour fast. Plasma glucose, insulin, and proinsulin levels are assessed at admission, and then serially every 4 to 6 hours. Patients are monitored for symptoms of hypoglycemia, which, in combination with low blood glucose and high proinsulin and insulin levels, clinch the diagnosis.[32] When a fasting gastrin level is equivocal for diagnosis of a gastrinoma, a secretin stimulation test may be helpful. Patients are administered intravenous secretin, and gastrin levels are measured approximately every 5 minutes for 30 minutes. An increase of serum gastrin levels greater than 200 ng/L confirms a gastrinoma.[33] In patients treated with proton pump inhibitors who are unable to stop therapy during their diagnostic workup, integration of imaging, biopsy, and IHC are useful.[34] Suggested laboratory tests for various NET tumor types are outlined in Table 135.2.

Imaging

After a thorough history, imaging is essential for NET diagnosis. Standard modalities such as endoscopy, computed tomography (CT) and magnetic resonance imaging (MRI) can localize the primary tumor, define anatomic relationships crucial for surgical planning, and monitor for progression or recurrence. Somatostatin-targeted imaging is a modality unique to NETs that can localize tumors in multiple tissue types and identify individuals who may benefit from somatostatin receptor (SSTR)-targeted therapy. Frequently, multiple modalities are used throughout the care cycle.

Endoscopy. Endoscopy is helpful in a variety of settings for GEP NET of the foregut and hindgut. Esophagogastroduodenoscopy (EGD) can detect primary tumors, treat small tumors using snare or

TABLE 135.2 Suggested Baseline Laboratory Tests for Neuroendocrine Tumor Types

Tumor Type	
Insulinoma	Fasting: Proinsulin Insulin C-peptide Blood glucose
Gastrinoma	Gastrin (fasting) Gastric pH
Glucagonoma	Glucagon (fasting)
Somatostatinoma	Somatostatin
VIPoma	VIP
Gastric NET	Gastrin (fasting) Chromogranin A or u5-HIAA
Jejunoileal, colorectal NET	Chromogranin A or u5-HIAA
Nonfunctional PNET	No NET-specific biomarker recommended
Lung NET	No NET-specific biomarker recommended

The suggestions follow recommendations set forth by the North American Neuroendocrine Tumor Society[30,114] and the European Neuroendocrine Tumor Society. In small intestine and nonfunctional pancreas NETs, obtaining pancreastatin and neuron-specific enolase levels can be considered. Institutional practices vary.

VIP, Vasoactive intestinal peptide; *u5-HIAA,* urinary 5-hydroxyindoleacetic acid.

electrocautery, and provide tissue for diagnosis. When combined with endoscopic ultrasound (EUS), it may provide information about T and N stage, and allows for ultrasound-guided fine-needle aspiration of PNETs or regional lymph nodes. In PNETs, EUS localizes tumors with 93% sensitivity and 95% specificity. Duodenal NETs are often more difficult to detect, as they are small and submucosal. EGD detects these tumors in only 40% to 60% of cases.[35] Double balloon enteroscopy or capsule endoscopy may be employed to detect small bowel primaries, but this is not part of the standard workup, as detection rates are less than 50%.[36,37] Colonoscopy is used analogously to EGD for NETs of the colon, rectum, and terminal ileum. Bronchoscopy, with or without ultrasound, can be used for detection, biopsy, local staging, and surveillance of lung and bronchial NETs.

Computed Tomography. Computed tomography is the most frequently used imaging modality in the workup and surveillance of NETs. In GEP NETs, CT demonstrates a mean sensitivity of 73% and 96% specificity for localizing the primary tumor, with an overall detection rate of 73%. It performs better for hepatic metastases, with a mean sensitivity of 82% and specificity of 92%. Efficacy in soft tissue metastases is similar to that of hepatic metastases. CT is useful for detecting typical lung carcinoids, although the positive predictive value of CT in detecting pathological regional lymphadenopathy is a disappointing 20% to 45%.[5] CT enteroclysis, which involves distending the small bowel with 2 L of tap water before imaging, can be used to detect small intestine NETs and increases the detection rate of these often small tumors, with a mean sensitivity and specificity of 85% and 97%, respectively.[38]

Regardless of primary tumor site, CT should be obtained with intravenous contrast (and oral contrast in cases of GEP NETs). NETs are typically hypervascular and detected in the early arterial phase of a triple phase (early arterial, late arterial, portal venous phases) scan.

Many institutions have dedicated CT protocols for various NET primary tumor sites (e.g., pancreas or appendix NET protocol), which differ from generic CT protocols by the types and timing of contrast administered.

Magnetic Resonance Imaging. MRI is less commonly used to detect sporadic primary tumors, but rather used for detection and surveillance of hepatic or, rarely, brain metastases.[5,38] In this latter context, the mean detection rate ranges from 82% to 95%. Occasionally, PNETs that escape detection by CT are detected by MRI. In these cases, MRI demonstrates an average sensitivity of 93% and specificity of 88%.[38] This modality is also useful in patients who cannot undergo disease surveillance with CT, such as those with renal failure or an allergy to iodinated contrast. As with CT, optimal imaging requires intravenous contrast, in this case gadolinium. NET are hyperintense on arterial phases. Magnetic resonance cholangiopancreatography can be used to define biliary ductal anatomy, especially in patients who cannot be imaged with endoscopy.

Somatostatin Receptor Imaging. Somatostatin is an inhibitory hormone produced by the delta cells of the gastric antrum, duodenum, and pancreas. The hormone binds to SSTR, a receptor with five different subtypes in humans (SSTR1–5).[39,40] NETs may express a combination of these receptors, commonly with a greater proportion of SSTR2, and it is these receptors that serve as the basis for SSTR imaging and treatment. SSTR expression declines with advancing tumor grade and loss of differentiation, and SSTR-based imaging is generally helpful in grade 1 and 2 (and some well-differentiated grade 3) NETs, but less frequently in NECs.[41] The newest iteration of SSTR imaging is a type of positron emission tomography (PET). The most common modalities use a ^{68}Ga-labelled radioligand conjugated to a somatostatin analog (SSA) (^{68}Ga-DOTATOC, ^{68}Ga-DOTANOC, ^{68}Ga-DOTATATE).[42] This novel PET scan is fused with either CT or MRI to aid anatomic localization. It has enhanced sensitivity (97%) compared with its predecessor, the OctreoScan (sensitivity of 85%), which is a scintographic imaging modality that uses ^{111}In-labeled diethylenetriamine penta-acetic acid octreotide to detect tumors expressing SSTR2 and SSTR5.[43]

DOTA PET is most appropriately used for initial staging after the histologic diagnosis of a NET, for localization of a primary tumor in patients with metastatic disease but unknown primary, and to select patients for SSTR-targeted peptide receptor radionuclide therapy (PRRT). It is not an absolute requirement in the workup and staging, but an adjunct when standard imaging cannot identify suspected primary or metastatic lesions, and for determination of SSTR status.[42] These studies are useful for both functioning and nonfunctioning NET, although insulinomas may demonstrate low expression of SSTR2 and thus localize poorly.[44,45] Other subtypes of functional NETs typically express high levels of SSTR, and thus detection may only be limited by their size, as tumors less than 1 cm are often below the limit of resolution.

(^{18}F)-Fluorodeoxyglucose Positron Emission Tomography. (^{18}F)-fluorodeoxyglucose (FDG) is a synthetic analog of glucose that is taken up by metabolically active cells, and thus FDG-PET is used to detect distant metastases in NECs. It has poor sensitivity for well-differentiated and low-grade NETs.[41] Metabolic intensity should not be confused with tumor function, as low- or intermediate-grade hypersecreting NETs are no more likely to be detected with FDG-PET than their nonfunctional counterparts. The extent to which cells take up the radioactive tracer is indicated by the maximum standard uptake value (SUV_{max}). Small, retrospective series have correlated an SUV

TABLE 135.3 **Syndromic Presentations of Functioning Neuroendocrine Tumors**

Syndrome	Primary Tumor Location	Hormones Secreted	Signs and Symptoms
Carcinoid syndrome	Small intestine, less commonly lung or pancreas	Serotonin Variety of bioactive amines (bradykinin, tachykinins, kallikrein)	Facial flushing Diarrhea Bronchospasm/wheezing Carcinoid heart disease
Insulinoma	Pancreas	Insulin	Hypoglycemia Autonomic or neuroglycopenic symptoms: shakiness, confusion, sweating
Gastrinoma	Pancreas Duodenum	Gastrin	Gastric reflux Peptic ulceration Gastrointestinal bleeding
VIPoma/watery diarrhea hypokalemia achlorhydria (WDHA) syndrome	Pancreas	Vasoactive intestinal peptide	Watery diarrhea Hypokalemia Achlorhydria
Glucagonoma	Pancreas	Glucagon	Glucose intolerance Necrolytic migratory erythema Stomatitis Glossitis Hypoaminoacidemia Thromboembolism
Somatostatinoma	Pancreas	Somatostatin	Hyperglycemia Cholestasis Steatorrhea Achlorhydria

The primary tumor location refers to the most common locations of these tumors. There are a number of case reports of ectopic tumors that may hypersecrete hormones and cause a clinical syndrome.

ratio (tumor SUV_{max}/normal SUV_{max}) of 2.5 or more with poor survival and a 4-year survival rate of 0%.[46]

Biopsy

Histopathologic evaluation is essential for a formal diagnosis of NET, although there are circumstances under which biopsy can be avoided. NETs commonly diagnosed with EGD or colonoscopy (gastric, duodenal, or colorectal) are discovered and biopsied in the patient's initial encounter. As well, appendiceal NETs are often diagnosed during the course of an appendectomy for appendicitis. Decisions to biopsy other NET subtypes depend on primary site and the likely course of management. Often the combination of high-quality imaging and clinical history strongly suggests a diagnosis of NET. If the disease is amenable to surgical resection for cure, preoperative biopsy is unnecessary. In cases where the disease has metastasized, but may still be amenable to surgical cytoreduction, biopsy of an easily accessible metastasis may help the team decide whether surgical resection or systemic therapy is most appropriate, based on the histologic characteristics of the tumor and the Ki-67 index. Patients with nonfunctional PNETs that are small (<1 cm) and are observed do not require histologic confirmation of the disease unless imaging characteristics and clinical history are discordant. Similarly, MEN1 patients with small, multifocal PNETs can be observed without undergoing an invasive biopsy. Biopsy is most helpful in patients who have an unknown primary tumor, or who have disease that is not amenable to resection, in which case biopsy is the only opportunity for pathologic diagnosis to guide further treatment. In patients where the location of the primary tumor is unknown, biopsy samples may be tested with a panel of IHC stains to identify the tissue of origin.[47]

KEY POINTS

- A thorough history and physical examination will aid in differentiating a functional neuroendocrine tumor (NET) from a more common condition, such as diabetes mellitus or inflammatory bowel disease. Laboratory studies are useful to confirm hypersecretion of peptide hormones, with selection of labs driven by a patient's symptomatology. Contrast-enhanced computed tomography or magnetic resonance imaging are required for initial workup and staging. Somatostatin receptor imaging is an adjunct to standard imaging when the extent of metastatic disease burden is unclear, if the diagnosis of NET is suspected but the primary tumor site is unknown, or to determine candidacy for peptide receptor radionuclide therapy. Biopsy can provide useful information such as cellular grade and differentiation, but is unnecessary if a patient is destined for surgical resection.

CLINICAL FEATURES OF FUNCTIONAL NET AND THEIR SYNDROMES

Insulinoma

In 1935, Dr. A. O. Whipple and Dr. V. K. Franz detailed six cases of symptomatic sporadic hyperinsulinism apparently caused by a pancreas adenoma and laid out an algorithm for their diagnosis and treatment. Although 85 years have passed, many of their original management guidelines are used today.[48]

Insulinomas are typically localized (90%) and located in the body or tail of the pancreas.[49] They are the most common type of functional PNET, and approximately 5% are found in patients with MEN1. The clinical syndrome caused by these tumors is characterized with the “Whipple triad” of (1) hypoglycemia, (2) autonomic or neuroglycopenic symptoms of shakiness, confusion, or sweating, and (3) resolution of these symptoms with eating (Table 135.3). As mentioned above, a monitored fast may be required to provoke the syndrome. Insulinomas are often less than 2 cm in diameter and escape detection by imaging, making surgical planning difficult. In these situations, arterial calcium stimulation with hepatic venous sampling is an invasive procedure that has been shown to localize radiographically invisible tumors with 93% sensitivity and 86% specificity.[50] Patients with poorly controlled symptoms but occult primaries can be taken to the operating room for exploration, as some tumors may be identified with palpation or with intraoperative ultrasound. This latter procedure has a sensitivity of 89% in this context.[45]

Metastatic insulinomas are more likely intermediate-grade and have elevated CgA in more than 50% of cases.[51,52] These tumors, like most NET subtypes, most commonly metastasize to the liver. Only 20% of malignant insulinomas present with only locoregional metastases. Reports of patients with malignant disease suggest that Whipple's triad is present and ultimately helpful for diagnosis in the majority of cases. Interestingly, even in floridly symptomatic patients, the diagnosis can be delayed for many months after the clinical syndrome manifests.[52]

Gastrinoma

Dr. Zollinger and Dr. Ellison described their eponymous syndrome, and its unfortunate consequences (Table 135.3), in a 1955 report of two patients who underwent repeated gastric resections to treat recurrent peptic ulcers. They suspected an "ulcerogenic humoral factor of pancreatic islet origin," as both patients were ultimately found to have pancreas tumors—one uncovered at autopsy, and the other at the time of their total gastrectomy.[53] These tumors are found in the pancreas, duodenum, and stomach, with their most common locations defined by the gastrinoma, or Passaro's, triangle (Fig. 135.1).[54] These tumors are often very small and submucosal, making their detection by conventional imaging or EGD difficult. Approximately 50% to 60% of patients present with metastases at diagnosis.[55]

VIPoma

The clinical syndrome caused by vasoactive intestinal peptide–secreting PNETs described by Dr. Verner and Dr. Morrison in 1958 features progressive, large-volume watery diarrhea that results in profound hypokalemia, achlorhydria, and dehydration.[56] It is colloquially referred to as "pancreatic cholera" or "watery diarrhea hypokalemia achlorhydria syndrome," and can also include hypercalcemia, facial flushing, or a skin rash. Eight percent of patients report intense facial flushing during episodes of diarrhea (Table 135.3).[57] When refractory to treatment, patients can require at-home intravenous fluids or inpatient admission for resuscitation. They may ultimately succumb to multiorgan failure and death from the electrolyte derangements. These rare tumors are solitary, located in the body and tail of the pancreas, and typically larger than 3 cm at diagnosis. The majority are malignant, and 60% to 80% have metastasized on diagnosis. Approximately 5% are found in patients with MEN1.[58]

Glucagonoma

Glucagonomas typically arise from the alpha cells of the islets of Langerhans in the tail of the pancreas. Glucagonoma syndrome is associated with diabetes, necrolytic migratory erythema (NME), diarrhea, neuropsychiatric disturbances, anemia, venous thromboembolism, and weight loss. Most symptoms are a result of the elevated glucagon levels, although the cutaneous manifestations likely result from poor nutrition and amino acid deficiency secondary to glucagon- and tumor-induced catabolism. The rash typically involves the face, abdomen, perineum, or extremities. It appears reddish-brown and can form erythematous bullae that eventually open and encrust. Depending on the case series, approximately 50% to 80% of patients will present with NME, and 25% to 60% with diabetes (Table 135.3). Diagnosis is often delayed, and more than 50% of patients present with distant metastases.[59]

Somatostatinoma

Somatostatinomas are exceedingly rare and associated with a clinical syndrome of diabetes, cholestasis, and steatorrhea as a result of somatostatin's inhibitory effect on insulin, cholecystokinin, and pancreatic exocrine secretion (Table 135.3). More than 75% of somatostatinomas present with distant metastases. The majority of pancreatic somatostatinomas are sporadic. However, some of these tumors arise from the duodenum and, in this context, are associated with neurofibromatosis in up to 50% of cases and are less likely to have metastasized at presentation.[60]

PPoma

Classification of a pancreatic polypeptide (PP)-secreting PNET as functional is controversial, as these tumors are not associated with a distinct clinical syndrome. PP is secreted as part of the parasympathetic response to meals, and high levels are associated with increased satiety, inhibition of gallbladder contraction, and delayed gastric emptying. There are reports of PP hypersecretion and new-onset glucose intolerance, although the rarity of the tumor, retrospective nature of the case series, and prevalence of metabolic syndrome in the general population limit the conclusions that can be drawn.[61,62]

Serotoninoma

A small proportion of PNETs secrete serotonin, cause carcinoid syndrome, and are referred to as "pancreatic carcinoids." The incidence is estimated at between 1% and 4% of all PNETs, but given the low number of patients with PNETs tested for serotonin or u5-HIAA, this may be an underestimation. In a series of 255 sporadic PNET cases, 22 (8.6%) had u5-HIAA levels three times the normal limit, but only two (0.8%) of these patients had symptoms compatible with carcinoid syndrome. It is not uncommon for these patients to cosecrete another hormone, most often insulin. Of the 22 patients with elevated u5-HIAA, two patients had insulinomas, and one a gastrinoma. The majority of patients (81.8%) presented with elevated levels of serotonin or u5-HIAA at presentation, although four went on to develop elevated u5-HIAA later in their disease. High levels of u5-HIAA correlated with high levels of CgA. Patients with serotonin-secreting PNETs often presented with liver metastases (95%), and their median survival was significantly shorter (42 months) than those patients with normal u5-HIAA (116 months).[22]

Carcinoid Syndrome

The pathophysiology of carcinoid syndrome is incompletely understood, but the most common symptoms of diarrhea, facial flushing, and bronchospasm are associated with elevated circulating levels of serotonin and other bioactive amines such as histamine, prostaglandins, tachykinins, and kallikrein (Table 135.3). Patients can also have elevated levels of u5-HIAA, although a proportion of patients manifest the syndrome with normal levels of these factors, while patients with elevated levels may be completely asymptomatic. The syndrome is frequently found in patients with hepatic metastases. When these metastases secrete high concentrations of bioactive substances, they enter directly into the systemic circulation, avoiding breakdown in the liver.

Fig. 135.1 The gastrinoma triangle. The anatomic region in which most gastrinomas are found is indicated by the circle. The vertices of passaro's triangle are marked by stars and located at the junction of the cystic and common bile ducts, the junction of the neck and body of the pancreas, and the junction of the second and third portion of the duodenum. The triangle is best visualized intraoperatively, after the second portion of the duodenum and head of the pancreas have been reflected medially (a kocher maneuver). Kocherization of the duodenum and pancreas is required to thoroughly palpate the duodenum during exploration for the primary tumor(S). (From Netter F: Atlas of Human Anatomy, 7e. ISBN: 9780323393225. Plate 291. "Arteries of Liver, Pancreas, Duodenum, and Spleen.)

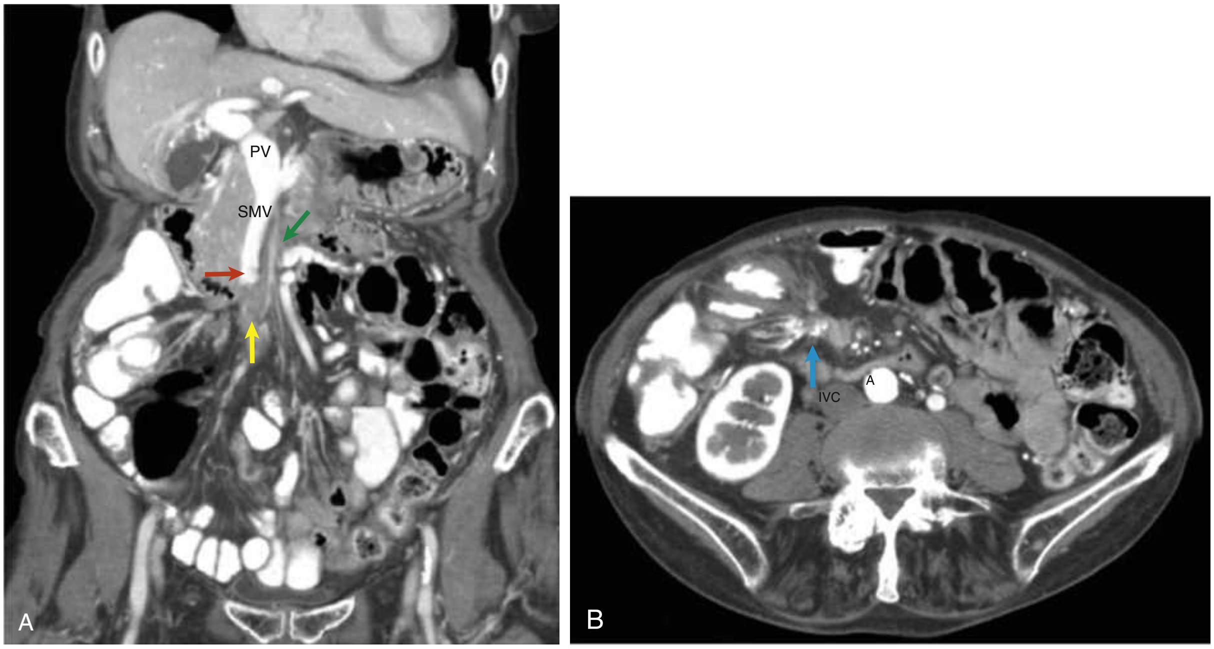

Fig. 135.2 **Consequences of serotonin hypersecretion, mesenteric fibrosis.** An 81-year-old woman with a grade ii ileal neuroendocrine tumor, metastatic to the liver and bone. She presented with surgically unresectable mesenteric fibrosis that encased her superior mesenteric vein (*SMV*) and superior mesenteric artery (SMA). Fibrosis will appear grey and hazy on arterial and portal venous phases of computed tomography scans. (**A**) Coronal view, portal venous phase. The red arrow shows a tumor thrombus within the smv. The green arrow shows the SMA encased by fibrotic tissue. The fibrosis narrowed the proximal mesenteric vessels and obliterated sma branches to a portion of the terminal ileum *(yellow arrow).* (**B**) Axial view, portal venous phase. The blue arrow demonstrates the same anatomic region as the yellow arrow in the coronal image. The desmoplastic reaction causes tethering of the mesentery, which can lead to kinking of the bowel and obstruction in severe cases. As the fibrosis progresses, inflow and venous drainage are impaired, and the bowel wall will thicken and can progress to frank necrosis and perforation. *PV*, portal vein; *IVC,* inferior vena cava; *A*, aorta.

Chronically elevated levels of these factors are thought to contribute to fibrotic complications such as valvular heart disease (predominantly right-sided) and mesenteric fibrosis (Fig. 135.2).[63] Carcinoid syndrome is most commonly associated with small bowel NET, and as an homage to Dr. Oberndorfer's original discovery, small bowel NETs are often referred to as carcinoid tumors, regardless of whether they are associated with carcinoid syndrome. Carcinoid syndrome is also associated with colorectal, lung, and pancreas NETs, albeit at much lower frequencies.

Flushing is reported in 90% of patients with carcinoid syndrome. It is episodic and can be triggered by amine-rich foods such as chocolate, avocadoes, and nuts; alcohol; and physical activity or stress (Table 135.4). Carcinoid-associated diarrhea is also intermittent, secretory, and usually accompanied by abdominal cramping, as serotonin functions to increase intestinal motility. Bronchospasm is found in approximately 15% of patients with carcinoid syndrome, and patients also often suffer from concurrent flushing, sneezing, and dyspnea. Pellagra is found in a minority of carcinoid syndrome patients and is the result of tryptophan metabolism to serotonin rather than nicotinic acid. In extreme cases, peripheral tryptophan consumption may deprive the brain of adequate levels of centrally-synthesized serotonin, which can result in neurocognitive dysfunction.[63] In a 2014 study, NET patients with carcinoid syndrome and hepatic metastases were compared to a group of patients with hepatic metastases from other primary sources. Patients

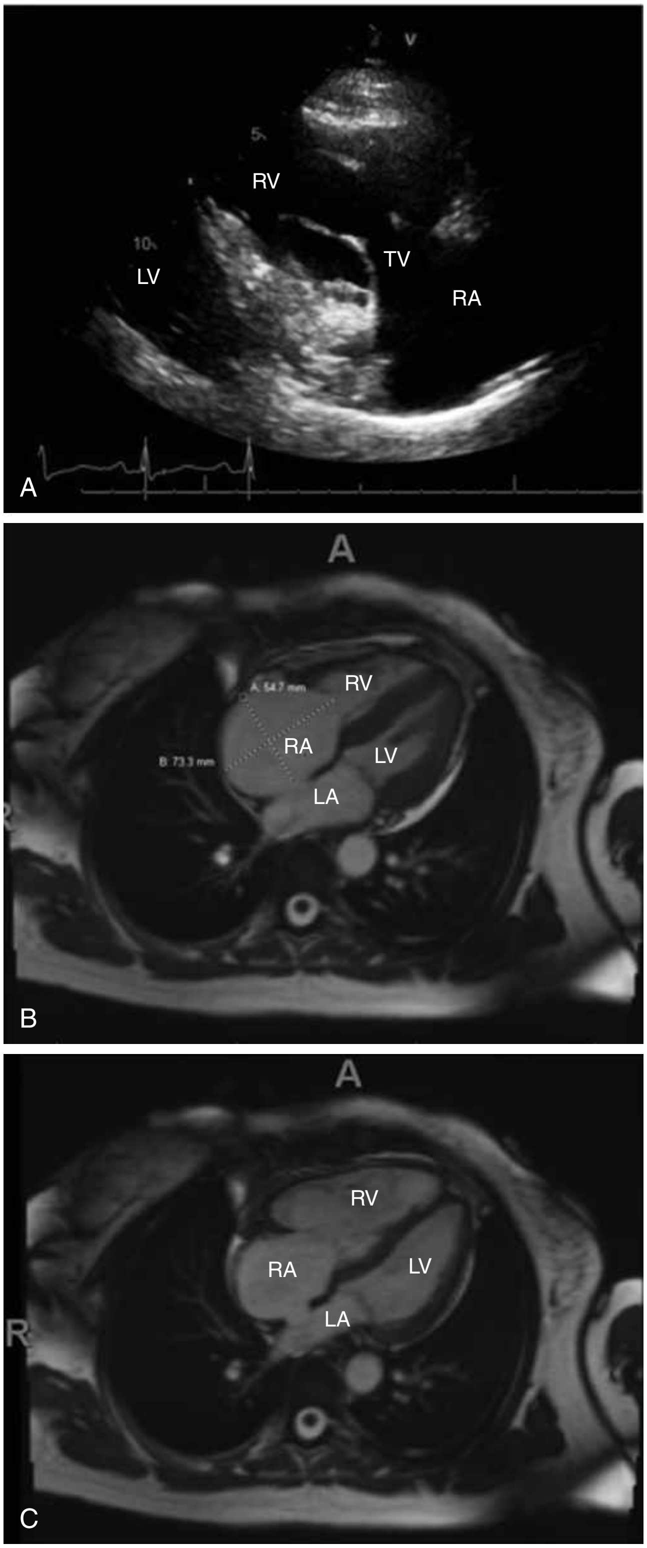

Fig. 135.3 **Carcinoid heart disease.** A 49-year-old woman with a jejunal neuroendocrine tumor, large-volume liver metastases, and carcinoid syndrome. Her serotonin hypersecretion resulted in carcinoid heart disease requiring replacement of both her pulmonic and tricuspid valves. (**A**) transthoracic echocardiogram, midsystole, demonstrating a lack of tricuspid valve coaptation during systole. (**B**) cardiac magnetic resonance imaging (mri), end systole. Right atrial enlargement as a result of severe tricuspid regurgitation. A normal atrium measures approximately 4–5 cm. (**C**) cardiac mri, systole. Severe, prolonged pulmonic and tricuspid regurgitation ultimately resulted in right heart failure. The right ventricle chamber is dilated, and right ventricular wall hypertrophy is evident. *RA,* right atrium; *RV*, right ventricle; *LA,* left atrium; *LV*, left ventricle; *TV*, tricuspid valve.

were matched for age, sex, and educational levels. All NET patients were currently being treated with SSAs, and although all had presented with elevated levels of u5-HIAA, 33% had levels in the normal range at the time of the study. Patients were surveyed across five cognitive domains. NET patients self-reported greater cognitive dysfunction than the non-NET cancer group and also performed worse on formal neurocognitive testing, particularly in the delayed recall domain.[64]

Carcinoid heart disease is a result of plaque-like deposits on the endocardial surfaces of the valve leaflets, cardiac chambers, and occasionally the intima of the aorta, pulmonary arteries, and inferior vena cava. Patients may present with dyspnea, fatigue, and a systolic murmur that is best heard at the sternal border. Left uncorrected, patients may develop right heart failure (Fig. 135.3) and manifest ascites, peripheral edema, and pleural effusions. Ninety percent of cases involve the right side of the heart. Left heart involvement is seen in situations of a patent foramen ovale with right-to-left shunt, with bronchial carcinoids, and when circulating concentrations of bioactive amines overwhelm the degradative capacity of the hepatic and pulmonary systems.[19]

Carcinoid crisis is a controversial hemodynamic phenomenon that is often considered in patients with carcinoid syndrome, as the underlying pathophysiology of the two entities is thought to be similar.[65] There is no consensus definition for carcinoid crisis, and thus its true prevalence is unknown. In patients undergoing surgical resection, rates are reported to be between 0% and 35%.[66,67] Crisis is generally described as an acute, prolonged episode of hemodynamic instability temporally related to an invasive procedure that cannot be ascribed to other periprocedural factors such as medication administration, hypovolemia, hemorrhage, or decreased venous return. Patients diagnosed with crises manifest cutaneous flushing and diarrhea and may also describe chest or abdominal pain. In addition to surgical procedures, carcinoid crises have been described in patients undergoing hepatic artery embolization, selective internal radiation therapy, peptide receptor radionuclide therapy, and tumor biopsy. As with carcinoid syndrome, therapy includes a bolus injection of 500 to 1000 ug of octreotide, or a continuous infusion of 50 to 100 ug/hour. Some practitioners administer prophylactic doses of octreotide to patients at risk for developing crisis, and others use intraprocedural infusions that are tapered over the next 8 to 24 hours after surgery. The efficacy of these treatments has been called into question, and institutional practices vary widely.[65,67]

KEY POINTS

- Functional neuroendocrine tumors (NETs) hypersecrete hormones and/or bioactive amines that result in a clinical syndrome. Although each described syndrome has hallmark features, the spectrum of signs and symptoms experienced by the patient can vary in number and severity. Insulinomas are the most common functional pancreas NET. Carcinoid syndrome is most often associated with small bowel NET. A fraction of these patients will develop carcinoid heart disease, typically manifest by right heart valvular dysfunction, and thus cardiac testing should play a role in these patients' ongoing disease surveillance.

MANAGEMENT STRATEGIES FOR FUNCTIONAL NEUROENDOCRINE TUMORS

Management of NET syndromes is achieved through cytoreduction of the secreting tumor bulk, antineoplastic agents that control cellular proliferation, or symptom management with medication. Cytoreduction can be attempted by a number of means, with surgical extirpation of the primary and all metastatic disease offering the only chance of cure. Unfortunately, metastasectomy is associated with high rates of recurrence. There is no consensus on the appropriate ordering of the various modalities, and medical management of symptoms can be difficult and require disease-specific expertise. Therefore, management discussions amongst members of a multidisciplinary team are crucial in the design of an optimal strategy (Fig. 135.4).

Surgical Resection

Regardless of functionality, patients presenting with a unifocal primary, limited regional disease, and good performance status should undergo resection of their primary tumor and locoregional lymph nodes. Patients with pancreas primaries are treated with pancreaticoduodenectomy when the tumor is located in the head, or distal pancreatectomy when the tumor(s) is located in the body or tail of the pancreas. Every effort should be made to operate upon patients with functional tumors to prevent progression of their symptoms. Some subtypes of PNET, especially gastrinomas, are often multifocal, which can complicate resection. Tumors distributed throughout the gland can be treated with total pancreatectomy. This is often reserved for only the most symptomatic patients refractory to other management because the operation is extremely morbid and can have a significant effect on postoperative quality of life. It is common for patients considering this option to meet with an endocrinologist before surgery to discuss the resulting brittle diabetes, and its management with an insulin pump, so that the full range of risks and benefits of the surgery are considered. In response to this issue, and the fact that some functional tumors seem to be more exophytic and encapsulated, “sitting” on the surface of the pancreas, enucleation is another option for tumor extirpation. Institutional practices of this technique vary, but it is a reasonable option when formal resection is suboptimal. Enucleation does spare pancreas parenchyma, but also increases the risk of postoperative pancreatic fistula.

Small intestine NETs are most appropriately approached in an open fashion (Fig. 135.5). This allows for resection of the dominant primary tumor, often located within 100 cm of the terminal ileum, regional lymphadenectomy that may include removal of bulky lymph nodes near the root of the mesentery, and careful palpation of the entire small bowel.[68] High-volume NET centers report small bowel tumor multifocality rates of up to 45%.[69]

The presence of distant metastases does not preclude surgical intervention, especially in cases of functional tumors, but it does make the risk-benefit calculus more difficult. Regardless of primary tumor site, the most common site for metastases is the liver. It is well accepted that surgery is the optimal management strategy for distant disease when removal of all microscopic and macroscopic disease (R0 resection) can be achieved. Survival benefit is hotly debated and has not been demonstrated prospectively, although retrospective series support the assertion that patients able to undergo aggressive resection have longer survival compared with those unable to have surgery (whether because of disease burden or fitness). Metastasectomy or parenchymal-sparing techniques (such as radiofrequency ablation) do confer symptomatic relief when 70% to 90% of the hepatic tumor bulk can be treated. This strategy has been used successfully for initial resections and in patients who present with recurrence of their symptoms years after their primary was removed.[70-72] There is only anecdotal evidence supporting isolated lymphadenectomy for symptom control, and it is only occasionally done in cases of recurrence of symptoms after resection of a functional tumor where the lymph nodes appear to be the only site of disease.

Ablation of Primary Pancreas Neuroendocrine Tumors

A variety of ablative techniques have demonstrated efficacy treating functional PNETs in patients with multifocal tumors or in those who

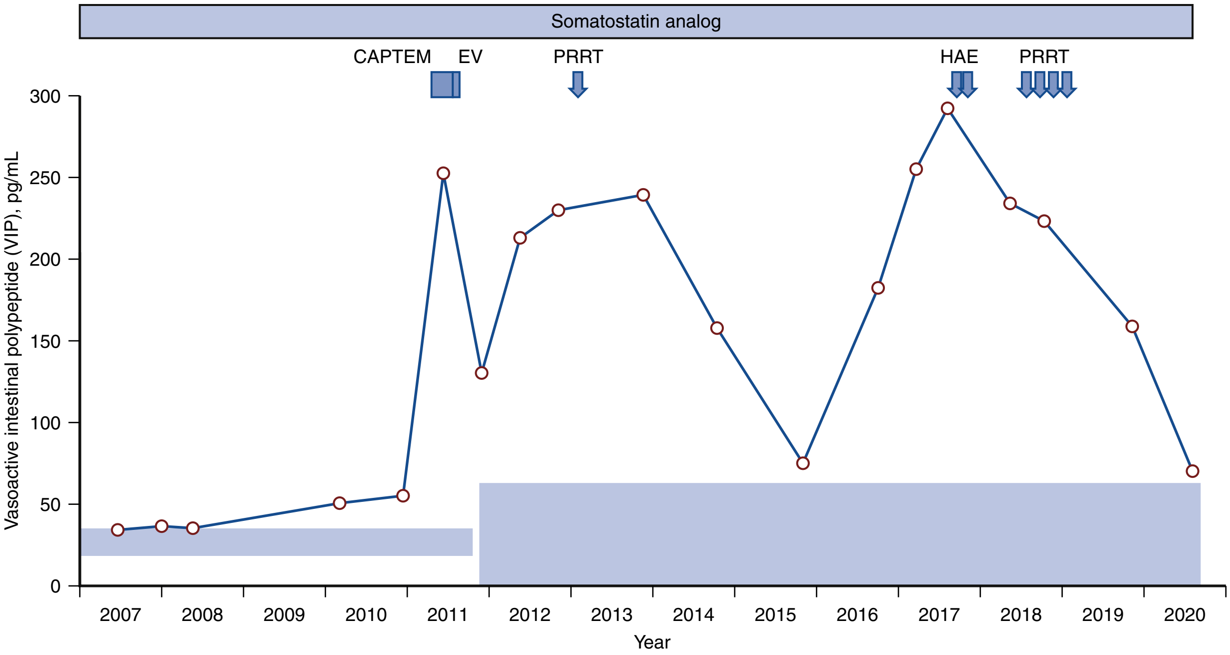

Fig. 135.4 **Treatment strategy in a patient with a well-differentiated, vasoactive intestinal peptide (*vip*)-secreting pancreas neuroendocrine tumor that was metastatic to the regional lymph nodes and liver.** The patient was diagnosed in 1996 and underwent distal pancreatectomy and liver debulking in 1998. Sequential ordering of the treatments required multiple discussions with a specialized, multidisciplinary team. The patient's clinical, radiographic, and biomarker responses to each therapy were monitored. Clinical features, including severe diarrhea, tracked closely with the vip levels. Therapies included distal pancreatectomy and liver debulking (1998), streptozocin and 5-fluorouracil (1996–2000), liver transplantation (2001), liver debulking surgery (2007), capecitabine and temozolomide (*Captem*, poorly tolerated, 2011), everolimus (*Ev*, not tolerated, 2011). The patient had one cycle of yttrium-90 peptide receptor radionuclide therapy (*Prrt*, 2013), two hepatic artery bland embolizations (hae, 2017), and four cycles of lutecium-177 prrt (2018). The patient was treated with a somatostatin analog throughout his disease course. Normal vip range indicated by the hatched bars.

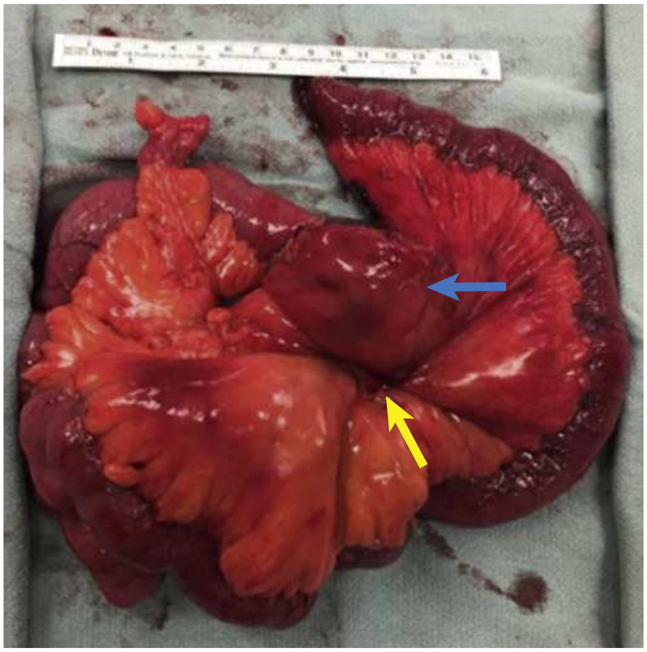

Fig. 135.5 **Mesenteric fibrosis in a surgical specimen, small bowel resection.** This patient had a large mesenteric mass *(blue arrow)*. The desmoplastic reaction caused puckering of the mesentery *(yellow arrow)*. The fibrosis occluded many venous branches, causing impaired drainage and congestion of the nearby small intestine. The patient complained of abdominal pain that was occasionally worse after meals.

are poor candidates for formal pancreatectomy. Tumors can be targeted laparoscopically or endoscopically with ultrasound guidance. Ablation may be achieved with ethanol, radiowave, or microwave ablation, or with electroporation. Treatment success is gauged by radiographic and symptomatic response. The majority of series report amelioration of symptoms and normalization of hormone levels within 24 hours after treatment. Patients can undergo multiple treatments of the same tumor, either in short succession if complete ablation is not achieved, or in cases of tumor recurrence. The most common complication is pancreatitis and most patients are observed for 1 to 2 days after the procedure. Late complications, such as duct stricture, are rare (<5%).[73-75]

Hepatic Arterial Embolization

NET liver metastases are supplied by the hepatic arteries, rather than the portal venous circulation. Embolization of the supplying artery results in targeted ischemia of the tumor and leaves normal parenchyma relatively spared. There are three techniques available—bland embolization, chemoembolization, and drug-eluting bead transarterial chemoembolization—although bland and chemoembolization are the most widely used. A prospective study is underway to determine the optimal embolization technique to treat NET liver metastases, and was written to compare all three modalities (www.clinicaltrials.gov; NCT02724540). However, the DEB-TACE arm closed early because of toxicity concerns.[76]

Retrospective studies in patients with functional NETs report objective tumor responses of approximately 50% and symptomatic responses ranging from 9% to 100% (average 56%), but

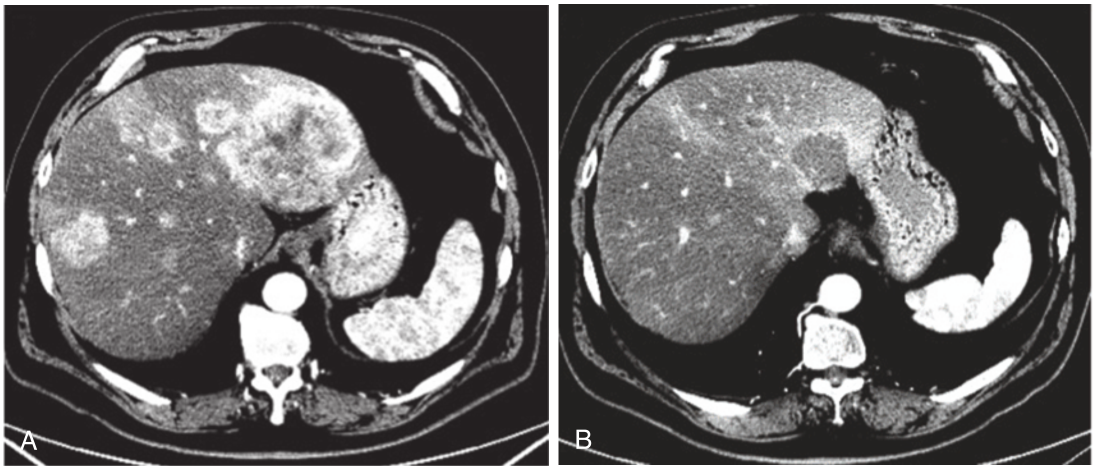

Fig. 135.6 **Radiographic response to the combination regimen of capecitabine and temozolomide.** A 70-year-old man with metastatic grade i pancreatic neuroendocrine tumor. Serial computed tomography scans of the abdomen, axial view, arterial phase. Images obtained (**A**) 2 weeks prior and (**B**) 2 months following 12 cycles of capecitabine 750 mg/m^2 by mouth daily on days 1–14 and temozolomide 200 mg/m^2 by mouth daily on days 10–14 of a 28-day cycle.

mean clinical response rates do not seem to differ by technique.[77] Biochemical responses are noted in more than 50% of patients, and are enhanced in patients with carcinoid syndrome when simultaneously treated with an SSA.[78] Smaller case series report symptom relief in patients treated with hepatic arterial embolization (HAE), even in situations where patients had other hepatic or distant metastases left untreated.[79] A patient with hepatic, bone, and mediastinal metastases from a malignant insulinoma underwent bland HAE for symptoms refractory to multiple treatment modalities. The patient's hypoglycemic symptoms resolved within 24 hours. Symptoms recurred 5 months later.[80]

Survival correlates with objective tumor response but has only been shown in one retrospective study to correlate with biochemical or symptom response.[78] The most common complication is postembolization syndrome, where patients develop abdominal pain, nausea, fevers, leukocytosis, and transient transaminitis that resolve with time. Serious complications such as cholangitis, gastrointestinal bleeding, hepatic abscess, gallbladder necrosis, and renal failure are rare (<5%).[78,81] Late complications such as biliary ischemia and hepatic failure occur in fewer than 2% of patients.[78]

Selective Internal Radiation Therapy

Selective internal radiation therapy is another technique for the treatment of unresectable hepatic metastases that uses yttrium-90–coated microspheres. Delivery of this agent to nontarget organs can cause disastrous complications, and thus each procedure is preceded by an angiogram of extrahepatic arteries and determination of lung shunt fraction. This has not shown superiority in survival over other embolization techniques, but is known to induce radiographic objective tumor responses, increases in PFS and OS, and symptomatic improvement.[82-84] This procedure is safe, with low rates of postembolization syndrome and postprocedural infection.[82] More serious complications, such as hepatic cirrhosis, are only rarely reported.[85]

Systemic Therapies

Somatostatin Analogs. SSAs are synthetic versions of the endogenous hormone somatostatin. There are a number of formulations that differ in their duration of action or SSTR specificity, with octreotide and lanreotide being the best known. These medications demonstrate efficacy in controlling symptoms and slowing tumor proliferation.[86-88] They are typically the first agents selected in patients with advanced disease and hormonally driven symptoms negatively impacting quality of life. Octreotide is available in intermediate-acting and long-acting forms. Lanreotide is exclusively a long-acting formulation that is administered once per month.

Meta-analyses detailing the efficacy of intermediate-acting octreotide in patients with functional GEP NETs demonstrate resolution or improvement of diarrhea and flushing in 71% of patients, with biochemical responses in 77%. Long-acting forms of octreotide are similarly efficacious in controlling symptoms in patients with functional tumors, with the majority of data derived from studies examining use in small intestine NET and carcinoid syndrome.[89] Episodic symptom control can be achieved by using intermediate-acting octreotide in addition to monthly injections. The utility of lanreotide for symptom control was most recently demonstrated in the 2016 ELECT trial. In the 115 patients with carcinoid syndrome studied, those randomized to lanreotide used breakthrough octreotide significantly less frequently for symptom control compared with the control group.[88] A follow-up study of patient-reported outcomes found that patients in the lanreotide group had improved diarrhea and flushing compared with the placebo group.[90] Lanreotide can also induce a biochemical response in patients with elevated CgA or u5-HIAA, regardless of whether the tumor is functional. Pooled analysis of the patients enrolled in the CLARINET[87] and ELECT trials showed biochemical responses in 43.1% of patients with elevated u5-HIAA and 38.5% of those with elevated CgA.[91]

Despite the efficacy of these drugs, a subset of treated patients will either develop resistance to the medication or not respond at all to standard doses. In these situations, escalated doses of SSA have been tried. Escalated doses are safe, and approximately one-half to three-quarters of patients reported at least some improvement in frequency of diarrhea and flushing.[92] A multinational study of escalating dose lanreotide reported a decrease in bowel movements from 4.7 to 2.6 per day, with 76% of patients reporting that they were "completely or rather satisfied" with their diarrhea control at

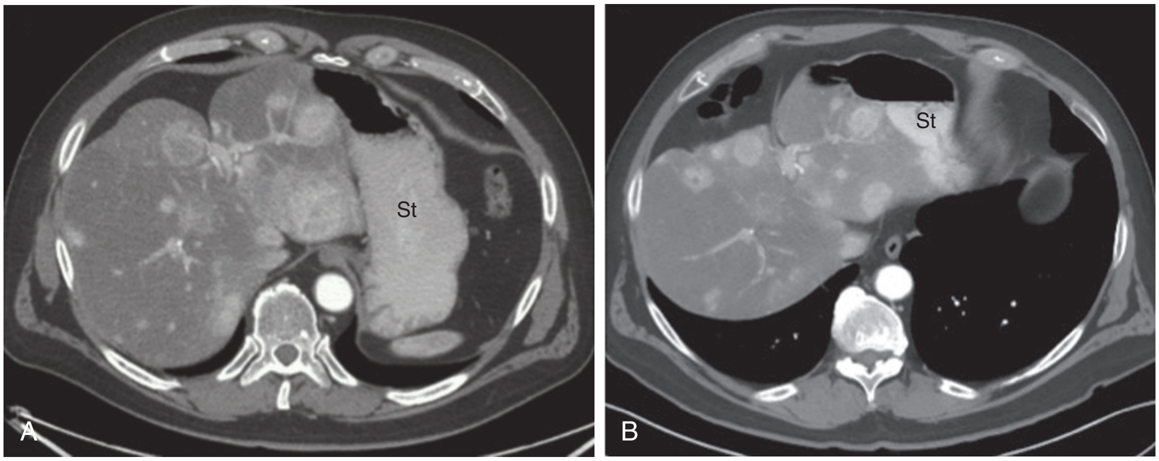

Fig. 135.7 **Radiographic response to peptide receptor radionuclide therapy.** A 65-year-old man with metastatic grade II pancreatic neuroendocrine tumor. Serial computed tomography scans, axial view, arterial phase. Images taken (**A**) 1 month before and (**B**) 1 month following four doses of 200 mci of ^{177}lu-dotatate, at 8-week intervals. *St*, stomach.

these doses. Investigators noted that patients reporting the greatest satisfaction often reported subjectively worse symptoms before treatment.[93]

Chemotherapy. Choice of chemotherapeutic regimen depends on tumor histology and grade. In general, well-differentiated extrapancreatic NETs respond poorly to cytotoxic chemotherapy, with PNETs responding better. The first chemotherapy regimens were streptozocin-based, and randomized studies showed improvements in survival and biochemical responses.[94,95] Experience with 5-fluorouracil, doxorubicin, and streptozocin was described in a group of 84 patients with PNETs, of which 20 were functioning. Median PFS was estimated at 18 months, and median OS at 37 months. Patients with radiographic responses to treatment were most likely to demonstrate a 30% or greater decrease in their CgA levels. Symptomatic response was not documented.[96] Temozolomide combined with capecitabine is another commonly used regimen in PNET (Fig. 135.6). A prospective study comparing this combination of drugs to temozolomide alone found that patients treated with the combination had improved PFS (22.7 vs. 14.4 months) and OS (not reached vs. 38 months).[97] Platinum-based regimens are most common for NECs[24] and lung NETs. In lung NETs, the overall response rate is only 8%.[98]

Targeted Therapy. Targeted therapies such as sunitinib and everolimus have been approved for use in NET and demonstrate efficacy in a variety of histologies. Sunitinib is a vascular endothelial growth factor inhibitor approved for use exclusively in patients with advanced PNET. In the study that led to the drug's approval, patients randomized to the treatment arm demonstrated a hazard ratio (HR) for progression or death of 0.42, favoring sunitinib. The drug was used in both functioning and nonfunctioning PNETs, but biochemical and symptomatic responses were not detailed.[99] Sunitinib has limited proven benefit in extrapancreatic gastrointestinal NET.[100]

The mammalian target of rapamycin pathway regulates cell growth, proliferation, and metabolism and is implicated in NET pathogenesis. The RADIANT-2 study was a phase III, placebo-controlled study investigating the effects of everolimus plus octreotide long-acting release in a group of patients with metastatic, functional GEP and lung NET. The study failed to demonstrate a statistically significant improvement in the time to disease progression or death. The participants' subjective responses to treatment were not characterized, but a greater proportion of patients in the treatment group had biochemical responses in u5-HIAA and CgA compared with the placebo group.[101] RADIANT-3 randomized patients with advanced, progressive PNET to everolimus or placebo. The HR for progression or death was 0.35, favoring everolimus.[102]

Everolimus has demonstrated efficacy in treating symptoms associated with a variety of functional NETs. One retrospective study including patients with small intestine, pancreas, and lung NETs reported that 70% of patients started on everolimus for the indication of symptom control had significant improvement of their diarrhea and flushing for a median duration of 13.9 months. These patients had simultaneous radiologically stable or responsive disease.[103] The drug has unique efficacy in insulinoma and demonstrates simultaneous antitumor and symptom effects. Everolimus can improve or resolve hypoglycemic episodes in patients with metastatic disease and refractory hypoglycemia.[104] In a series of 12 patients, 11 had near-immediate improvement in symptoms and ability to discontinue other medications used to control their hypoglycemia. The median duration of symptomatic response was 6.5 months.[105]

Peptide Receptor Radionuclide Therapy. PRRT is a treatment option for patients with metastatic disease (Fig. 135.7). The radiolabeled SSA 177Lu-DOTATATE was approved for use in SSTR-positive GEP NETs in 2018. In 2017, the phase III NETTER-1 trial compared patients with progressive, well-differentiated, metastatic small intestine NETs treated with PRRT versus high-dose octreotide. The study demonstrated an improvement in PFS of 79% in the treatment arm, a statistically significant survival advantage, although a response rate of only 18%. Patient-reported outcomes have not yet been reported.[106]

A number of retrospective studies have cataloged patient response to PRRT. The patient populations are heterogeneous and include both functional small intestine NETs and PNETs. Biochemical responses and symptomatic improvements correlate with radiographic responses, as only 30% of patients with stable or progressive disease reported a reduction in symptoms after treatments. In patients who eventually progressed, loss of symptomatic control occurred after or concurrent with radiographic progression.[107] The majority of patients are treated with four cycles of PRRT, but biochemical

TABLE 135.5 Adjunctive Treatments for Functional Neuroendocrine Tumors

Tumor Type/ Syndrome	Symptom	Treatment
Insulinoma	Hypoglycemia	Diazoxide Infusion of crystalloid dextrose Corticosteroids Everolimus SSA
Gastrinoma	Reflux Peptic ulceration	High-dose proton pump inhibitor SSA
Carcinoid diarrhea	Secretory diarrhea	Telotristat SSA

SSA, Somatostatin analog.

and symptom responses may begin to manifest after the first one to two cycles. Most patients reported clinical response to treatment, with response rates greater than 50%.[107,108] When patients' reported responses were broken down by individual symptom type, those with poorly controlled diarrhea experienced the greatest benefits (70.7% had improvement), whereas the majority of patients struggling with weight saw little improvement (48% reported no change, and 22.9% had worsening of their weight loss).[108] Fifty percent of patients presenting with elevated serum serotonin had a decrease of greater than 50% in these levels after treatment, with only 25.2% and 15.6% experiencing biochemical responses in CgA and u5-HIAA, respectively.[108]

Palliative Symptom Management

Patients with advanced disease may require palliation of their symptoms beyond the control that may be provided by the cytoreductive or cytotoxic treatments previously discussed (Table 135.5).

Insulinoma. Patients with insulinomas can experience profound episodes of hypoglycemia. In early stages of the disease, patients may be able to maintain normoglycemia with frequent meals. Many will experience significant weight gain, as the frequency of meals and caloric intake required exceed a patient's basal metabolic rate. As the disease progresses, patients develop nocturnal hypoglycemia and risk developing severe side effects such as seizure. These episodes can be treated with nocturnal parenteral or enteral nutrition, which will require the patient have an enteral feeding tube placed, or a tunneled central venous line. Diazoxide is a medication that controls insulin secretion by opening potassium channels. It is administered daily in doses ranging from 50 to 1500 mg. Unfortunately, it is only effective in 50% of cases. Side effects, experienced by approximately 50% of patients, include palpitations, nausea, anorexia, hirsutism, and peripheral edema. Corticosteroids can also be used for symptom control. They are fast-acting, but also cause immunosuppression.[51]

Gastrinoma. Zollinger–Ellison syndrome because of hypersecretion of gastrin can cause recurrent, devastating peptic ulcer disease. Symptoms can be controlled with proton pump inhibitors. Administered at high doses (omeprazole 60 mg three times daily, either intravenously or orally), studies have shown increases in gastric pH and a decrease in the volume of gastric fluid secreted. Patients report improvement of regurgitation and reflux within 2 weeks of treatment initiation. Endoscopy performed 1 month after treatment initiation demonstrated healed ulcers.[109,110]

Carcinoid Syndrome Diarrhea. Elevated levels of serotonin are associated with diarrhea. Recently, telotristat ethyl was approved by the US Food and Drug Administration for use in patients with carcinoid syndrome diarrhea refractory to treatment with an SSA. This drug inhibits tryptophan hydroxylase, the rate-limiting step in serotonin synthesis. The phase 3 TELESTAR study reported a reduction in bowel movement (BM) frequency of 2.1 BM/day from baseline, but –0.81 BM/day compared with placebo. Responders did have a significant decrease in u5-HIAA levels.[111] TELECAST, a phase III companion study to TELESTAR, demonstrated similar results, with treated patients reporting fewer BMs per day and a decrease in u5-HIAA levels.[112] Patients in a phase II study of telotristat ethyl were interviewed about their experiences taking the medication approximately 29 months after study initiation. Their reactions were favorable, as 82% reported improvements in diarrhea, 45% noted improved abdominal pain, 36% suffered less abdominal cramping, and 36% had fewer episodes of flushing.[113]

KEY POINTS

- Optimal treatment of hypersecreting neuroendocrine tumors (NETs) involves cytoreduction of the secreting tumor bulk, control of cellular proliferation, and symptom management. There are a variety of means available to practitioners to achieve these goals, but no consensus on appropriate ordering, thus multidisciplinary discussion amongst NET specialists is crucial to optimize outcome. Surgical resection is helpful in patients with unifocal primary tumors, limited regional or distant disease, and good performance status. Liver-directed therapies may induce symptomatic responses as well as radiologic responses. Systemic treatments include peptide receptor radionuclide therapy, targeted therapies, cytotoxic chemotherapy, and somatostatin analogs. These are typically employed when the disease has spread beyond what is reasonable to resect or treat with more directed therapies. Medications for symptom management can be employed at any point during a patient's treatment course, but will rarely durably ameliorate symptoms in isolation.

CONCLUSION

NETs are unique in their ability to produce hormonal syndromes that can significantly impact a patient's quality of life. The rarity of these tumors and their associated clinical syndromes can make diagnosis difficult, and it is often delayed by many years. Once a diagnosis is made, treatment selection and ordering can present challenges, and optimal care requires a multidisciplinary team of surgeons, endocrinologists, medical oncologists, nurse clinicians, pathologists, nuclear medicine physicians, and interventional radiologists experienced in managing these unique diseases. Recent trials in targeted therapies and inhibition of serotonin synthesis have led to improvements in the quality of life of NET patients. Ongoing and future studies of agents and techniques aimed toward cytoreduction and symptom control will deepen the armamentarium available to treat this unique set of patients.

HISTORY

Tightly regulated production of hormones from specialized endocrine glands is usually under the control of higher centers, ultimately the brain, and is normally subject to negative feedback. This affords a mechanism for influencing diverse tissue function throughout the body. Apparently, inappropriate hormone production by nonendocrine tissue causes a spectrum of rare syndromes. These disorders are important because they may be the first manifestation of an underlying tumor, and the hormonal manifestations can induce morbidity and affect quality of life. Ectopic hormone secretion also sheds light on mechanisms of tissue-specific gene expression and regulation. Ectopic hormone production reveals important linkage between cell differentiation and gene expression. Ectopic expression of a peptide may also be useful as a tumor marker (e.g., human chorionic gonadotropin, α-fetoprotein).

Initial reports of endocrine activity associated with tumors appeared in the 1920s. These examples included features of parathyroid-like activity with disseminated carcinoma and adrenocortical activity in patients with lung and thymic tumors.[1,2] At the same time, initial reports of tumor-associated hypoglycemia were documented.[3,4] Later, based on the metabolic similarities to hyperparathyroidism, Albright and Reifenstein[5] proposed the secretion of parathyroid-like hormone activity in a patient with renal cell carcinoma as the cause of hypercalcemia.

Proof of tumor-derived endocrine factors had to await the development of accurate and sensitive hormone assays. These assays allowed identification of adrenocorticotropic hormone (ACTH), and antidiuretic hormone secretion from tumors causing ectopic ACTH syndrome and the syndrome of inappropriate antidiuretic hormone secretion (SIADH), respectively.[6–9] Since these breakthroughs, further advances in cell and molecular biology have sought to explain how and why such ectopic hormone production occurs and its consequences.

THEORETICAL CONSIDERATIONS

Circulating hormones are almost exclusively derived from specialized cells in endocrine glands. However, low-level hormone production or gene expression, at the very least, can be found much more widely. For example, the gene encoding ACTH is expressed at a high level in anterior pituitary corticotroph cells, but its expression has also been detected in a wide array of normal and tumoral extrapituitary tissues. This “ectopic” expression can give rise to the clinical syndrome of ectopic ACTH production, a cause of Cushing’s syndrome. However, it is also possible that POMC gene expression may have a role in healthy tissue, especially in the placenta, lymphocytes, testes, and lungs.

There must be compelling evidence that the hormone is produced by the tissue or tumor in question for the diagnosis of ectopic hormone production to be secure. Production is the most fundamental level of hormone control. Thus mRNA or the peptide should be demonstrated in tissue sections or hormone secretion can be shown to persist in vitro in primary cell culture or there may be an arteriovenous gradient of hormone across the tissue *in vivo*. Other criteria, such as reduction in hormone level postresection, are weaker because the tumor may express a hormone secretogogue (e.g., growth hormone–releasing hormone [GHRH] rather than growth hormone [GH] itself).

Hormones most frequently associated with ectopic production tend to be those with the most widespread distribution. The *POMC* gene is widely expressed in nontumorous, nonendocrine tissues and is frequently overexpressed in tumors, giving rise to the ectopic ACTH syndrome. Insulin is almost never produced ectopically by tumors, consistent with its restricted expression only in specialized β cells within the pancreatic islets.

Peptide hormones are often processed differently in tumors compared with their usual organs of production. They may undergo incomplete proteolytic cleavage or altered glycosylation, but the peptides themselves are the products of the same genes responsible for their production in their normal cells. Tumors that produce one hormone ectopically frequently express other hormones and proteins inappropriately; however, it is rare to have clinically significant secretion of more than one peptide.

Theories of the Origin of Ectopic Hormones

With the development of sophisticated molecular techniques, low levels of hormone gene expression have been documented in a wide range of normal tissues.[10] Therefore it is not surprising that tumors arising from these tissues can give rise to ectopic hormone-producing syndromes. If hormone production in the tumor remained under physiologic control, ectopic hormone production would not pose a clinical problem. Sometimes aberrant control has an obvious mechanism (e.g., lack of specific neural connection, physical distance from a portal system, absence of receptors for hormonal modulators of gene expression).

Several theories have been proposed to explain ectopic hormone production.

Amine Precursor Uptake and Decarboxylation Hypothesis[11,12]. A number of endocrinologically active cells are dispersed through normal tissues, but they are not usually considered to be endocrinologically active. These cells share amine precursor uptake and decarboxylation (APUD) properties. At one time, these cells were thought to derive from a common source in the embryonic neural crest. Although an appealing concept, evidence of this common origin is lacking. Nonetheless, their common features suggest that they may respond to transformation in a similar way. Many ectopic hormone-producing tumors have features of APUD cells, and these tumors may originate from APUD precursor cells. However, other ectopic hormone-producing tumors have no features of APUD tissue, and these tumors are often the most aggressive, secreting high levels of hormone, evidence that contradicts the importance of APUD characteristics for hormone production.

Dysdifferentiation Theory[13–15]. Problems with the previous theories have led to the dysdifferentiation hypothesis. It proposes that neoplastic changes occur in progenitor cells rather than in terminally differentiated cells. As a result of one or more mutations, the transformed progenitor cell undergoes variable differentiation. If this theory holds true, it predicts a tumor with a mixed population of cells at different stages of development. Depending on the blocks to normal differentiation, a subset of cells may develop into an endocrine cell type and give rise to an endocrine-type tumor. This model explains why some tissues produce particular hormones because the tumor would tend to transcribe the same genes as its parent tissue, although these may be expressed aberrantly (Fig. 136.1).

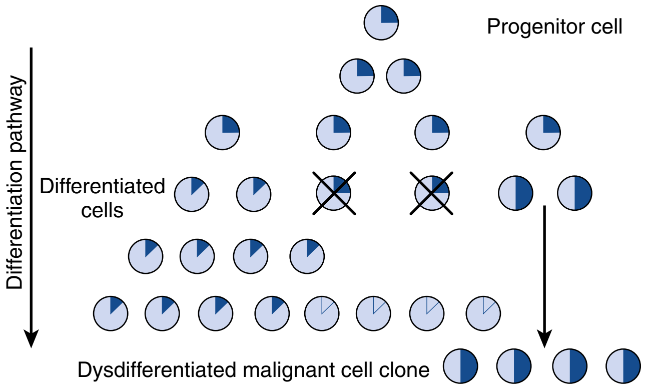

Figure 136.1 Dysdifferentiation results in aberrant gene expression. The malignant transformation of a progenitor cell results in a clonal population of cells that have undergone atypical differentiation. These cells share some features with their progenitor cells *(shaded areas)* and may continue to express genes associated with these immature, incompletely differentiated cells. Malignant transformation of a cell can lead to persistent, or enhanced, hormone gene expression in the clone of proliferating cells *(heavily shaded area).*

Extrapituitary expression of the ACTH gene (pro-opiomelanocortin [*POMC*]) is described in detail in the following section. Ectopic ACTH production shares many features of other ectopic hormone syndromes and may provide a paradigm for understanding general mechanisms of ectopic hormone production.

Hormones in Small-Cell Lung Carcinoma

Small-cell lung carcinoma (SCLC) is the most common and aggressive neuroendocrine tumor. Patients with SCLC seldom present to the endocrinologist, but because there is evidence of hormone expression, it is a useful model from which to extrapolate to other, less common, syndromes.

The normal adult lung contains a diffuse population of cells that synthesize very low levels of peptide hormones including ACTH, GHRH, and gastrin-releasing hormone. In fetal life, these cells are more densely represented and produce higher concentrations of hormones, suggesting a possible role in differentiation. These scattered endocrine cells have APUD properties and comprise part of a diffuse neuroendocrine system.

SCLC, a bronchogenic tumor, produces most of the hormones found in normal bronchial epithelium. ACTH, vasopressin, and calcitonin secretion have been studied most extensively because of the clinical syndromes that they cause and because they produce potential disease markers that can be used for diagnosis or response to treatment. In a study of 157 primary lung tumor extracts, 83% expressed at least one peptide hormone. Multiple hormone production is common and includes ectopic ACTH syndrome in 20% of cases, although production of one hormone tends to dominate the clinical picture.[16,17] However, only approximately 1% of patients with SCLC have clinical features of cortisol excess, possibly because of the short duration of disease.[18] Peptide hormones often undergo incomplete processing. In particular, POMC is not efficiently cleaved to ACTH, resulting in high–molecular-weight forms of ACTH in tumor extracts and in the circulation.[16,19] It is now clear that these alternate forms represent the prohormones POMC and pro-ACTH. The abnormal protein processing may result from a lack of specific cleavage enzymes, prohormone convertases 1 and 2, which are expressed only in specialized endocrine tissue or from a switch from the regulated secretory pathway to the constitutive one.[20]

KEY POINTS

- Ectopic hormone production likely results from abnormal differentiation of a stem cell population lying within the organ.

ECTOPIC ADRENOCORTICOTROPIC HORMONE SYNDROME

The *POMC* Gene

Pituitary corticotroph cells are the only cells that express the *POMC* gene at a high level. The human *POMC* gene is encoded in three exons on chromosome 2. The first exon is noncoding. The second exon contains the signal peptide, which targets the protein product to the regulated secretion pathway. The third exon encodes the majority of the mature protein, including ACTH.[21] The mature mRNA from the *POMC* gene is 1200 nucleotides. In addition, a short form of the mRNA has been found at low levels in most tissues analyzed. This arises from a transcription start site 5′ to exon 3 and thus only includes the coding sequence for exon 3.[22] Therefore this transcript lacks a signal peptide and does not give rise to the mature POMC molecule. There is no evidence that this transcript produces a peptide product, and its physiologic role is unclear. A third POMC transcript has also been described that is longer than the pituitary form (~1500 nucleotides). It arises from a site, or multiple sites, within the 5′ flanking region of the human *POMC* promoter.[23,24] This mRNA species includes the entire coding region of the peptide and does give rise to a secreted peptide product. This "long" form of the POMC mRNA is particularly found in extrapituitary tissues and tumors.

Regulation of *POMC* Gene Expression

Expression of the *POMC* gene appears to be predominantly controlled at the level of gene transcription.[25] The rat *POMC* gene has been most extensively studied, and pituitary expression is conferred by the 5′ flanking region of the gene. It has recently been found that pituitary corticotroph expression of POMC requires the action of a tightly restricted transcription factor, a member of the T-box family, termed Tpit.[26] This factor acts with the homeodomain protein PitX1 and promotes recruitment of SRC family coactivators to the *POMC* promoter, leading to enhanced gene transcription.[27]

Corticotropin-releasing hormone (CRH) acts on pituitary corticotroph cells to increase cyclic adenosine monophosphate (cAMP) accumulation and activates mitogen-activated protein kinases. There is also evidence of activation of the orphan nuclear receptor nerve growth factor–induced clone B (or Nur 77)[28–30] leading to enhanced *POMC* transcription through the recruitment of SRC coactivators to nerve growth factor–induced clone B.[27,31] As nerve growth factor–induced clone B and Tpit act synergistically, this suggests the formation of a regulatory complex on the *POMC* promoter with Tpit, NGFI-B, and SRC coactivators.[27] It is important that expression of Tpit promotes corticotroph cell differentiation and that its expression is more limited than that of POMC. Therefore there is no Tpit expression in hypothalamic POMC-expressing neurons, suggesting that Tpit is specific for corticotroph-specific expression of POMC; other mechanisms are responsible for expression elsewhere. Tpit expression has been found specifically in human pituitary corticotroph adenomas.[26]

Glucocorticoids repress transcription of the *POMC* gene by binding to two DNA elements in the 5′ flanking region of the promoter. The more proximal element, an imperfect palindrome 63 nucleotides upstream from the transcription start site, is thought to bind three glucocorticoid receptor molecules in an unusual trimer formation.[32–34] This conformation of receptors on DNA directs repression of transcription rather than enhancement. Further upstream, between −480 and −320, there is another glucocorticoid-regulated element, suggesting that these two DNA elements interact to achieve the full effect of glucocorticoid repression.[35] It is interesting that Tpit expression, essential to the corticotroph cell type and to POMC expression, is not affected by glucocorticoids, in contrast to POMC, which is repressed.[36] However, it now appears clear that the activated glucocorticoid receptor can antagonize the actions of Nur 77, and so by removing a positive transactivator lead to *POMC* gene repression.[37] The mechanism of glucocorticoid receptor interaction with Nur 77 requires the chromatin remodeling protein Brg1, which stabilizes their binding. Furthermore, Brg1 assists recruitment of a further chromatin remodeling enzyme HDAC2 to the glucocorticoid receptor bound to the *POMC* gene. The pathophysiological importance of Brg1 and HDAC2 is illustrated by finding deficient expression of one or both in 50% of glucocorticoid-resistant pituitary corticotroph adenomas.[38] The expression of Brg1 and HDAC2 in ectopic ACTH syndrome has not been explored.

A number of other hypothalamic factors act on the pituitary corticotroph to influence POMC expression. However, their modes of action are not well defined. In particular, arginine vasopressin stimulates POMC expression rather weakly but augments CRH action. The intracellular pathways activated by arginine vasopressin appear to be protein kinase C dependent, but arginine vasopressin also potentiates the action of CRH on cAMP generation.[25,39]

However, many other peptide growth factors and cytokines are capable of activating cAMP, mitogen-activated protein kinase, and Janus kinase/signal transducers and activators of transcription signaling cascades and thus are potentially capable of regulating POMC expression in nonpituitary tissue. Although extrapituitary tissues lack expression of corticotroph-specific transcription factors, activation of common signaling cascades might be expected to result in *POMC* gene expression. In extrapituitary tissues, the *POMC* gene may be modified to render it transcriptionally silent. One such irreversible modification is DNA methylation. The loss of methylation in tumor tissue may allow transcription of the gene to be activated by the common signaling pathways described previously. There is some evidence that such changes in DNA methylation do occur in cell line models of ectopic ACTH syndrome.[40,41] It seems likely that POMC expression per cell is less in most extrapituitary tumors compared with the pituitary corticotroph, but this relative inefficiency of expression is compensated for by the greater number of cells expressing the gene in extrapituitary tumors.

Ectopic Adrenocorticotropic Hormone Syndrome

ACTH immunoreactivity has been recognized to show size heterogeneity for many years, with the presence of high–molecular-weight forms detected in human plasma.[42,43] Ectopic ACTH syndrome was the first of the ectopic hormone syndromes to be recognized. In its most florid form, it is rare, in one study affecting 4.5% of patients with SCLC, although there is evidence of derangement in the hypothalamic-pituitary-adrenal axis in the majority of patients with SCLC[42,44] (Table 136.1). Analysis of tumor tissue surprisingly suggests the presence of immunoreactive ACTH, even in the absence of clinical features of hormone excess. ACTH is present predominantly in a high–molecular-weight form of approximately 20 kD, but this purified material can be cleaved to mature ACTH (4.5 kD) by the action of trypsin. Further work identified the presence of immunoreactive ACTH-like peptide in a variety of normal tissues, suggesting that extrapituitary ACTH expression is less ectopic than it is inappropriately regulated. The ACTH immunoreactivity was found to have no biologic activity and was assumed to be "big" ACTH. However, identification of predominantly high–molecular-weight forms of ACTH in the circulation of patients with clinically apparent Cushing's syndrome suggests that the precursors of ACTH may have some activity at the ACTH receptor.

Pro-Opiomelanocortin Processing

The *POMC* gene leads to the generation of a pre-pro hormone, POMC. This protein undergoes a series of proteolytic cleavages at dibasic

TABLE 136.1 Types of Tumors Causing Ectopic Adrenocorticotropic Hormone Secretion

Small-cell lung carcinoma

Carcinomas (breast, gastrointestinal tract [esophageal, gastric, colorectal], ovarian, cervical, prostate)

amino acid residues to give rise to a series of small molecules, including ACTH, melanocyte-stimulating hormone, and β-endorphin.[45–47] In the anterior pituitary, ACTH is cleaved by the action of a specific protease, termed PC1 (for prohormone convertase type 1).[48] In the rodent intermediate lobe melanotroph, the POMC molecule undergoes more comprehensive digestion to give smaller fragments, melanocyte-stimulating hormone, β-endorphin, and corticotropin-like intermediate lobe peptide as a result of cleavage by prohormone convertase 2. Expression of prohormone convertase 2 and thus detection of circulating ACTH fragments have been described in ectopic ACTH syndrome tumors.[49]

In the majority of extrapituitary tumors that cause ectopic ACTH syndrome, processing of the preprohormone is incomplete. Therefore ectopic ACTH syndrome is characterized by high–molecular-weight forms of ACTH in the circulation.[17,19].It is likely that the extent of processing correlates with the degree of neuroendocrine differentiation of the tumor, and hormonal manifestations are probably only seen in tumors with significant hormone-processing capacity. A number of small, highly differentiated, slow-growing tumors (typically bronchial carcinoid) have been shown to process POMC in the neurointermediate lobe manner, giving rise to small fragments in the circulation, such as corticotropin-like intermediate lobe peptide and α-melanocyte-stimulating hormone. These have been used to aid diagnosis in some cases of Cushing's syndrome, although the series are small.[8,50]

Dysregulation of *POMC* Gene Expression in Extrapituitary Tumors

In contrast to *POMC* gene expression in pituitary corticotroph cells, expression in extrapituitary tumors is characteristically resistant to glucocorticoid.[7,51] This is the basis of the high-dose glucocorticoid suppression test used to distinguish eutopic from ectopic sources of ACTH in Cushing's syndrome. As the test has approximately 10% false-positive and 10% false-negative rates, it has largely been superseded by sophisticated imaging and inferior petrosal sinus sampling for differential diagnosis.[52] With the availability of recombinant CRH, responses of extrapituitary tumors to this peptide have been measured. In general, only pituitary corticotrophs stimulate POMC expression in response to CRH, but exceptions are increasingly being identified.[53]

As pituitary expression of POMC was defined with the aid of a cell line model, so a cell line model was sought for extrapituitary expression. To this end, a panel of human SCLC cell lines was established. These cell lines express the *POMC* gene, and expression is resistant to glucocorticoid suppression.[16,54–58] Further, the cell lines secrete predominantly unprocessed POMC and partially processed forms, again reflecting the pattern of activity characterized *in vivo*.[54]

It is intriguing that the majority of extrapituitary tumors are resistant to glucocorticoid inhibition of POMC expression. Receptors for glucocorticoids are present in most cells, including malignant cells, so exploring the mechanisms of glucocorticoid resistance was important. Using the panel of cell lines, expression of glucocorticoid receptor was identified using both Western blot with a polyclonal anti–glucocorticoid receptor antibody, and ligand-binding assays using tritiated dexamethasone.[56–58] To determine whether the receptors were sufficient for glucocorticoid signaling, a synthetic, glucocorticoid-responsive gene was used. This gene was transfected into the cells, and the effects of glucocorticoid incubation on expression of the reporter measured. In contrast to the brisk induction of expression seen in control pituitary cells, none of the human SCLC cells responded to either natural or synthetic glucocorticoids.[56,58] Thus resistance of the POMC gene to glucocorticoid is only part of a global resistance of malignant cells to glucocorticoid action. High concentrations of wild-type receptor in the cells were found to be sufficient to restore glucocorticoid signaling, thereby suggesting that resistance resides at the level of the endogenous receptor.[56] Because one of the actions of glucocorticoids on pituitary corticotrophs is to inhibit proliferation and in the developing lung glucocorticoids act to promote differentiation, it is possible that evasion of glucocorticoid signaling confers a survival advantage on the malignant cells. Indeed, it has recently been shown that overexpressing the wild-type glucocorticoid receptor in human SCLC cells powerfully induces apoptosis. Intriguingly, this effect occurs even in the absence of added glucocorticoid.[59] As yet, a single, unifying molecular mechanism of glucocorticoid resistance in the human SCLC cell lines remains to be defined.

It is interesting that well-differentiated carcinoid tumors causing ectopic ACTH syndrome sometimes show appropriate POMC suppression to supraphysiologic glucocorticoid levels, as in pituitary-dependent Cushing's disease, but these tumors express high levels of the glucocorticoid receptor.[60]

Diagnosis

The diagnosis of Cushing's syndrome and the differential diagnosis of ACTH-dependent Cushing's syndrome are described elsewhere (see Chapter 7). Dynamic endocrine testing is required to diagnose Cushing's syndrome, and detection of ACTH using a sensitive two-site immunoradiometric assay is useful for making the diagnosis of ACTH-dependent Cushing's syndrome. A variety of dynamic endocrine and imaging protocols is used to identify a pituitary or extrapituitary source of the ACTH excess (Tables 136.2 and 136.3). These all have variable sensitivity and specificity, but combined tests afford near 100% diagnostic accuracy.[61]

Most occult tumors are carcinoid, pheochromocytoma, or medullary thyroid carcinoma and originate in the neck, chest, or abdomen. Computed tomography or magnetic resonance imaging can be used to detect chest tumors in patients with a normal chest radiograph. There has been some success in using indium-labeled octreotide scanning to identify occult neuroendocrine tumors, although its diagnostic performance is poor, tending only to confirm the presence of tumors found with conventional imaging.[61]

Treatment

Treatment is based on two objectives: (1) to control endocrine manifestations and (2) to manage the underlying tumor. Individual patients will present with different priorities. The ideal treatment is curative resection of the primary tumor, achieving both objectives. If this is not possible, patients with small, occult primary tumors may be managed by chemical or surgical adrenalectomy; in most cases, the primary tumor is not life-threatening. Patients with extensive carcinoma, for example, small-cell carcinoma where ACTH excess coexists, may be best managed by chemotherapy, which indirectly reduces ACTH expression. Chemotherapy should be tailored for the cell type and tumor stage, regardless of hormone excess.

Persistent sodium excretion in urine (>20 mmol/L)
Normal renal, thyroid, and adrenal function
No hypovolemia, edema, or diuretic use

In some patients with florid Cushing's syndrome, control of cortisol production may help in preparation for surgery. In these cases, treatment with metyrapone, mitotane, or ketoconazole, in combination or individually, is helpful.[62] Side effects are common with these agents in the doses required, and so combinations (e.g., ketoconazole and metyrapone) may allow more effective control. Rapid control of hypercortisolemia may require intravenous etomidate.[61] There are case reports of good responses to long-acting somatostatin analogues[63] (Table 136.4).

KEY POINTS

- Ectopic ACTH syndrome is a frequent cause of Cushing's syndrome, can be hard to detect, but must be excluded before assuming a pituitary cause.
- Treatment is of the underlying tumor, which can be very small and hard to detect. Adrenalectomy may be necessary to save the patient from Cushing's.

ECTOPIC CORTICOTROPIN-RELEASING HORMONE SECRETION

It has been more than 30 years since the original description of ectopic CRH secretion, and it is now clear that true, isolated secretion of CRH is very rare (Table 136.5). In tumors secreting ACTH peptides, there are frequent reports of CRH immunoreactivity, which may play a paracrine role in the development of the hormone syndrome, but such a role has not been defined.[64,65] CRH is expressed outside the central nervous system, particularly in sites of inflammation, and may subserve other roles, including vasodilatation. CRH is seldom measured in the peripheral blood during the workup of Cushing's syndrome or in inflammatory disease, and so evidence is lacking for a true endocrine role of this hormone in the peripheral circulation.

The clinical features are typical of Cushing's syndrome, and the hormonal features may resemble either pituitary secretion of ACTH (if the ectopic source secretes purely CRH) or ectopic ACTH syndrome (if the tumor cosecretes ACTH-related peptides). Measurement of CRH is probably best left to those cases with definitive pituitary ACTH production and confirmed corticotroph hyperplasia by histology.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

SIADH is the most common cause of hyponatremia and one of the most frequent hormone syndromes associated with malignant disease (Table 136.6). It may be caused by a wide range of underlying disorders that can be categorized into four broad groups: malignancies, neurologic disorders, and lung disease; and drugs. These conditions cause hyponatremia as a result of abnormal hypothalamic vasopressin, when secretion comes under aberrant control from either neuronal inputs or circulating humoral factors.

The *vasopressin* gene is expressed in a number of separate neuronal nuclei and peripheral tissues. Regulation of vasopressin expression is dependent on the site. For example, hyperosmolality increases vasopressin expression in the supraoptic nucleus and the magnocellular division of the paraventricular nucleus, but vasopressin mRNA in other sites is unaltered. For example, vasopressin expression in the suprachiasmatic nucleus is under diurnal regulation. Androgens upregulate expression of vasopressin in the striae terminalis, and glucocorticoids suppress expression in the parvocellular division of the paraventricular nucleus. Differential regulation, even within anatomically related sites, likely results from differential expression of hormone receptors in the cells and different neuronal afferents. Vasopressin gene transcription is under positive regulation by cAMP and protein kinase C pathways. Little is known about regulation of vasopressin outside the central nervous system, but glucocorticoids have been shown to suppress its expression in an SCLC cell line.

Ectopic secretion of vasopressin occurs in squamous cell carcinoma; small-cell carcinoma; neuroblastoma; pancreatic, duodenal, prostatic, and urothelial tumors; and undifferentiated carcinoma[65–68] (Table 136.7). In one series, 16% of patients with SCLC had hyponatremia (<130 mmol/L) at diagnosis compared with 0% of patients with

non-SCLC. Hyponatremia was found to be an independent predictor of poor prognosis in extensive stage disease. *In vitro* studies found that 7 of 11 tumors in culture produced vasopressin, 9 of 11 tumors produced atrial natriuretic factor, and 5 of 11 tumors produced both hormones. All the cells studied from patients with hyponatremia produced one of the two hormones.[65]

The active hormone, vasopressin, is the product of a precursor peptide cleavage, which also gives rise to neurophysin II, and a C-terminal glycopeptide. Similar to the identification of partially processed forms of ACTH in the circulation in ectopic ACTH syndrome, the vasopressin-neurophysin precursor has been found in plasma from patients with SIADH due to SCLC.[69] This is in contrast to patients with SIADH caused by central nervous system disease. Differential hormone processing may provide an additional diagnostic test for the underlying cause of SIADH.

Diagnosis

Hyponatremia presents with features of neuropsychiatric dysfunction in most cases (Table 136.8). The elderly and the young are more likely than others to be symptomatic. The absolute sodium concentration is less reliable as a predictor of symptoms than the rate of decrease in sodium concentration, although almost all symptomatic patients will have plasma sodium concentration of less than 120 mmol/L. Clinical features include lethargy, fatigue, impaired conscious level, coma, seizures, and psychosis. Hyponatremia may cause death as a result of cerebral edema, uncontrolled seizures, and the consequences of coma. Although mild hyponatremia (>125 mmol/L) is usually regarded as a straightforward condition, which may not require specific treatment, hyponatremia should not be regarded as benign.

A set of diagnostic criteria must be fulfilled before a secure diagnosis is reached (see Table 136.8). The underlying cause is then sought. Neurologic, lung-related, drug-related, and miscellaneous causes can result in dysregulation of vasopressin regulation in the hypothalamus and should not, therefore, be regarded as ectopic hormone secretion states. In contrast, a variety of tumors (see Table 136.7) has been shown to aberrantly secrete vasopressin and express the vasopressin gene inappropriately. There is evidence from T_1-weighted magnetic resonance imaging scans of the pituitary that such ectopic vasopressin secretion results in central suppression of vasopressin synthesis.

Management

The management of this disorder falls into two parts. The first is to diagnose and treat the underlying cause, and the second is to remove excess, free body water. Discussion of specific therapy on the variety of underlying tumors is beyond the scope of this chapter, but surgical cure or debulking, chemotherapy, and radiotherapy have all been applied. In general, the circulating vasopressin concentration bears a direct relationship to tumor bulk in an individual patient, but there is a low correlation across a patient cohort, presumably reflecting intertumoral differences in cellular differentiation and hormone production. Decisions about the acute correction of hyponatremia are complicated by the occurrence of both pontine and extrapontine myelinolysis as consequences of therapy. The risk of myelinolysis is linked to the rate of change in sodium concentration. Therefore a prudent approach is always justified, with an increase of between 0.5 and 1.0 mmol/L sodium per hour and a maximum of 8 mmol/L over 24 hours. This requires close monitoring every 2 to 3 hours[70]. In symptomatic patients, treat with furosemide and hypertonic saline until convulsions cease and the level of consciousness improves. This is usually achieved by an increase in sodium concentration of 10% (~10 mmol/L) and subsequent water restriction. In asymptomatic patients, the condition is almost always chronic; these patients should be treated by water deprivation initially.

Specific approaches to antagonize the action of vasopressin usually rely on demeclocycline, in divided doses up to 1200 mg daily. These agents induce a state of nephrogenic diabetes insipidus. Alternatively, oral sodium supplementation, up to 3 g daily, with furosemide, 40 to 80 mg, results in net loss of free water. More recently, a vasopressin receptor antagonist (Vaprisol, Astellar Pharma) has been approved. The indications for intravenous use are currently limited to moderate to severe hyponatremia which would warrant the use of hypertonic saline.[70] In the future chronic treatment with orally available agents seems likely, although the precise indications remain undefined.

KEY POINTS

- Hyponatremia is common in hospital inpatients and is associated with poor outcomes. Apply simple diagnostic tests to determine the cause, and aim for gentle correction. The outlook depends on the underlying cause

HUMORAL HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia is a common complication of malignancy (Table 136.9). It may result from the direct lytic effect of bony metastases or the action of tumor-derived humoral factors, although it is now clear that a spectrum of disorders lies between these two extremes, and, in most cases, there is a humoral component. Calcitonin has been detected in peripheral blood in a number of patients with malignancy and appears to be incompletely processed, in a manner similar to ACTH, with higher–molecular-weight variants.[71] However, there is no clinical syndrome ascribed to such ectopic production. Calcitonin secretion appears to be most commonly associated with a multihormonal secretory phenotype, with other peptide hormones including ACTH and gastrin[55,71–74] (Table 136.10).

Parathyroid Hormone–Related Protein

The humoral syndrome has been explained by the isolation and characterization of a peptide hormone, parathyroid hormone–related protein (PTHrP). This hormone is closely related in amino acid sequence to parathyroid hormone (PTH) in its N-terminal region (amino acids 1–34), but after residue 34, the two peptides have unique sequences. The discovery of PTHrP as the circulating mediator of hypercalcemia in malignancy ruled out earlier theories that ectopic production of PTH was the cause. There have been isolated reports of ectopic PTH production by tumors, but these are rare. There is convincing evidence of PTH production in SCLC,[75] an ovarian tumor,[76] thymoma,[77] and neuroectodermal tumor.[78] In most cases, patients with malignancy and hypercalcemia with increased PTH concentrations will have coincident primary hyperparathyroidism rather than ectopic PTH secretion. As many as 70% of cases of hypercalcemia in malignancy are caused by excess PTHrP secretion.[79–84]

PTHrP is seldom detectable in the circulation of normal subjects, but its expression has been shown in a number of normal tissues. PTHrP may be regarded as a product of the diffuse paracrine system and may have evolved to perform quite different physiologic roles compared with the structurally related PTH. Under these circumstances, it is hard to describe production of PTHrP from a tumor arising from any tissue as truly ectopic because no definite eutopic source for the peptide has been defined. However, humoral hypercalcemia of malignancy is most conveniently considered with the group of ectopic hormone secretion syndromes.

Prostate	Hematologic
	Lymphoma

PTH and PTHrP share a common receptor that they recognize through their homologous N-terminal sequences. The PTH/PTHrP receptor mediates the action of both peptides in bone and kidney and is a member of the G-protein–coupled seven-transmembrane receptor family. The common receptor explains how PTHrP is able to generate cAMP in membrane preparations of PTH-sensitive renal tubule and, further, why the humoral hypercalcemia of malignancy syndrome resulted in hypercalcemia with hypophosphatemia. In addition, there are receptors that specifically recognize PTHrP, and these are presumed to be the natural targets for the peptide within the tissues in which it is produced.[85–86] In the past, there was controversy about 1,25-dihydroxyvitamin D levels in primary hyperparathyroidism versus humoral hypercalcemia of malignancy syndrome. PTHrP and 1,25-dihydroxyvitamin D appear to be loosely correlated in humoral hypercalcemia of malignancy syndrome, suggesting that PTHrP shares with PTH the capacity to induce 1α-hydroxylase. Occasionally, reported discrepancies may stem from the action of other tumor-derived, circulating factors, from the metabolic consequences of malignancy, or from some other mechanism related to hypercalcemia.[87,88]

PTHrP may also play a role in hypercalcemia related to osseous metastases in that the hypercalcemia associated with bony metastases has a significant humoral component. Furthermore, expression of PTHrP by primary tumors is a predictor of bony, metastatic disease development. This suggests that the local production of PTHrP by bone micrometastases may facilitate bony invasion and destruction.[89–92] PTHrP expression is under complex regulation. A number of cytokines and growth factors have been shown to induce its expression, and both glucocorticoids and 1,25-dihydroxycholecalciferol, which have an antiproliferative effect on epithelial cells, inhibit expression.[93–96]

Hypercalcemia in Hematologic Malignancy

Hypercalcemia occurs in as many as 30% of patients with multiple myeloma. Skeletal involvement causes extensive bone destruction with pain and risk of pathologic fracture. Histologic evidence suggests that the bone disease is caused by increased osteoclastic activity in the absence of significant osteoblastic activity. Loss of osteoblastic activity is also supported by the characteristically negative bone scan and suppressed circulating osteocalcin concentration. A number of cytokines, produced by activated immune cells, have been shown to have direct effects promoting bone resorption. Such cytokines include tumor necrosis factor α, tumor growth factor β, interleukin-1, and leukemia inhibitory factor. A superseded generic term for these factors was osteoclast-activating factor. However, it is noteworthy that in three of nine patients with multiple myeloma complicated by hypercalcemia, there was an elevation in circulating PTHrP, suggesting that a mechanism similar to humoral hypercalcemia of malignancy syndrome may be operating in at least some patients with hematologic malignancy-associated hypercalcemia.[83,97,98]

Generally, hypercalcemia is rare in lymphoma, with the exception of adult T-cell leukemia/lymphoma. This disease occurs in Japan and the West Indies and is caused by infection with the human T-cell lymphotrophic virus type I. At least one-fourth of patients will develop hypercalcemia, which is associated with suppressed 1,25-dihydroxyvitamin D. Hypercalcemia predicts outcome and is implicated in causing patient mortality. There is strong evidence that the hypercalcemia is mediated by PTHrP.[99–102]

Diagnosis

Hypercalcemia is the most common metabolic complication of malignant disease and the cause of much morbidity (Table 136.11). Most cases are due to humoral mechanisms, principally PTHrP, rather than direct damage of bone by malignant cells. This is clear from the observation that even patients who have bone metastases and hypercalcemia have a poor correlation between extent of skeletal involvement and calcium concentration in the circulation.

The presentation of hypercalcemia may be confusing and may be attributed to the underlying disease process itself. Patients may be nonspecifically unwell and may complain of constipation, nausea, vomiting, confusion, or dehydration. Hypercalcemia induces a diuresis and may cause profound dehydration, particularly in association with vomiting or drowsiness. Further manifestations include lethargy, depression, poor concentration, and drowsiness.

It is sometimes necessary to distinguish malignancy-induced hypercalcemia from other causes of hypercalcemia, such as hyperparathyroidism. PTH levels are low in hypercalcemia of malignancy. An elevated PTHrP level confirms the diagnosis, and it is increased in approximately 80% of patients with hypercalcemia with cancer. 1,25-Dihydroxyvitamin D levels may be increased in patients with lymphoma. Recognition of hypercalcemia and its appropriate treatment allow retrospective allocation of symptoms in an individual patient. Therefore it is almost always worth treating such patients, irrespective of their underlying disease prognosis.

Treatment

There is little evidence that hypercalcemia is a significant cause of premature mortality in cancer, but it is a significant cause of morbidity.[103] Even if the underlying malignancy is beyond cure, effective relief of hypercalcemia is a most useful palliative intervention. There are few patients in whom treatment should not be seriously considered because intervention is quick, easy, and largely free of serious complications. In the past, calcitonin and/or mithramycin were used, but these have been replaced by the bisphosphonate drugs, in conjunction with rehydration with intravenous saline.[104] The saline promotes a calcium diuresis. Usually, single infusions of pamidronate or clodronate are sufficient, with a suggestion that pamidronate is slightly more effective.[105,106] There are newer bisphosphonates that have become available (e.g., ibandronate), but further head-to-head comparisons are lacking.[107] These drugs are usually administered by slow intravenous infusion. There may be a transient febrile reaction within the first 24 hours, but this is usually self-limiting. The calcium response is typically rapid and may last as long as 1 month. In patients in whom a more rapid acute effect is desired, bisphosphonates can be combined with calcitonin.[108]

The bisphosphonates are rapidly cleared from the circulation and concentrated in the bone. They appear to inhibit osteoclast activity and may induce osteoclast apoptosis. Their duration of action is significantly longer than predicted by their plasma half-life, reflecting their distribution and mode of action.[107]

TABLE 136.11 Non–Islet Cell Tumor Hypoglycemia vs Insulinoma

	Non–Islet Cell	Insulinoma
IGF-1	↔	↔
IGF-2	↑	↔
IGFBP-3	↓	↔
Insulin	↓	↑
Glucose	↓	↓
Growth hormone	↓	↔ or ↑
β-Hydroxybutyrate	↓	↓

↑, increased; ↓, decreased; ↔, equivocal. *IGF,* Insulin-like growth factor; *IGFBP,* insulin-like growth factor–binding protein.

KEY POINTS

- Humoral hypercalcemia of malignancy is commonly seen, and simple tests can be used to confirm the diagnosis, the main differential being coincident primary hyperparathyroidism. Bisphosphonates are effects agents.

ONCOGENIC OSTEOMALACIA

Osteomalacia associated with malignancy was first described in 1947.[109] It is characterized by hypophosphatemia, normal or low calcium, elevated alkaline phosphatase, and suppressed 1,25-dihydroxyvitamin D. It is usually found with benign mesenchymal tumors, of which hemangiopericytomas are the most common. The disorder exhibits biochemical features similar to those seen with inactivating mutations in the PHEX gene, the cause of hereditary X-linked hypophosphatemia. The PHEX gene encodes a protease that activates phosphatonins, including the protein fibroblast growth factor type 23, which seems to be the phosphaturic factor produced by tumors that cause oncogenic osteomalacia.

ECTOPIC GROWTH HORMONE–RELEASING HORMONE

Ectopic GHRH-releasing tumors, often the bronchial or upper gastrointestinal carcinoid cell type, are a very rare cause of acromegaly (Table 136.12). In patients who present with acromegaly, the syndrome is usually of several years' duration to allow development of the typical clinical features. Accordingly, it is not surprising that the underlying tumors are usually small and benign. Clinical features are similar to those of typical acromegaly. Pituitary imaging is unhelpful because the radiographic features reveal an enlarged pituitary or an asymmetric mass that can be confused with an adenoma.[110] The histologic identification of true pituitary somatotroph hyperplasia, with a preserved reticulin network, led to the identification of GHRH in extracts from islet cell tumors.[111–114] Since then, many tumors and tumor cell lines have been shown to express or secrete GHRH.[115–119] For example, 25

TABLE 136.12 Tumors Associated With Ectopic Renin Secretion

Kidney (Wilms' tumor, renal cell carcinoma)
Lung (small-cell lung carcinoma, adenocarcinoma, leiomyosarcoma)
Pancreatic carcinoma
Ovarian tumors
Liver (hepatocellular carcinoma, hamartoma)
Ileal carcinoma
Adrenal paraganglioma
Orbital hemangiopericytoma

of 97 carcinoid tumors expressed GHRH in one study,[120] 17% of gastrointestinal and pancreatic tumors stained for GHRH in another,[121] and 63% of endometrial adenocarcinomas expressed GHRH.[122] In addition, subtle abnormalities in GH secretion and regulation may be found in patients harboring carcinoid tumors.[123] GH secretion has been associated with the development of several malignant tumors, notably prostate and colon adenocarcinoma. Therefore a complex long feedback loop may confer survival advantage on these tumors.

It has been suggested that all patients with acromegaly should be screened for ectopic GHRH because measurements in the plasma of greater than 0.3 ng/mL are virtually diagnostic of GHRH production by a tumor.[124] However, the assays are not widely available and currently remain research tools. In addition, the incidence is rare. In one series of 177 unselected patients with acromegaly, only one had detectable GHRH concentrations in plasma.[113,125]

Most commonly, the diagnosis is made after hypophysectomy, when histology shows somatotroph hyperplasia. In these cases, measurement of GHRH is necessary, as is the search for its source. The best treatment is curative resection of the primary tumor, but in cases in which the tumor is elusive or metastatic, success has been achieved using long-acting somatostatin analogues.[110,126–128]

NON–ISLET CELL TUMOR HYPOGLYCEMIA

Fasting hypoglycemia may arise as a consequence of non–islet cell tumor formation (see Chapter 38). Such tumors do not express insulin, which appears to be very tightly regulated in its tissue distribution, but rather the insulin-related molecules insulin-like growth factor (IGF)-1 or, more commonly, IGF-2. These two growth factors are members of the insulin family of peptide hormones along with relaxin, and both are capable of signaling through the IGF-1 receptor or the insulin receptor. IGF-1 is the liver-derived circulating mediator of GH action, whereas IGF-2 has a more important role in development. In normal subjects, IGF-1 and IGF-2 circulate at much higher concentrations than insulin and, if unopposed, cause profound hypoglycemia due to their actions through the insulin receptor. That this does not occur due to the presence of high-affinity, high-capacity, circulating IGF-binding proteins.[129-130] These result in very low concentrations of free IGFs, and they act to chaperone the IGFs and deliver them to their tissue beds of action.

A number of tumors, typically of mesenchymal origin, have been identified as the cause of non–islet cell hypoglycemia. The apparent mechanism is overproduction of IGF-2.[131] In addition to aberrant overproduction of IGF-2, there is also secretion of a partially processed form of IGF-2, "big" IGF-2, which includes a C-terminal extension peptide and frequently an abnormal glycosylation pattern.[132,133] The circulating IGF-2 would be expected to cause few problems if it were effectively sequestered by IGF-binding proteins, but this does not occur.[134,135] IGF-2 exerts a negative feedback at the pituitary somatotroph to suppress GH secretion. GH is the key regulator of hepatic IGF-binding protein 3, a component of the principal, ternary circulating IGF complex (Fig. 136.2). Therefore in the absence of effective GH drive to IGF-binding protein 3 production, the tumor-derived IGF-2 is left in a free state and is thus capable of acting through the insulin receptor and causing hypoglycemia.[136]

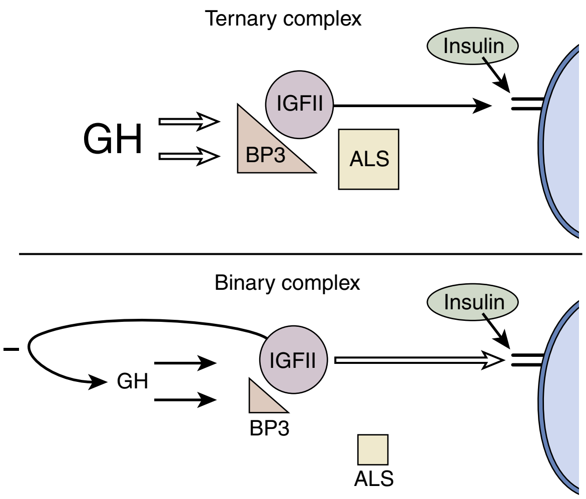

Figure 136.2 Formation of the ternary complex between insulin-like growth factors *(IGFs)*, IGF-binding protein 3 *(BP3)*, and the acid-labile subunit *(ALS)*. Normal physiology *(top)* in ectopic production of IGF (usually IGF-2) by tumor *(bottom)*. Increased activity of IGF inhibits pituitary production of growth hormone *(GH)* and so reduces hepatic production of ALS and IGF-BP3. The resulting binary complex has increased insulin-like activity and, acting through the insulin receptor, causes hypoglycemia.

Diagnosis

The diagnosis is based on the recognition that the patient's symptoms are due to hypoglycemia, which involves a detailed history and confirmation of either hypoglycemia occurring during a symptomatic episode or fasting hypoglycemia. The diagnosis should be considered in all unconscious cancer patients without signs of vascular events or brain metastases. The typical biochemical accompaniment to hypoglycemia is suppressed insulin, suppressed ketone bodies (β-hydroxybutyrate), and suppressed GH. In addition, IGF-2 is usually elevated or normal, with suppression of IGF-binding protein 3 as a consequence of low GH.[131,137]

Most tumors are large and intraabdominal, although thoracic tumors have also been reported.[138] The underlying tumor may be benign, in which case curative resection is the aim. Histologic confirmation of the diagnosis is by specific immunostaining of a biopsy for IGF-2.

Management

Effective management requires either surgical excision or debulking of the tumor. This is best achieved by close consultation between oncologist, surgeon, and interventional radiologist, who may be able to perform tumor embolization. These tumors tend not to be radiosensitive, although there are isolated case reports of therapeutic response. Because these tumors are rare, management is tailored to the individual patient and is usually based on pragmatic approaches. In patients whose tumors are inoperable, relief of hypoglycemia can be achieved by using glucocorticoid, usually dexamethasone, either alone or with recombinant human GH.[136,139,140]. Glucocorticoids exert a direct anti-insulin and anti-IGF effect, and GH acts both by its anti-insulin action and by increasing the IGF-binding protein concentration, which then acts to "mop up" the excess IGF.

KEY POINTS

- Spontaneous hypoglycemia can be hard to diagnose, but non–islet cell tumors should be considered. Typically tumors are large, and abdominal, and the biochemical features are low insulin with raised IGF2.

OTHER PITUITARY ECTOPIC HORMONES

The two pituitary hormones prolactin and GH are of interest because they have wide extrapituitary expression and yet are very seldom the cause of clinically significant ectopic hormone syndromes. Prolactin is expressed in decidualized endometrium, T lymphocytes, mammary epithelial cells, skin, sweat glands, and the brain. It is the same gene that is transcribed in all these cases, rather than the related placental lactogen-type gene, but the regulation of the gene appears completely different.[141] Whereas in the pituitary lactotroph cell, prolactin is under the transcriptional control of the pituitary-specific factor Pit1, in extrapituitary tissues, Pit1 is not expressed, and the pituitary promoter of the prolactin gene is silent. The gene is transcribed from an upstream promoter, which gives rise to a slightly longer mRNA, with a unique 5′ end but, after processing, results in a protein with the same amino acid sequence. Because the gene is transcribed from a different promoter, the control of gene transcription, its basal rate, and regulation by external signals is different. For example, in T-lymphocyte prolactin, gene transcription is responsive to the immunophilins, including cyclosporin A. The function of this extrapituitary prolactin is subject to debate, and it is not clear why such widespread expression is accompanied by such rarity of overexpression in malignant disease, in contrast to ACTH or vasopressin expression. Because prolactin receptors are found in a variety of tissues that cannot be reconciled with an exclusive action on mammary milk production, prolactin may have a more diverse role than so far determined.

Ectopic prolactin secretion is a rare occurrence.[142] There are reports of ectopic prolactin secretion from a bronchial tumor,[143] a gonadoblastoma,[144] a renal cell carcinoma,[145] and undifferentiated lung cancer.[145] However, breast cancers have been shown to express both prolactin and prolactin receptors.[146–148] There is some evidence of a weak tumor-promoting effect of prolactin on breast adenocarcinoma cells[149,150] that has led to the suggestion of a paracrine role for prolactin in the development or progression of breast malignancy. Prolactin may have other activities in addition to its best characterized function on lactation, and, in particular, a 16-kD fragment of prolactin has antiangiogenic potential and may influence tumorigenesis.[151,152] In addition, prolactin can activate nuclear factor-κB, a survival-promoting transcription factor.[153]

GH is also found in extrapituitary tissues, again in cells of hematopoietic lineage. This expression has been suggested to result in paracrine signaling, although hard data are lacking.

Ectopic GH secretion was first described in 1968 in a man with lung cancer. Resection of the tumor caused a decrease in GH concentrations, although GH was not measured in the primary tumor.[154] There are very few cases in which the criteria are met for true ectopic secretion of GH. One such case was described by Melmed and coworkers,[155] who carefully showed GH secretion from a pancreatic islet tumor, with demonstration of a gradient of GH across the tumor *in vivo* and resolution of abnormal GH and IGF-1 after tumor resection. They also showed GH expression in tumor sections, at both the mRNA and protein level. It is interesting that there is hypertrophic osteoarthropathy in cases of ectopic GH secretion, although this is not a feature of acromegaly; it may result from other humoral factors secreted by the tumors or from neural influences.[155–157]

Gonadotropins

Human chorionic gonadotropin is expressed in trophoblast and from both germ cell and trophoblast tumors. The most frequent nontrophoblast tumor associated with human chorionic gonadotropin overproduction is lung,[158] but other tumors have been described including adrenal, breast, bladder, maxilla, hepatoblastoma, osteosarcoma, and lymphoma.[159–163]

The production of human chorionic gonadotropin in men causes gynecomastia as a result of increased estrogen secretion and may cause precocious puberty in children.[164]

ECTOPIC GUT HORMONE SYNDROMES

Clinical syndromes associated with ectopic production of gut hormones by tumors are very rare, but vasoactive intestinal polypeptide causing typical watery diarrhea has been described (see Chapter 135). Tumors of the lung, medullary thyroid carcinoma, pheochromocytoma, and neuroendocrine tumors of the kidney have all been reported to produce vasoactive intestinal polypeptide.[165–167]

Ectopic Renin Secretion

Renin production is usually tightly restricted to the juxtaglomerular apparatus of the kidney, and true ectopic secretion by nonrenal tumors is very rare. In cases described, hypertension is a feature, along with hypokalemia.[168] As is often the case with ectopic production of usually processed hormones, renin precursors are described, with an increased prorenin-renin ratio.[169–171] Resection of the primary tumor affords cure, if identified, but medical therapy with angiotensin-converting enzyme inhibitors or with angiotensin-blocking agents may be beneficial in noncurable disease.[172]

Extrarenal tumors secreting renin include lung,[173–175] pancreas,[171] ovary,[176,177] liver,[178] ileum,[179] adrenal,[180] and orbital hemangiopericytoma.[181]

KEY POINTS

- Almost all hormones have been reported as ectopically produced in cancer but for most experience is limited to case reports. Key considerations are proven tumor production and loss of hormone excess after tumor resection.

ACKNOWLEDGMENTS

The author is grateful to Professor Wass and Dr. Turner, who wrote the previous version of this chapter, for inspiration and for the use of tables.

THE US POPULATION IS LESS HEALTHY TODAY

Although the United States is one of the wealthiest countries in the world, it is not the healthiest by far. The United States is below average compared to peer economies in 9 health domains, including adverse birth outcomes, obesity and diabetes, heart disease, and chronic lung disease.[1] While this health disadvantage is greater in socioeconomically disadvantaged populations, wealthy Americans are also less healthy than their counterparts in peer countries. In their extensive analysis of the health disadvantage in America, an Institute of Medicine (now National Academy of Medicine) Panel concluded that while there is no single cause, the environment is an important contributor.[1] These trends have been recently chronicled by front-line scientists in books aimed at informing the public.[2–5]

Complex, noncommunicable (chronic) diseases and disorders today represent the largest burden on the health care system in the United States.[6] (This statistic does not include the human and economic impact of SARS-Cov-2 infections COVID-19]). In fact, nearly half of the adult population in the United States has at least one chronic condition.[7] These diseases include cardiovascular disease, cancer, diabetes, obesity, reproductive disorders, psychiatric diseases and disorders, thyroid disease, and others. By 2030, it is estimated that 50% of Americans will be obese and the prevalence will be greater than 50% in 29 states.[8] Obesity is associated with co-morbidities including cardiovascular disease, hypertension, diabetes mellitus, and other chronic diseases.[7] Note also that these diseases are linked to a poorer outcome of infectious diseases like COVID-19.[9] This national disease profile is not sustainable, so it is important to address not only appropriate therapies, but also ways to reduce this population disease burden.

The increase in chronic disease is not likely to be related to changes in population demographics or to genetic drift. Because of the availability of sequence information for the human genome and of rapid whole-genome platforms for analysis, genome-wide association studies have been performed to explore the heterogeneous nature of these complex chronic diseases and to identify potential genetic risk factors. These studies, in general, identify important single nucleotide polymorphisms (SNPs) that contribute to disease risk. However, these data indicate that the contributions of SNPs to disease are small.[10] Therefore, elements of the environment represent risk factors for many chronic diseases,[11] and gene-environment interactions are becoming increasingly attractive to identify the major contributions to disease risk.[12] Indeed, it is likely that all noncommunicable diseases have both a genetic and an environmental component. Here we focus on the environmental component, which not only has changed over the last few decades but is also the only disease risk that is modifiable on a population level.

The environment in this regard can be broadly defined as the complex array of nongenetic variables, including but not limited to nutrition, stress, drugs, and environmental chemical exposures. Each of these components is complex in nature and can contribute to disease risk independently and in combination with other environmental components and with genetic profiles. However, unlike with other components, chemical exposures can be modified in part by actions on the population and individual level.[13] Studies have documented the degree to which the human population is exposed to environmental chemicals.[14] The human population is exposed to these chemicals through a variety of mechanisms including food and food packaging, water, work, the home, personal care products, and the environment. The Agency for Toxic Substances and Disease Registry has developed a method for taking an exposure history for primary care physicians that addresses this in part.[15]

ENVIRONMENTAL CHEMICALS CONTRIBUTE TO HUMAN DISEASE

In the Centers for Disease Control and Prevention (CDC) fourth national report on human exposure to environmental chemicals,[14] 212 compounds were measured in blood and urine of participants identified in a statistically representative sample of the US population. In this report, acrylamides, cotinine, trihalomethanes, bisphenol A (BPA), phthalates, chlorinated pesticides, pyrethroids, heavy metals, aromatic hydrocarbons, polybrominated diphenyl ethers, benzophenone from sunblock, perfluorocarbons, and a host of polychlorinated biphenyls (PCBs) and solvents were found commonly in the average US resident.[14] This program—the National Health and Nutrition Examination Survey (NHANES)—has been an enormously valuable tool for researchers to identify chemical exposures and relationships between chemical (and chemical mixture) exposures and human health. These studies have provided important evidence that environmental chemical exposure is contributing to human disease. But as important as this program is to characterize human exposures to environmental chemicals, it is also important to recognize that the number of chemicals measured in this program is only about 0.2% of chemicals licensed for use in the United States.[16] Moreover, about 3000 chemicals are produced at over 1 million pounds per year. While some of these chemicals have been tested for safety to various degrees, most have not been tested at all.

The mechanisms by which chemicals produce toxicity are variable, including chemical reactivity resulting in covalent binding to cellular targets, metabolic production of reactive species, induction of oxidative or nitrosative stresses leading to the production of reactive species,[17] or multiple mechanisms of mutagenicity and carcinogenicity.[18,19] There is also another important mechanism—chemicals that exert adverse effects by interfering with hormone actions—endocrine-disrupting chemicals (EDCs).

ENDOCRINE-DISRUPTING CHEMICALS ARE NOT TYPICAL POISONS

Unlike other toxicants, an EDC is defined by its ability to interfere with hormone actions, independent of its chemical structure. The World Health Organization (WHO) defines an EDC as an "…exogenous substance or mixture that alters function(s) of the endocrine system and consequently causes adverse effects in an intact organism, or its progeny, or (sub)populations."[13] This definition was designed to be applied by government regulators. In contrast, from a biological perspective, the Endocrine Society has defined an EDC as "an exogenous chemical, or mixture of chemicals, that interfere(s) with hormone action."[20] It is important to focus on hormone action in this definition rather than "endocrine function," because it is ultimately the interference with hormone action at the receptor that can cause adverse effects, regardless of where the chemical acts in the pathway of the regulation of hormone action. If an environmental chemical interferes with hormone action at a critical time when hormonal control is actively changing, for example, during development, puberty, or aging, adverse health effects in the human population will most certainly be the result and will be permanent.

The science of endocrine disruption has proceeded rapidly since the mid-2000s as evidenced by reports commissioned by the United Nations Environment Programme (UNEP) and the WHO published in 2013[13] and by the European Commission.[21] These publications make it clear that EDCs are widespread globally; in fact, there are no longer any pristine places on Earth. In addition, EDCs are chemically highly variable; some are lipophilic with long residence times in the environment and in the human body, whereas others are hydrophilic and short-lived. Thus, there are few general statements that can be made about the chemistry of this class of chemicals. In this chapter, we provide information about EDCs: what they are, how they interfere with hormone action, the evidence for their effects in humans, and some thoughts about how these insights may affect clinical care.

CHARACTERISTICS OF ENDOCRINE-DISRUPTING CHEMICALS

EDCs are identified according to their ability to interfere with hormone actions, not by their physicochemical characteristics.[22,23] For example, perchlorate (ClO_4) is a highly water soluble anion that inhibits iodide uptake through the sodium/iodide symporter,[24,25] which can interfere with thyroid function. In contrast, PCBs are highly lipophilic compounds[26] that can interact with an array of nuclear receptors and enzyme systems and also interfere with thyroid function.[27] These are two very different types of chemicals with different physicochemical properties and different pathways through which people are exposed. But both are examples of an endocrine disruptor and both are linked to cognitive deficits in the offspring of exposed pregnant women.[28,29]

Likewise, the particular structure of the chemical is not always indicative of its hormone action. For example, BPA is a diphenolic compound that interacts with the estrogen receptor, and to a lesser degree, the androgen and thyroid hormone (TH) receptors.[30–32] Its structure is quite different from that of estradiol 17β, but its structure is such that it binds to the ligand binding domain of the estrogen receptor nonetheless.[33] Finally, because they interfere with hormone action, EDCs are not typical poisons. That is, their effect is not acute but rather is more sustained, contributing to the prevalence of chronic disease. What this means is that identifying EDCs requires an approach that is different from identifying "traditional" toxins.[21] Thus, identifying endocrine-disrupting properties of environmental chemicals is both challenging and debated. Recently, a new approach to identifying EDCs was published that focuses on the key features that characterize the action(s) of EDCs.[34] There are 10 key characteristics of an EDC as shown in Table 137.1.

These key characteristics of EDCs are useful to show the ways/mechanisms that EDCs can interfere with hormone action. They can also guide determinations of which chemicals act via an endocrine mode of action and therefore are EDCs. A short list of common EDCs—those to which human exposure is common and characterized—is provided in Table 137.2.[35,36]

KEY POINTS

- Industrial chemicals are manufactured for commercial purposes but many of these chemicals are known to interact with endocrine systems in ways that are not typical of a "poison".
- Endocrine-disrupting chemicals (EDCs) exert effects on endocrine systems in ways that are typical of hormones and of drugs designed to target hormone systems. However, these mechanisms are not evaluated by industries or regulatory agencies. Moreover, EDCs are not identified by specific physicochemical properties, but by their actions.

TABLE 137.1 **10 Key Characteristics of an EDC**

Key Characteristic	Description
1	Interacts with or activates hormone receptors by binding to or agonism of hormone receptors
2	Antagonism of nuclear or cell surface receptors
3	Alters hormone receptor expression
4	Alters signal transduction in hormone-responsive cells
5	Induces epigenetic modifications in hormone-producing or hormone-responsive cells
6	Alters hormone synthesis
7	Alters hormone transport across cell membranes
8	Alters hormone distribution of circulating hormone levels
9	Alters hormone metabolism or clearance
10	Alters fate of hormone-producing or hormone-responsive cells

EDC, Endocrine-disrupting chemical.

HEALTH EFFECTS OF ENVIRONMENTAL CHEMICALS

At first glance, it may seem a relatively simple endeavor to identify the relationship between chemical exposure and adverse outcome. For example, organophosphate pesticides account for about 200,000 deaths per year in developing countries,[37] the symptoms of cholinesterase inhibition are syndromic, and the severity of symptoms is associated with the severity of exposure. Pyrethroid pesticides also are known to produce acute effects when ingested exposure is greater than about 250 mL, although a significant number of patients exhibit atypical symptoms.[38] In both cases, high exposure is immediately linked to adverse effects, so the cause of the symptoms and the treatment regimen for clinical care are clear. It is also clear when well-known, naturally occurring EDCs produce acute effects, such as the relationship between excess licorice consumption and symptoms of mineralocorticoid excess,[39] or cassava consumption and goiter.[40]

However, identifying the relationship between chemical exposure and health outcome is much more complicated when low-dose chronic exposure produces effects observed at the population level or when exposure occurs at a time of life that is different from the manifestation of effect. Knowledge in this area has been hard won, and the human population has suffered to teach us these lessons. The following cases illustrate a few of these lessons and how they inform us about EDCs in general.

The Lessons of Lead

The acute neurotoxicity of lead exposure in adults has been known for thousands of years.[41] However, it was generally believed that only high exposures would produce toxicity, and only in adults. As a result, in 1924, the Ethyl Corporation was founded in the United States to produce tetraethyl lead (TEL) as a gasoline additive to reduce engine knock in cars. Within a few months of operation there were numerous deaths among company workers and other workers with neurological symptoms. Nonetheless the Surgeon General's report of 1926 approved the use of TEL for the purpose of a gasoline additive, in part because the studies at the time were focused on adult men and the end point was acute lead toxicity.[42] During the ensuing years, there was virtually no independent research on the health effects of lead. The only published research was performed or sponsored by industry, and the results of these studies supported the industry position that low-level lead exposure was natural and safe.

The first independent research funds that were awarded to study the health impacts of lead on children occurred in 1970, resulting in a seminal article by Dr. Herb Needleman, who reported that children's IQs were inversely related to measures of lifetime lead exposure.[43] Despite considerable controversy,[44] the U.S. Environmental Protection Agency (EPA) issued new standards for lead including its removal from gasoline. However, lead was removed from gasoline because it damaged catalytic converters, which were required on all new cars beginning in 1975. Lead consumption in gasoline declined by 50% during the next 4 years, and blood lead levels in average Americans declined by 37%, and by 71% by 1984. As blood lead levels have fallen over time, it has been possible to identify the relationship between lead exposure and IQ at lower levels of exposure. It is currently concluded that there is no safe level of lead exposure for children and that the annual economic cost of lead exposure in children worldwide is in the trillions of dollars.[45]

This history shows first that recognition of lead toxicity derived initially from acute high-dose exposure and severe and immediate consequences. Then, new data began to show that lead could affect child health without the acute effects that served as the primary endpoint of harm. Ultimately, it was determined that there is no safe exposure level for children. This path required nearly 100 years, during which generations of children were exposed to lead.

The early work of Needleman also highlights the importance of identifying the correct measure of exposure. Specifically, Needleman recognized that the half-life of lead in blood was about 30 days, but the half-life in bone was about 30 years. Because bone biopsies were out of the question, he collected shed deciduous teeth, which reflect lifetime exposure to lead. Evaluating lead exposure using a metric that reflects lifetime exposure (in a child) was one of the reasons that exposure measurements were so strongly associated with health outcome. Today it is clear that lead exposure *in utero* and in early childhood when the brain is developing will lead to brain damage, that environmental lead—especially in paint—is an important source of exposure to control, and that lead in paint is a worldwide source of adverse public health effects.[46]

The problem of lead exposure is not one relegated to the past only. The water crisis in Flint, Michigan, demonstrated that lead in drinking water is a pervasive problem and that vigilance is required.[47] Moreover, the events leading up to this crisis were not only a lesson in poor governance and unethical behavior, but also a lesson in the ways in which scientific knowledge is understood by various actors.[48] Finally, the magnitude of the crisis was exacerbated by the sheer complexity of the laws regulating how government agencies maintain and monitor safe drinking water.[49] Considering what we know about the health effects of lead exposure with certainty, the failure of public health and government agencies to avoid the drinking water crisis in Flint demonstrates that health care professionals need to remain vigilant for the role of the environment—broadly defined—in the health and care for patients.

The Lessons of PCBs

PCBs are a mixture of synthetic organic chemicals (biphenyls) that have been chlorinated to different degrees (different numbers of chlorine atoms). These chemicals were used in a wide variety of applications from electrical equipment because of their insulating properties and resistance to high temperatures, wood finishes because of their optical properties, caulking because of their ability to soften the material and to remain stable for long periods, and many others.[50,51] In

TABLE 137.2 Selected Common Endocrine Disruptors in the Human Population

Chemical	Population With Measured Levels (%)	Source of Contamination	Effects
Lead	>90	Degradation of lead-based paint and the contaminated dust that it forms.	Effects on brain development and IQ. Multiple endocrine and toxic effects.
Mercury	>90	Diet is a significant source of blood mercury, especially in some seafood species. Some manufacturing can produce atmospheric mercury that enters the air and ultimately the food chain.	Effect on brain development, learning, and memory. Effects on thyroid and other endocrine and toxic effects.
Per- and Polyfluoroalkyl Substances (PFAS)[a]	~100	Used to repel oil and water from clothing, furniture, and food packaging such as pizza boxes and fast-food containers. Firefighting foams, cleaners, some paints, roof treatments, and hardwood floor products. Persist and bioaccumulate in environment and have long half-lives in humans.	Many different congeners. Linked to thyroid disease as well as several cancers.
Polybrominated Diphenyl Ethers (PBDEs)[b]	68–100	Used as flame retardants in foam, furniture, electronic equipment, and high-impact plastics. There are many individual congeners that have different exposure profiles in the population. Prevalent in the built environment, especially in dust. Persist and bioaccumulate in environment and have long half-lives in humans.	Many different congeners. Some interact with estrogen, androgen, and thyroid hormone actions. Metabolites may be most important.
Polychlorinated Biphenyls (PCBs)[c]	>95	Production was banned in the 1970s, but they are still used in a number of commercial and personal applications. They were used as dielectric fluids, wood treatments, printing ink, and in many other products. Because of their persistence and ability to bioaccumulate, they are still widely present in the environment.	Many different congeners. Some interact with estrogen, androgen, and the actions of thyroid hormones. Metabolites may be most important.
1,1-Dichloro-2,2-Bis(p-Chlorophenyl) Ethylene (DDE)	100	Metabolite of the insecticide dicloro-diphenyl-trichloroethane (DDT). Because of previous extensive and wide use, and because of its relatively long environmental half-life, DDE is ubiquitous in human samples.	Interacts with estrogen signaling. Associated with hormone-related cancers and precocious puberty.
BPA	>95	Can linings, epoxy resins, some plastics, thermal receipts, others	Interacts with estrogen receptor and at higher doses also interacts with the androgen and thyroid hormone receptor. Linked to a variety of chronic diseases including obesity, cardiovascular disease, and some cancers.
Triclosan	>85	Antimicrobial soaps and other products, clothing, kitchenware, body washes, and some cosmetics.	Appears to interact with thyroid hormone through several mechanisms.
Parabens	>90	These are esters of parahydroxybenzoic acid. Present as preservative in many consumer products including nail polish, hair spray, lipstick, fragrance, body wash, sunscreen, etc.	Class of chemicals with estrogenic activity.
Phthalates[d]	100	Different phthalates are used in different applications including personal care products, PVC plastics, some flooring, car products, insect repellents, etc.	Can interact with androgen and thyroid hormone systems. Associated with lack of masculinization in boys including reduced anogenital distance and lower sperm count in men.
Perchlorate	100	Widely present in foods including fruits and vegetables, beer and wine, and other products. It is FDA approved for use in food packaging.	Blocks iodide uptake into the thyroid and reduces serum thyroid hormone levels in animals. Linked to lower thyroid hormone levels in some women, and to negative cognitive impacts on children.

[a] Perfluorinated chemicals including perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA).
[b] Polybrominated diphenyl ethers. Many different congeners based on bromine number and placement.
[c] Polychlorinated biphenyls. Many different congeners based on chlorine number and placement.
[d] There are several variations of chemical structure for phthalates.
BPA, bisphenol A; *FDA*, Food and Drug Administration; *PCBs*, Polychlorinated biphenyls.
Data are derived in part from Woodruff TJ, Zota AR, Schwartz JM. Environmental chemicals in pregnant women in the United States: NHANES 2003-2004. *Environ Health Perspect.* 2011;119(6):878–885 and from Calafat AM, Ye X, Wong LY, Bishop AM, Needham LL. Urinary concentrations of four parabens in the U.S. population: NHANES 2005-2006. *Environ Health Perspect.* 2010;118(5):679–685.

1899, just a few years after they were first synthesized in the laboratory, a condition called chloracne (a painful skin disease) was noted in PCB production workers. In 1936, workers in a production plant also were affected by chloracne and liver disease, and some subsequently died. Animal studies showed that high doses of PCBs can cause liver damage. In the late 1960s, it was reported that PCBs were found at high concentrations in Baltic Sea animals, and, in 1968, a human population was accidently exposed to high levels of PCBs as a result of rice-oil contamination in Japan.[52] This was followed by studies showing that PCBs were found throughout the environment and were bioaccumulating in a variety of animals including fish. In 1972 Sweden banned the use of PCBs in situations where environmental contamination was likely. In the United States, Congress banned all manufacturing, processing, and distribution of PCBs in 1979. That same year there was another serious accident in which PCBs contaminated rice oil, this time in Taiwan (using the same manufacturing equipment that produced the accident in Japan).[53]

Until the 1990s, the general theory was that PCBs were toxic because they interact with the aryl hydrocarbon receptor (AhR),[54] thereby acting like dioxin. Of the 209 different PCB congeners, some are "dioxin-like", and some are not. This concept led to categorizing PCB mixtures in terms of their "toxic equivalence" (TEQ)[55]; that is, their ability to exert dioxin-like effects. However, in 1990, there was a report in nonhuman primates and in cell culture that nondioxin-like PCB congeners could affect dopamine levels in specific brain areas.[56]. This spawned research focused on congener-specific effects of PCBs on health outcomes including cognitive function. It is now well known that background exposure to PCBs in pregnant women is associated with lower IQ as well as other cognitive deficits in their offspring.[29] Moreover, these studies were done 20 years or more after the ban on PCB production, demonstrating that these environmentally persistent chemicals have long-lasting impacts on human health. Today the Food and Drug Administration (FDA) considers PCB contamination in food to be "unavoidable" and set limits in 2010 for PCBs in various foods. For example, the acceptable limit of total PCBs in milk or cheese is 1.5 mg/kg (fat, not volume).[57] Considering that the half-life of PCBs in the human body is measured in years,[58] these FDA limits do not appear to be health protective.

Different PCB congeners appear to interact with different systems to impact brain development. For example, some PCB congeners can be hydroxylated by the P450 enzyme CYP1A1 and interact with the thyroid hormone (TH) receptor.[59,60] There are other PCB congeners that can displace T4 from the serum transport protein, transthyretin.[61,62] Still others can activate liver enzymes that increase T4 clearance from serum.[63] Finally, some PCB congeners can interact with the ryanodine receptor, an important component of calcium signaling.[64]

Again, an important lesson is that early recognition of toxicity was related to very high exposures and acute symptoms including death. However, the assumption that toxicity was limited to high exposure levels was again mistaken, and this caused a delay in the recognition of more widespread toxicity. We now have very good mechanistic data demonstrating that specific PCB molecules (congeners) can directly interact with, for example, the thyroid system at low concentrations.[65] In addition, other PCB congeners can interact directly with the ryanodine receptor to influence intracellular calcium signaling at very low concentrations.[64] Both of these pathways are important for brain development and may well help explain much of PCB's effects on cognitive function.

The Lessons of Diethylstilbestrol (DES)

DES is a relatively potent nonsteroidal estrogen that was prescribed to pregnant women from the 1940s to the 1970s ostensibly to prevent miscarriages based on the belief that spontaneous abortion was the result of a decrease in estrogen levels (now shown to be a consequence, not a cause). DES was marketed using more than 200 names, and during that time tens of millions of women and their offspring worldwide were exposed to this drug. The first indication of a problem occurred when DES was linked to a rare form of vaginal cancer, vaginal clear cell adenocarcinoma, in a small number of young women exposed *in utero*.[66] It was subsequently shown to be associated with a number of reproductive problems in the DES-exposed daughters including increased uterine fibroids, endometriosis, breast cancer, miscarriage, preterm delivery, and ectopic pregnancies later in life, as well as reproductive tract malformations.[66] Moreover, data have demonstrated abnormalities in adult male offspring of women taking DES during pregnancy.[67–69]

A critical lesson from the DES experience—and one that could not have been gained without formal records of exposure and the astute perception of a physician—was that exposure to a synthetic estrogen during fetal development could increase the risk of various adverse effects in the adult offspring, decades after the chemical has disappeared from the body. We know from many population-based endocrine studies that developmental hormone exposure can have lifelong impacts. For example, serum T_4 levels at age 2 are associated with verbal IQ in adulthood.[70,71] Thus, the findings of DES exposure during fetal development are consistent with our understanding of the impacts of various hormones on development and the manifestation in adulthood of developmental endocrine interference. The effects of DES exposure shown in humans have been reproduced in animal studies; in fact, some effects were first observed in rodent studies and were then discovered in humans. Thus, DES is an example of an estrogenic agent that produces adverse effects in the human population. Not only do these studies demonstrate a proof of principle for developmental exposures to estrogenic compounds leading to birth defects, but they also demonstrate the temporal dissociation between exposure and manifestation of effects—the so-called "developmental origins of health and disease" (DOHaD).[72]

An important lesson common among the three examples is that the risk of adverse outcomes of chemical exposures was initially underestimated in each example. This is also a common feature in a broader analysis of human health effects of chemical exposures.[73,74] This failure to recognize the risk is due in part to a reliance on insensitive measures of chemical effects. In the case of lead and PCB exposures, there was reliance on measures of acute toxicity. In the example of DES, it was a reliance on measures of adverse outcome in the mother, not in the fetus. Therefore, as independent research progressed, more sensitive measures of adverse outcome were implemented. In the case of DES, the recognition that fetal exposure could lead to adverse outcome 20 years later was a novel and unexpected insight. These are not just lessons of academic interest but are chronicles of avoidable harm to fellow humans on a population level and over generations.

KEY POINTS

- We have highlighted the history of 3 chemicals that illustrate important features of EDCs: Lead, Polychlorinated Biphenyls (PCBs), and Diethylstilbestrol (DES). In each case, the risk to human health was dramatically underestimated because the outcome measures evaluated were insensitive. Generations of people have been damaged by these mistakes.

Windows of Susceptibility

Hormones are well known to produce effects on development during very specific developmental times ("windows"). For example, the "critical period" of TH action was initially viewed as the early postnatal period.[75] However, it is now recognized that there are different critical periods of TH action for different development events and cognitive domains.[76,77] Likewise, testosterone acts during specific times to affect male phenotypic development,[78] which is very different from the effects of testosterone in the adult.[79] Moreover, the effect of androgens in adulthood can depend on the action of testosterone during development.[80]

Considering this background of information about critical periods of hormone actions on different organ systems, it is not surprising that EDCs would be found to have different effects when exposures are studied at different life stages. Awareness of the developmental effects of chemical exposures has been heightened by studies of DES exposures (above) and of fetal alcohol exposure.[81] Focus on EDC action has been, for the most part, limited to specific windows of sensitivity including *in utero* exposures, neonatal exposures, and adult exposures. It is not clear what mechanisms account for a sensitive window of exposure to EDCs and thus how many sensitive time points there might be across the lifespan, largely because this issue is not well understood for hormones either. Nonetheless it is likely that preconception, preimplantation, early development, puberty, aging, as well as pregnancy itself are particularly sensitive times for the adverse effects of environmental exposures. Thus, it is clear that an approach is needed that includes not only a lifespan approach but also examination of effects across generations. There are now multiple examples of EDC effects that are heritable across not just one generation but also two, three, and four generations.[82,83] Thus exposures during pregnancy may lead to increased disease susceptibility that may last for generations.

Everyone is exposed across their lifespan starting with fertilization. Actual exposures depend on where one lives and one's lifestyle, such that exposures within and between chemicals can be quite variable. However, it is not just the level of exposures that are key to causing health concerns but perhaps more importantly when the exposure occurs. It is now absolutely clear that *in utero* and/or early in life, when tissues are forming, they are very sensitive to the adverse health effects of EDC exposures leading to an increase in noncommunicable diseases. There are two reasons for this sensitivity to the action of EDCs. First, development is a highly sensitive and orchestrated process controlled by hormones and growth factors. They act by controlling gene expression to stimulate the development of specific tissues. Thus, any EDC that interferes with endogenous hormone signaling will upset the normal control of gene expression leading to the development of a tissue that may "look" normal but that will not function normally. This phenomenon, first observed in the nutrition field, is now guiding research in the environmental chemical field and is called the DOHaD.[72] The second reason for this sensitivity to EDCs is that the enzymes that metabolize chemicals are not fully developed so the EDCs are active for longer than "normal times" along with a lack of DNA repair and a lack of blood/brain/organ barriers.[84] Because tissues develop at different times, the effects of EDCs on tissue development will depend on tissue specificity and timing of their development. Data in support of this DOHaD concept are sufficiently robust and repeatable across species to support incorporation into clinical practice.[85] The difficulty arises in that the exposure *in utero* may not result in increased disease until years or decades later, making it difficult to link the exposure to the disease. Thus, the clinical focus needs to be on reducing the risk of adult disease by limiting exposures before and during pregnancy and early childhood.

Exposures to EDCs occur across the lifespan. Adult exposures to EDCs can also cause health effects, but those effects typically remain only while the exposure exists; for example, the effects are reversible, and they may require higher concentrations due to the fact that the tissues are fully formed.

Integrating Mechanistic Information to Interpret Exposures and Health Outcomes

Mechanistic information from experiments using animal models or cell-based/biochemical studies provide important information to support epidemiologic data linking chemical exposures to human health outcomes at both the individual and population level. This body of research is highly multidisciplinary—from cell-free and cell-based experiments, to animal models across most vertebrate classes and some invertebrates, including the use of various genetic strains of animals. This of course requires high-quality research in these various domains and this level of information is not available for a large number of chemicals. A good example is BPA for which there are well over 1000 publiations.[86] Mechanistic research shows that exogenous chemicals can interact with biological systems much the way drugs do—by interacting with hormone receptors, biosynthetic enzyme systems, catabolic and metabolic pathways, and with various transport processes.[23] The regulation of hormone action is highly complex, and the consequences of interfering with hormone action are likewise highly complex. Mechanistic research since the mid-1990s has provided insight into the many ways in which chemicals can and do interfere with hormone action. We present here examples that provide some insight into these issues.

MECHANISMS OF EDC ACTIONS

Chemicals can interfere with hormones anywhere along the chain of events that control hormone action, from synthesis, release, and transport of the hormone to hormone effects on receptor function or on hormone degradation and elimination (metabolism).[34] In general, this means that chemicals can either interfere with the delivery of the hormone to and from its target tissues and cells or interfere with the action of the hormone on the receptor—or both. There are situations in which EDCs can interfere with the delivery of some hormones to specific target cells; in this case the effects are tissue-specific. Likewise, there are known cases in which EDCs must be metabolized before they can act on a hormone receptor, and this metabolism occurs only in certain tissues.[59,87] Thus, there are few rules about EDC actions that can be generalized to all cells and all organs of the body and all EDCs.

Hormone receptors have a high affinity for their natural ligand, but they often have a much lower affinity for endocrine disruptors—with some exceptions. However, it is important not to confuse *affinity* (ability to bind) for the receptor with *potency* (dose at which a given effect occurs) or *efficacy* (maximum effect). It is clear from clinical chemistry that differences in affinity do not always translate to differences in potency or efficacy. Recently, for example, it was shown that mutations in the gene coding for the estrogen receptor alpha (ESR1) that are associated with estrogen insensitivity in patients alter the effects of ligand binding without affecting affinity.[88] This can be true for exogenous ligands. For example, the endocrine disruptor BPA has the same potency as 17β-estradiol in pancreatic beta cells,[89] although its affinity for endoplasmic reticulum the estrogen receptor alpha (ERalpha) is much lower compared to that of 17β-estradiol. The way in which BPA exerts the same effect on the ER as the natural estrogen in one cell type is not known, but it should be emphasized that affinity measurements usually are made in completely artificial circumstances that do not reflect the environment of the cell. Moreover, these studies also emphasize that endocrine disruptors can act on a hormone receptor in one tissue type without affecting the receptor in another tissue type. Thus, just like the hormones they mimic or disrupt, the effects of endocrine disruptors will be receptor, tissue, and coregulator specific. Some endocrine disruptors actually have an affinity that is similar to or greater than that of the natural ligands. An example of this is tributyltin (TBT), which has an affinity for the nuclear proteins, Retinoid-X-Receptor (RXR) and Peroxisome Proliferator-Activated Receptor gamma (PPAR(gamma symbol)) in the low nanomolar range. Indeed, it is the most potent agonist known for these receptors.[90] See Table 137.2 for a list of examples of EDCs and how they interact with hormone systems.

DOSE-RESPONSE CHARACTERISTICS OF EDCS

A significant challenge in the area of EDCs is to understand fully the dose-response characteristics of EDCs on various elements of hormone action in a manner that provides useful insight into the potential for human health effects. Within this context, the concepts of *homeostasis* and *compensation* need to be considered carefully. The term "homeostasis" refers to the property of a dynamic system that maintains "internal constancy." The term "compensation" is related in that when a homeostatic system is perturbed, various elements within the system are activated or inhibited to compensate for the perturbation. For example, when glucose levels rise, insulin is secreted and glucagon secretion is inhibited such that glucose levels fall again. But homeostatic systems can reset in the face of chronic perturbation, as illustrated by baroreceptor resetting in the face of even short-term changes in mean arterial pressure.[91] Thus, in the face of chronic (lifetime) exposure to low doses of environmental chemicals, we need to be cautious about using the concepts of homeostasis and compensation when no studies have been designed to inform us about whether—or how—homeostatic endocrine systems may change in the face of these chronic exposures.

These issues are particularly important when considering the potential adverse effects of low-dose exposure to the fetus compared to the adult. Fetal development is a time when disruption of hormone action may not be reversible because early developmental events become the substrate for subsequent events (see "Windows of Susceptibility"). In addition, the fetus may have fewer homeostatic and compensatory mechanisms to ameliorate effects of EDCs. Finally, a variety of hormone receptors are much more abundant during development than in the adult, and this may also serve to make the fetus much more sensitive to chemical interference.[92] Thus, adults may be both less sensitive to EDC actions and more able to compensate—if homeostatic set points do not shift with chronic lifetime exposure.

Considering this, it is important to recognize that the field of "endocrine disruption" is focused on a novel area within the established fields of both endocrinology and toxicology, and the dose-response characteristics observed in short-term, high-dose toxicity studies may bear little resemblance to the dose-response characteristics in real life. Moreover, because endogenous hormones exhibit nonlinear dose responses, it is expected that environmental chemicals interacting with hormone systems will also exhibit nonlinear responses. These nonlinear dose responses can take several forms.[13] In its simplest form, because hormones act on receptors, which are limited in number, the response itself is "saturable." That means that there is a dose of hormone—or endocrine disruptor—beyond which there is no further response on a measured outcome. Hormones and EDCs can also produce nonmonotonic dose responses. Technically, the term "nonmonotonic" simply means that the slope of the curve changes sign (positive to negative or vice versa) over the dose-response range.[93] For example, when fetal mice are exposed to low or high doses of DES, a synthetic estrogen, their adult prostate weights are relatively low. However, intermediate doses of DES produced significantly heavier prostates.[94] Research also suggests that nonmonotonic responses can be extended to the population level. For example, individuals in the highest quartile of environmental exposure to 1,1-Dichloro-2,2-Bis(p-Chlorophenyl) Ethylene (DDE) (an estrogenic Dichlorodiphenyltrichloroethane [DDT] metabolite) have decreased body mass index (BMI) and blood triglyceride levels compared to individuals in the third quartile.[95] Moreover, women exposed to the lowest and highest doses of dioxin had no changes to the age at which they entered menopause, whereas those women exposed to intermediate doses showed an increased risk of early menopause.[96] Finally, low or high free T4 in first trimester women were both associated with IQ deficits in the offspring.[97] The mechanisms underlying these effects have not always been defined, but it is important to recognize that these dose-response characteristics are fully within the realm of our understanding of hormone action and endocrine disruption.[93]

Chemical Exposures in the Human Population

If the human population is being affected by exposures to EDCs, then those exposures must be sufficient in abundance and timing to impact human health outcomes. The CDC manages a biomonitoring program in part to characterize human exposures to environmental chemicals in a nationally representative manner. The fourth national report on human exposures to environmental chemicals was published in 2009,[98] and this information is updated regularly on the CDC website (http://www.cdc.gov/exposurereport/). Although the fourth national report makes it clear that the presence of a chemical in the human population does not mean that it causes disease, it is also clear that the US population is simultaneously exposed to a large number of chemicals with a wide range of chemistries and biological actions, and that most of these chemicals are not tested for safety. This is true for the general population as well as for subgroups that might be expected to be particularly vulnerable, including pregnant women[35] and newborns, and people living near areas of intense pollution. In fact, in a 2005 study of cord blood samples, nearly 300 chemicals were identified, with each cord blood sample containing at a minimum more than 100 different chemicals.[99] This means that babies are born pre-polluted, and it is likely that some of those exposures will cause adverse effects that could lead to increased sensitivity or susceptibility to disease later in life. Thus, the human population is exposed to a great many environmental chemicals throughout the life cycle, and most of these chemicals are not tested for safety.

It should also be noted that the chemicals included in the NHANES biomonitoring program are only a subset of chemicals to which the human population is exposed. The reason for this is that analytical methods for identifying chemicals are not available for the large number of chemicals licensed for commerce (more than 70,000), or even the several thousand high-production volume chemicals. In addition, there are estimated to be about 10,000 synthetic chemicals approved as food additives, the majority of which include little or no toxicity data.[100] Thus, we do not know the complete picture about human exposures to anthropogenic chemicals, which increases the difficulty in linking exposures to human health. Nonetheless, it remains important to know that everyone is exposed to uncharacterized chemicals throughout his or her lifespan.

An important lesson that is reflected in the experience of lead toxicity, PCBs, and DES is that ambient low-dose exposure and/or exposures during critical periods of development can produce adverse effects that go unnoticed without considerable and costly study. Furthermore, these adverse effects can be predicted and mechanistically understood by experimental studies in animals as well as cell-free and cell-based biochemical and molecular studies. Therefore, considering this large and largely unregulated chemical exposure pattern, studies designed to identify relationships between chemical exposure and human health outcomes particularly need to be incorporated into a logical framework quickly so that the findings can reliably inform patient care and public health policy.[101]

KEY POINTS

- The human population is heavily contaminated with industrial chemicals, many of which have not been tested for health effects and very few of which have been tested for activities other than acute toxicity. In fact, chemical measurements of cord blood demonstrate that babies are born pre-polluted with at least one hundred known chemicals.
- Regulatory agencies have not evolved to test the ability of chemicals to interact with endocrine systems, nor to test the ability of chemicals to produce chronic disease.
- EDCs can produce effects in animal studies at concentrations consistent with human exposures and with concentration-response characteristics that do not fit the regulatory assumption that the "dose makes the poison."

ENDOCRINE SYSTEMS: DISEASE TRENDS AND EFFECTS OF EDCs

This section focuses on the state of the science linking EDC exposures to human disease. There are a number of lessons that we have learned from this work, which should be considered when reviewing data from human health studies. These are highlighted as follows:

- Outcome measures linked to EDC exposures in humans occur at exposure concentrations lower—often considerably lower—than predictions based on regulatory studies.
- EDC effects in the human population depend on genetic background creating a heterogeneity in responses that require large population studies using a genomic and statistical approach.
- EDC effects are almost certainly the result of mixtures of EDCs, as that is what humans are exposed to, and also are a result of low environmentally relevant concentrations that are difficult to measure that require highly sensitive assays of mixtures.
- The effects will be a result of "multiple hits" across the lifespan with the most sensitive exposure window during development (*in utero* and early life), which will require a lifespan approach.
- EDC effects may occur after a long latent period including effects transmitted across multiple generations (transgenerational), requiring long-term prospective studies.
- Effects will vary depending on other environmental stressors: medications, stress, socioeconomic status, infections, and microbiome, which will require the analysis of confounders.
- Effects can vary according to sex, tissue, dose, and route of exposure. Indeed, effects noted at high doses may be different from those at lower doses.
- Epidemiological studies identify potentially avoidable risks to individual health much like smoking, drinking and dietary choices. This can be applied to adults as well as pregnant women and children.

Disease Trends and Effects of EDCs

Temporal trends in the incidence and prevalence of disease in the human population can provide circumstantial evidence for a causal relationship between chemical exposure and human disease.[13] Although these trends do not constitute proof of causation, they are important elements of the evidence. Chronic disease has increased during the past 50 years and is now more prevalent than infectious disease worldwide, with the exception of COVID-19.[102] Public agencies around the world have invested heavily in research on EDCs in large part because the human population manifests increased chronic diseases such as obesity, diabetes, infertility, and certain cancers.[103,104] increased incidence of anomalies of male reproductive development[105] and various aspects of fertility. In addition, there are also clear increases in the incidence and prevalence of neurobehavioral disorders including attention deficit (AD),[106] autistic spectrum (ASD),[107] and measures of cognitive function. One of the most visible changes in the human population is the increased incidence and prevalence of obesity,[108] especially in the pediatric population,[109] with attendant increases in type 2 diabetes and heart disease. The incidence of some cancers is also increasing, including cancers of the brain, breast, male and female reproductive tract, and thyroid.[110,111] A disease trend that is increasing during just a few decades and that cannot be accounted for by changes in diagnostic criteria is important evidence for a role of environment in disease because genetic drift does not occur during such a short time frame. EDCs play an important role in the etiology of such disease trends.

The Endocrine Society's Second Statement on EDCs,[23] which provides an overview of the effects of EDCs on many of the most prevalent human diseases in 2015 along with a shortened executive summary.[112] This review states, "The Endocrine Society's first Scientific Statement in 2009 provided a wake-up call to the scientific community about how environmental EDCs affect health and disease. Five years later, a substantially larger body of literature has solidified our understanding of plausible mechanisms underlying EDC actions and how exposures in animals and humans—especially during development—may lay the foundations for disease later in life".

Obesity. The prevalence of obesity has increased dramatically both in the United States and in many countries worldwide since the mid-1990s[13] such that there are currently more than one billion overweight adults, with 400 million being classified as obese; 20 millions of these are children. Obesity is an intractable problem in that nearly 90% of those who lose weight gain it back within a year.[113] Obesity is a complex endocrine condition caused by an interaction between genetics and environment with the environmental component consisting of nutrition, drugs, behavior and some EDCs. Conventional wisdom posits that obesity is an energy-balance disorder resulting from excess calories and decreased exercise. However, both the increased incidence during the past few decades and data showing that only a subset of people become obese suggest that there is more to obesity than this simple explanation. Moreover, the incidence of obesity among infants is also increasing, which would appear to counter the energy-balance hypothesis. Hormones such as estrogens, androgens, glucocorticoids, insulin, and thyroid hormones play important roles in controlling adipose tissue development, metabolism and satiety, and body-weight regulation is also sensitive to environmental chemicals and drugs that can affect these hormonal pathways. Indeed, some drugs include a side effect of increasing weight gain, such as some antipsychotics[114] and antidiabetic drugs such as Avandia.[115] The fact that there are drugs with side effects of weight gain provides proof of the principle that the endocrine systems controlling weight gain and metabolism are sensitive to perturbation.

Events occurring in early life—during pregnancy and early childhood—may increase the risk of obesity.[116] There are considerable data linking altered development to increased susceptibility to disease later in life including obesity (DOHaD). Although the initial focus of these studies was on altered nutrition during development, it is now clear that there also are EDCs that can cause altered developmental programming, likely because of altered epigenetic regulation of gene expression, potentially leading to weight gain later in life. These EDCs have been called obesogens.[117] It is key to note that exposures to obesogens during development can permanently alter programming of the system regulating body weight, producing an altered "set point" for adipose tissue formation, regulation of satiety, and metabolic rate that persists throughout life. Tributyl Tin, for example, induces an increase in fat cell number and these fat cells are abnormal in their response to hormones including impaired glucose uptake and insulin signaling.[118] In fact, even after body weight reduction, there are long-term changes in a profile of hormones that support obesity.[119] In addition, EDC exposure can trigger changes in the hypothalamus that play a particularly important role in feeding behaviors. Improper hypothalamic programming may adjust metabolic "set points" in adolescents and adults, and these adjustments may help explain differences between the eating behaviors of lean and obese individuals.[120] Thus, the obesogen hypothesis offers an explanation for both the increase in obesity rates and also the differences between lean and obese individuals.

The obesogen hypothesis was developed in the early 2000s in response to the startling rise in the incidence and prevalence of obesity in the human population, especially in children.[121] Although a relatively new field of study, there is now strong evidence in experimental animals showing that developmental exposure to a variety of environmental chemicals, including those that activate PPARγ such as TBT, and estrogenic chemicals such as BPA, some organochlorine and organophosphate pesticides, and chemicals acting through other mechanisms such as elements of air pollution, lead, perfluoroctanoic acid, phthalates, and nicotine, can lead to weight gain later in life.[13] There are now about 50 chemicals and chemical classes classified as obesogens.[122] These animal studies provide significant evidence for a role of EDCs in affecting specific elements of body weight regulation, including appetitive behavior and metabolism. An important example is that of TBT, which is a potent activator of the nuclear receptor PPARγ, a key receptor involved in the development of new adipocytes.

Human studies are more difficult to perform and interpret in part because humans are exposed to complex chemical mixtures and are more genetically variable as well as variable in their environmental conditions.[123] Nonetheless, animal studies have produced data that are concordant with epidemiological data linking exposures to obesogens during development to increased body weight in infants and later in life. Some of the strongest associations between exposures during pregnancy and obesity in their offspring include smoking, BPA, persistent organic pollutants, DDT/DDE, per- and polyfluoroalkyl substances (PFAS), and air pollution.[120]

It has been proposed that the confluence of developmental programming of metabolic set points by obesogens in association with continued obesogen exposures throughout the lifetime, overconsumption of processed foods containing added sugars, and EDCs from the packaging materials, together with decreased physical activity throughout life, creates an important combination that is driving the obesity epidemic.[124,125]

The obesogen hypothesis proposes both a mechanism for the increased epidemic of obesity and also a solution. If obesity results in part from continuous exposures to obesogens from development and later, then for the first time there is actually a path for individuals and for physicians to reducing the risk of obesity by reducing these exposures. Thus, rather than waiting for obesity to occur and trying with poor success to intervene and cause weight loss, we may be able to reduce the risk of overweight and obesity from the beginning.

Diabetes. Type 2 diabetes—especially in the pediatric population—is becoming recognized as a global epidemic.[126] Diabetes has increased dramatically since the mid-1990s to 347 million in 2011.[13] And, parallel to the incidence of obesity, there has been a significant increase in childhood type 2 diabetes, something that was rare just a few decades ago. Although type 2 diabetes can occur by itself, 70% of the risk associated with it is attributed to weight gain, indicative of the direct link between increased adiposity and insulin resistance. In animal studies, many chemicals that cause weight gain also disrupt glucose management. EDCs including phthalates, BPA, some flame retardants, arsenic, some persistent organic pollutants such as PCBs, and pesticides have been linked to the development of type 2 diabetes in both animal studies and in human epidemiologic studies.[120,127] Overall, there are significant data in both animal and human studies that support concern about the relationship between chemical exposures and the production of type 2 diabetes. In contrast, there is little information about the link between EDC exposures and type 1 diabetes. However, there are environmental chemicals that exhibit both EDC activity and immunotoxicity, which would be prime candidates for EDC effects on this hormonally and immune-mediated, largely childhood, disease.

Endocrine Disruptors, the Epigenome, and Developmental and Transgenerational Effects

Parents pass on their genes to their children and in so doing pass on various traits associated with those genes. The combination of all genes in a species is referred to as the "genome," and "genomic" studies refer to those studies designed to understand how various patterns of genes are controlled; but cells in the body can pass on heritable traits to their cellular progeny without altering their genome. Certainly, EDCs can also act across the lifespan just as hormones do. However, there is a major difference in effects noted after developmental exposures vs adult exposures.

The ability of endocrine disruptors to alter the normal hormonal control of development is perhaps the most significant consequence of exposure, because developmental effects will occur at lower doses than are required for effects in adults. Additionally, the effects of exposure to endocrine disruptors during development will remain throughout life and may have a long latency between exposure and disease outcomes; whereas, in many cases, exposures in adults remain only while the chemical is present. These differences in sensitivity to EDCs and persistence of effects are related to the epigenetic state of the organism.

During development, a single cell—the ovum—will divide, multiply, and differentiate into many cell types and tissues and ultimately will become a person. Development from this perspective is a process of "fate restriction"—permanently turning on or turning off different combinations of genes required for a cell to be a functional cell in the liver, kidney, brain, etc. The traits a cell passes on to its cellular progeny are controlled by "epigenetic" mechanisms. Epigenetics is broadly defined as those heritable changes not dependent on genetic sequences, and it is these epigenetic processes that define and control tissue development by controlling gene expression. Thus, a major route by which hormones act during development is by changing the epigenome and the combination of genes that can or cannot be expressed. The fact that endocrine disruptors can influence epigenomic mechanisms during the times when tissues are forming is likely the mechanism whereby development (*in utero* and early childhood, when tissues are developing) is a sensitive window for EDC action. It is also the reason that developmental exposure leads to effects long after the exposure is gone and may occur after a long latent period across the lifespan. In adults, the tissues are already formed, and the epigenetic marks are relatively stable; thus, EDCs may not act on the epigenome but may act directly on genomic pathways—effects that are more easily reversible when exposure is controlled.

Endocrine disruptors have also been shown to produce transgenerational effects as a result of their ability to alter epigenetic processes. This issue first arose with studies in which an antiandrogenic pesticide (vinclozolin) was administered to developing mice at a single time during development—when the testis was in a critical period of development. Not only did vinclozolin produce adverse effects on the developing testis, but also this was transmitted through four generations of mice. This effect is likely caused by epigenetic changes that were transmitted with high fidelity from one generation to the next via the germ cells (sperm). A number of endocrine disruptors have now been shown to influence epigenetic mechanisms and to produce effects in several generations of animals.[129] Grandmother exposures may be affecting the F2 and subsequent generations.

Reproductive System. Because the reproductive system was an early focus of studies on chemical toxicities in the 1930s and 1940s, it should be no surprise that there is abundant literature on EDCs that interfere with estrogen or androgen actions. In addition, the field of reproductive endocrinology has significantly matured both in terms of our understanding of the medicinal chemistry associated with estrogen and androgen receptors (ARs), but also in terms of the role of sex steroids in development, in puberty, and in the adult. Thus, there is a significant amount of information now about environmental chemicals and different aspects of reproduction, as discussed in the following text.

Male Reproduction. One of the most significant concepts in this field is that of the testicular dysgenesis syndrome (TDS).[130] Skakkebaek et al. proposed that poor semen quality, testis cancer, undescended testis, and hypospadias are symptoms of one underlying entity caused by defects in androgen action during fetal development. One of the most compelling observations in support of this hypothesis is a report of a novel AR mutation in a family that exhibits all of the hallmark characteristics of the TDS.[131] This mutation (c.2214T>G;p.il3738Met) produces an AR protein with only 50% of the transcriptional potency of the wild-type protein, suggesting that a 50% reduction in androgen action can produce all of the elements of TDS. However, the implication is that a reduction in AR action for any reason may also contribute to TDS. Importantly, each of these symptoms is increasing in incidence and prevalence, suggesting an environmental component.[132] In addition, a number of EDCs to which the human population is chronically exposed have antiandrogenic actions, including phthalates, BPA, and some pesticides.[133,134] In addition, evidence generated from controlled animal studies indicates that males exposed to estrogens and antiandrogens develop hypospadias, undescended testis, and low sperm counts.[130] Given the number of estrogenic and antiandrogenic chemicals to which the human population is chronically exposed, it is reasonable to posit that there is a significant contribution of EDCs to the increased incidence of TDS symptoms. These are described as follows.

Sperm Counts and Fertility. Infertility, as defined by the inability to conceive after frequent and unprotected sexual intercourse for 12 months, currently affects 15% of couples worldwide.[135] There has been a significant effort to associate infertility to sperm counts, and to further associate sperm counts to environmental stressors including EDCs. Since the mid-1990s, there has been a growing recognition that sperm count and sperm quality are declining in humans across the globe. The first report of this decline was published in 1992,[136] and since then the original data have been reanalyzed and confirmed. Although there was early and reasonable skepticism about these observations and conclusions, new prospective data have been added on a regional basis, which also demonstrate declines in sperm counts that vary by geographic location. At this time, there is general scientific consensus that sperm counts have declined throughout the past 50 years in the human population, and that there are likely to be both genetic and environmental contributors to this decline. A causal link between exposures to EDCs, especially those that act via the AR or those that decrease testosterone production, and sperm counts and fertility is plausible, and there is evidence that several pesticides as well as polybrominated diphenyl ethers are involved. It is possible that adult sperm production is sensitive to current environmental exposures because it is an ongoing process. However, it also appears that adult sperm counts are sensitive to developmental programming, especially to EDCs with antiandrogenic properties like phthalates. Phthalates can reduce serum androgens in rodents and have been linked to reduced anogenital distance in humans, a marker of fetal testosterone levels.[137] In animal models, there are strong and consistent data showing effects of EDCs, including BPA, vinclozolin, dioxin, and phthalates, on several aspects of male reproduction, including sperm counts. Indeed, all these chemicals also cause reduced sperm counts and fertility across four generations, indicating transgenerational effects in animal models.[138] These new data are significant, as they suggest that exposures during pregnancy may lead to toxic effects in grandchildren and great-grandchildren. Because of the lifelong sensitivity of sperm production to EDCs, along with the fact that there are hundreds of EDCs with varying exposures throughout the lifespan, it will be difficult to ferret out the exact contribution of individual EDC exposures to sperm counts and fertility. Nonetheless, data support a role for EDCs impacting both sperm counts and fertility and possibly the secular decline in these measures globally.

Hypospadias and Cryptorchidism. Normal differentiation and growth of the male external genitalia require normal androgen production and an adequate tissue response to the hormone. Hypospadias can be defined as a consequence of the abnormal development of urethral spongiosum tissue, with a defect of the ventral aspect of the prepuce and the skin of the distal shaft. There are many anatomic variants exhibited; minor forms are characterized by an ectopic urethral opening on the glans penis or more proximally, whereas the more severe forms present a proximal urethral opening even at the perineum. The different forms of hypospadias may represent phenotypes that are linked to different risk factors,[139] and this heterogeneity may be important in identifying specific causes.

The incidence of male urogenital abnormalities has increased during the past few decades.[13] Early estimates of hypospadias incidence may have been underreported in some countries, depending on the way the data were gathered. However, in the case of the more severe proximal phenotype, where surgical correction is required, the reporting metrics have not changed, and incidence has clearly increased in the United States, Australia, and many European countries.[132] There is increasing circumstantial evidence that at least some forms of hypospadias and other TDS symptoms are caused by environmental factors. One thread of evidence for this is that idiopathic partial androgen insensitivity syndrome can produce symptoms of TDS including hypospadias,[140] even in cases where the androgen system appears to be working normally. Despite this, there is no clear relationship between hypospadias and individual EDCs. Given the heterogeneous nature of hypospadias and the large mixture of chemicals known to produce this defect in animals, including those chemicals to which humans are exposed, it should be expected that relationships of interest will be difficult to identify.

Like hypospadias, cryptorchidism presents with different degrees of severity, from palpable undescended testes to abdominal testes that are not palpable. Epidemiologic studies with well-defined criteria for identifying the incidence of cryptorchidism have shown very large differences in the incidence between countries and increasing trends in Denmark and the United Kingdom.[132] Genetic associations with the presence of cryptorchidism do not account for a large proportion of cases.[141] In addition, genetic mouse models have shown important mechanisms of male genital development and provide insight into the mechanisms by which cryptorchidism and hypospadias may be triggered. Normal androgen action and tissue response are essential for penile development and testicular descent. However, estrogens can interfere with normal male genital development by downregulating insulin-like factor 3 and stimulating ATF3, leading to cryptorchidism and hypospadias, respectively. Therefore, endocrine disruptors that alter the estrogen-androgen ratio or act as hormone mimics (agonists or antagonists) can cause maldevelopment in animals, which is highly plausible in humans. Interestingly, BPA exposure is associated with poor outcomes in in vitro fertilization.[142]

Female Reproduction. Conception rates in both Danish and US women have declined 44% since 1960.[143] There are limited prevalence data on women's environmental health diseases including menstrual cyclicity, pubertal development, endometriosis, uterine fibroids, or polycystic ovarian syndrome (PCOS); however, it is clear that these diseases are common. Indeed, PCOS is the most common endocrine disorder in women of reproductive age, although, because the definition of PCOS is still under debate, diagnosis is variable and actual prevalence is unclear, which results in an estimated occurrence between 3% and 15% depending on criteria used (see Chapter 126).[144]

Uterine fibroids (leiomyomas) are common with estimates that they occur in 25% to 50% of all women; however, the effects of EDCs have not been examined in detail for possible impact on these diseases.[145] Interestingly, the incidence of endometriosis is thought to be in the range of 10% to 15% for reproductive-age women (see Chapter 127).[146]

As noted earlier, studies of DES in humans and animals establish the principle that estrogenic EDC exposure during development can produce adverse effects on women's reproductive health. In addition, data from animals models consistently show that developmental or adult exposure to some EDCs including organochlorine pesticides, heavy metals, phthalates, BPA, and dioxin can alter ovarian development including follicle formation, follicle growth, and disruption of steroid hormone levels.[147] Studies in humans show that adult exposure to some of these EDCs is associated with increased risk of miscarriage, time to pregnancy and reduced size for gestational age.[147] For example, BPA has been associated with infertility, shortened gestation, and increased preterm birth in women. These observations are concordant with those in animals showing that BPA affects the morphology and function of the oviduct, ovary, and hypothalamic-pituitary-ovarian axis.[148]

Puberty. Puberty is a complex physiological process involving central activation of the hypothalamic-pituitary-gonad axis. Two hundred years ago, the average age of puberty was around 17 years old, and this declined and stabilized in the 1950s at about 13 years of age.[149,150] However, the age of puberty has declined again during the past few decades; in girls, the average age of pubertal onset is 10 years, and in boys it is around 11.5 years.[151] Improved nutrition is reasonably proposed to contribute to these changes, especially as the average BMI has increased and the relationship between BMI, leptin, and puberty onset is well known (see Chapter 104). However, the incidence of precocious puberty in girls less than 8 years old has increased in general and is geographically variable, indicating that environmental factors can affect both the average age of puberty onset and the incidence of precocious puberty.[152] There are multiple reports that focus on a role of EDCs as an explanation for early puberty.[153]

Because of the role of sex steroids in the onset of puberty, it is reasonable to propose that exposures to a variety of EDCs during development or early life may contribute to the earlier onset of puberty.[154] There is convincing evidence from animal studies that prenatal and/or neonatal treatment with EDCs that act via the estrogen receptor can accelerate pubertal development in females, whereas estrogenic chemicals tend to delay puberty onset in males. EDCs acting by other mechanisms, which are shown to have effects in some animal studies, include lead, styrene, methoxychlor, phthalates, and BPA. Indeed, the data linking estrogenic EDCs to early puberty in animal models are strong. There are some epidemiologic studies linking exposures to EDCs (DDT/DDE, dioxins, PCBs, PBBs, some flame retardants, hexachlorobenzene, BPA, lead, and cadmium);[155] however, overall epidemiologic evidence for a role of EDCs in early puberty is still limited.[156] The importance of changes in puberty is partly a result of the effects of puberty on other health outcomes where early puberty is associated with reproductive tract cancers, depression and eating disorders, diabetes, and cardiovascular disease.[153] Note also that obesogens can increase weight leading to an increase in leptin and puberty advance,[157] and that early puberty is a risk factor for breast cancer.[158]

Endometriosis. Endometriosis is an estrogen-dependent disorder, but the exact etiology is unclear. The strongest data linking EDCs to endometriosis are those of dioxin causing endometriosis in primates,[150] which is supported by experiments in rodents. Although the mechanism for the dioxin effects on endometriosis is unclear, there are data showing that dioxin decreases circulating estradiol and also causes its degradation, and that dioxin reduces the expression of the progesterone receptor[159] as well as acting as an immunosuppressant.

Because of the role of the sex steroids in reproduction, it is biologically plausible that EDCs that mimic or antagonize sex steroids will play a role in the multicausality for female reproductive disorders.[160]

KEY POINTS

- Secular trends in chronic human disease and disorders represent evidence of the impact of EDC exposures on human health in part because these outcomes are endocrine in nature.
- Obesity and diabetes are epidemic in the United States and the world and evidence indicates that a variety of chemicals contribute to these human health problems.
- Infertility and male and female reproductive disorders represent significant human health issues today that are being exacerbated by chemical exposures.

Cancer

A large amount of research during the past several decades has established the involvement of endogenous estrogens and androgens in cancers of reproductive organs and the thyroid.[161] However, the possible contribution of environmental chemicals that interact with these hormone systems has only recently received attention for two primary reasons. First, cancers of the breast, endometrium, ovary, testis, prostate, and thyroid glands continue to rise among populations of Western countries, and more recently also among Asian nations. Second, the involvement of the synthetic estrogen, DES, in vaginal cancers and breast cancer has heightened concerns that a multitude of other hormonally active chemicals in everyday use can cause or increase the risk of these diseases. Most research into associations with endocrine disruptors has been performed with breast, prostate, and testis cancers, whereas other hormone-related cancers such as endometrial, ovarian, and thyroid cancers have received less attention.

Breast cancer is the most common endocrine cancer and is the second leading cause of cancer death. Its incidence has increased since the mid-1980s in almost all environmentalized/ Westernized countries[13] (see also Chapter 128). The genetic and metabolic aspects of breast cancer are responsible for up to 27% of breast cancer, with the other 70% or more related to environmental factors.[162] It is clear that excess estrogen across the lifespan is an important risk factor for breast cancer. Thus, there is an increased risk of breast cancer among current and recent users of oral contraceptives.[163] This has manifested in the effects on increasing breast cancer in offspring of mothers exposed to DES, the effects of hormone replacement therapy on increased breast cancer incidence, and the association of early puberty or increasing age of first pregnancy with increased breast cancer.

It is also clear that the development period is a sensitive time for EDCs to affect breast development, and effects can lead to cancer or precancerous lesions later in life. However, in contrast to most tissues, the breast continues developing until adulthood and even changes slightly with each menstrual cycle.

Polycyclic aromatic hydrocarbons are a class of chemicals that have both genotoxic/mutagenic properties as well as endocrine properties. Other EDCs that alter mammary gland development in animal models by affecting the organization of the tissue include BPA, dioxin, PFOA, the fungicide vincolozolin, polybrominated diphenyl ether (PBDE), nonophenol, and atrazine.[164] Genistein, a plant estrogen found in soy products, can protect against carcinogen-induced mammary gland tumors in some animal studies, canceling out the protective effect of tamoxifen in others, and can actually cause ductal hyperplasia in others depending on the timing and dose. Clearly, assessing the role of EDCs in breast cancer will remain highly complex.

For decades environmental health scientists studied the potential link between adult exposures to a variety of EDCs to breast cancer, but the results were inconsistent. After the animal data showed the importance of developmental exposures in increasing susceptibility to mammary cancer in animals, epidemiologists started to examine developmental exposures and breast cancer. However, because of the long latency to develop cancer, these studies are expensive and time consuming, requiring assessment of developmental exposures and follow-up for 4 to 5 decades to assess the incidence of breast cancer. A classic study examined exposure to DDT and its metabolites during childhood and throughout life and showed that there was no association of exposures in adults with breast cancer but a high correlation of exposure around puberty with adult-onset breast cancer.[165] This study provided the data that focused epidemiological studies on the *in utero* and childhood exposures as the sensitive window of exposure leading to increased susceptibility to breast cancer later in life.

Overall, the growing literature linking developmental exposure to EDCs and later development of breast cancer is particularly strong.[164] Singly and in combination, these EDCs—many of which are present in everyday products—may be contributing significantly to the public health burden of breast cancer. Thus, it is important to prioritize strategies to reduce risk in addition to improving breast cancer therapies.

Thyroid Disruption

TH plays an important role in development and adult physiology.[166] Therefore, it is important to recognize that there are a large number of chemicals that can interfere with thyroid function[167,168] and/or with TH action.[169] These different kinds of chemicals may interact to affect TH action during development. For example, perchlorate can reduce iodide uptake and in the face of low dietary iodine can affect thyroid function and TH levels.[170] In addition, a large number of chemicals can increase the clearance rate of TH, similar to that of phenobarbital.[171] Some chemicals also appear to interact directly with receptors for TH[172,173] and may produce effects that are not fully consistent with hypo- or hyperthyroidism.[174] Finally, there are chemicals that can displace THs from serum transport proteins,[175] and others that may interfere with cellular transport proteins such as MCT8 or OATP1c1, although this is less well-studied. However, because epidemiologic studies investigating the relationship between chemical exposure and the thyroid uniformly evaluate serum hormone levels, it will be a challenge to link exposure to the combination of chemicals that can impact thyroid function and TH action to human disease. The neurobehavioral impacts of TH insufficiency are so well known that it is reasonable to consider the possibility that environmental chemicals may play a role in the increased incidence and prevalence of neurobehavioral disorders. This may best be apparent for PCBs.[29] Likewise, environmental chemical interference with TH action may contribute to adult diseases including cardiovascular, obesity, and metabolic syndrome. These relationships are much less well understood. Given the variability in clinical manifestations of thyroid disease in adults, this will be a challenging topic.

Neurobehavior

Neurodevelopmental disorders have increased in prevalence during the past several decades, and the environment is likely to play a role.[176–178] Since the 1970s, there have been dramatic increases in previously rare neurodevelopmental disorders. For example, in the 1970s the prevalence of autism spectrum disorders (ASD) was estimated to be between 4 and 5 in 10,000 children,[179] but today this value is estimated to be 1 in 54 children.[180] There is significant debate about the role of broadening definitions of ASD related to this increase[181] or the role of other factors that may mask a real increase.[182] Similar trends have been observed for other neurobehavioral problems such as ADHD (attention-deficit hyperactivity disorder), learning disabilities, and childhood and adult depressive disorders. Predominant among these disorders are attention-deficit disorders (ADDs)—with or without hyperactivity—with a worldwide, pooled prevalence estimate of about 5.3%.[106] These are difficult trends to attribute unequivocally to the environment, although it appears clear that the increases are not fully attributable to artifacts related to more aggressive diagnosis and reporting and may involve genetic susceptibility.

KEY POINTS

- Secular trends in the incidence of some cancers (e.g., pediatric brain cancer), neurobehavioral disorders and thyroid dysfunction represent additional impacts of EDCs on the human population.
- In each case, scientific evidence from mechanistic studies support conclusions that associations between chemical exposures and these disease trends are causal. Moreover, these population studies represent evidence that can be employed in the clinic.

EMERGING ISSUES

Endocrine Disruptors, the Epigenome, and Transgenerational Effects

Parents pass on their genes to their children, and in so doing pass on various traits associated with those genes. The combination of all genes in a species is referred to as the "genome," and "genomic" studies refer to those studies designed to understand how various patterns of genes are controlled. But, cells in the body can pass on heritable traits to their cellular progeny without altering their genome. Certainly, EDCs can also act across the lifespan just as hormones do.

Epigenetics is broadly defined as heritable changes not dependent on genetic sequences, and it is these epigenetic processes that define and control tissue development by controlling gene expression. Endocrine disruptors have also been shown to produce transgenerational effects as a result of their ability to alter epigenetic processes. This issue first arose with studies in which an antiandrogenic pesticide (vinclozolin) was administered to developing mice at a single time during development—when the testis was in a critical period of development. Not only did vinclozolin produce adverse effects on the developing testis, but also this was transmitted through four generations of mice.[128] This effect is likely to be caused by epigenetic changes that were transmitted with high fidelity from one generation to the next via the germ cells (sperm). A number of endocrine disruptors have now been shown to influence epigenetic mechanisms and to produce effects in several generations of animals.[129] Grandmother exposures may be affecting the F2 and subsequent generations. Notably, in a mouse model, deleterious effects of EDCs are corrected in the mammalian germline by epigenomic reprogramming.[183] These deeply concerning and contradictory observations in animal studies with profound implications for the human population warrant further study.

Increasing Exposures Worldwide

There are no longer pristine areas worldwide without environmental pollutants.184 EDCs are everywhere; they are present in food, nature, and humans, and there is global transport through ocean, air currents, plants, and animals. Indeed, the Faroe Islands, off the coast of Iceland and Norway, which because of its isolated location should be one of the most pristine places in the world, has a human population that is severely affected by EDCs via the eating of contaminated whale blubber and meat.

Expanded List of Diseases Related to EDCs

Until recently, the focus of EDC research was on chemicals that affected the estrogen, androgen, and thyroid pathways, and diseases that result from their disruption. Endocrine disruption is no longer limited to these pathways, as chemicals have also been shown to interfere with metabolism, fat storage, bone development, glucose homeostasis, glucocorticoid regulatory pathways, and immune systems.[184] It is possible that all the endocrine systems will be impacted by environmental chemicals. Indeed, even the known EDCs may not be representative of the full range of relevant structures and properties of chemicals that may have endocrine-disrupting properties. Because only a limited number of chemicals in commerce have been tested for endocrine-disrupting activity, it is likely that there are many more chemicals with endocrine-disrupting activity than currently believed. In addition, metabolites or environmental transformation products and products formed during waste treatment are usually not examined for endocrine-disrupting activity. Thus, research is needed to identify other EDCs.

Mixtures

The focus of research identifying and characterizing the effects of EDC in animal models and in human populations has been on linking exposure to a single chemical at a single exposure leading to a single disease. However, humans are exposed to mixtures of chemicals throughout their lifetimes, and indeed each chemical has the potential to affect several endocrine diseases. DES is a good example of one exposure leading to many sequelae. A developmental "estrogenization syndrome" has been proposed.[96] In addition, it is now clear that exposures to many chemicals at low levels that individually have no effect can actually produce significant effects because of the additivity of their individual effects.[134] Although mixture studies are difficult to develop in animals and are expensive and complicated to interpret statistically in human studies, there is an urgent need to expand research into the effects of mixtures of EDCs both during development and across the lifespan.

E-Waste

Modern society has developed many electronic devices that are scrapped when broken or obsolete, including computers, televisions, phones, audio components, and refrigerators. Because these electronic components contain many endocrine-disrupting toxicants including lead, cadmium, brominated flame retardants, plastics, and plasticizers, they can involve significant risk to workers and communities that recycle or incinerate or otherwise dispose of the components. Although the majority of e-waste ends up in landfills, recycling involves chemical stripping, open burning, shredding, and melting of the e-waste under conditions where the workers are highly exposed to the toxic chemicals via air emissions, water, and soil contamination as well as direct physical exposures.[185]

Green Chemistry

Green chemistry, also called sustainable chemistry, is a new field that encourages the design and development of chemicals using principles that minimize the use and generation of toxic chemicals. Paul Anastas coined the term "green chemistry," and it consists of 12 principles that he developed.[97] Indeed green chemistry focuses on prevention of toxicity by producing the next generation of chemicals without toxicity. A joint project by green chemists and environmental scientists focused on the development of test methods (TIPED)[98] to detect endocrine activity in new chemicals being developed before their release into the environment. Green chemistry offers an alternative to chemical development that has the potential to reduce the number of new toxic chemicals released into the environment and also to develop nontoxic alternatives to chemicals currently in use.

KEY POINTS

- There are two categories of emerging issues that are important to monitor. The first category is that the current chemical mixture in the environment is being recycled in ways that contaminate workers and the general population. Thus, exposure routes are being identified that were not recognized previously. In addition, chemicals that have been banned (e.g., PCBs) or heavily regulated (e.g., lead) continue to pose health risks both because of their widespread use before being banned and because of their long-term effects on human health.
- A second category of emerging issue is that there is a nascent movement to produce safer chemicals. The traditional strategy is to produce and employ chemicals that have not been proven to cause harm and often are as toxic as the chemical it replaces. Proof of harm requires decades after deployment, harming generations of people. The revised strategy is to avoid the production and use of chemicals that exhibit any mechanistic signs of biological effects. This strategy will gain traction as innovation occurs.

CONCLUSION AND GUIDANCE FOR CLINICIANS

The human population is heavily contaminated with environmental chemicals. Most of those chemicals have not been studied for their impact on human health, but many have been shown to contribute to chronic disease prevalence. This observation has two important implications. The first is that every patient a clinician sees will have a certain burden of toxic chemicals. The second is that the current clinical and scientific evidence can and should be included in clinical recommendations. It is important to recognize that EDC effects on human health are observed at the population level. Thus, these data can inform clinicians about relative risk, just as other health-related domains such as smoking, exercise and nutrition inform clinicians about recommendations for health care.

There are several lines of evidence that support concern that chemicals in the environment are producing adverse health effects in the human population by interfering with hormone action. These are in part articulated and referenced more fully in the UNEP/WHO State of the Science of EDCs.[13] This evidence includes observations that there are a high incidence and increasing secular trends of many endocrine-related disorders in humans; that endocrine-related effects in wildlife populations are prevalent; and that laboratory studies have identified chemicals with endocrine-disrupting properties that can account for some of these observations in humans and wildlife. Considering the evidence, the Endocrine Society has released a Scientific Statement[84] that articulates the concern for the public health impact of chemical exposure. In addition, the American College of Obstetricians and Gynecologists in collaboration with the American Society of Reproductive Medicine has released a statement calling for a reduction in exposure to these chemicals and advising clinicians to be aware of the sources of contamination in women of reproductive age.[85] The Royal Society of Obstetricians and Gynecologists likewise released a statement providing advice on handling the potential consequences of chemical exposures (http://www.rcog.org.uk/files/rcog-corp/5.6.13ChemicalExposures.pdf), as has the International Federation of Gynecologists and Obstetricians.[186] The overriding message from all these society statements is that clinicians must play a larger role in providing information to their patients regarding how to avoid exposure to toxic agents. Although it is not expected that health care professionals be experts in toxic chemicals, they can still provide important information via literature provided to patients, specific focus on environmental health sciences in birth preparation classes and referring patients to specialists when a hazardous exposure is suspected. The noted reports provide information regarding key chemical exposures, sources of exposures at home, work, and in the community, and clinical implications of exposure. With the help of health care professionals, patients can become more aware of the risks to their health and the health of their children, including those unborn, and they can thus take action to reduce their body burden of toxic chemicals, thereby potentially improving overall health throughout the lifespan. An example of an exposure history is available at http://prhe.ucsf.edu/prhe/clinical_resources.html. Websites that contain useful information include: www.healthandenvironment.org, www.ewg.org, www.cehn.org, and www.prhe.ucsf.edu.

Simple steps that patients can take include the following: avoid smoking and secondhand smoke, avoid fast foods and processed foods, limit foods that are high in animal fat, limit fish that are known to contain PCBs and mercury (shark, swordfish, king mackerel, and tilefish), do not microwave items in plastic containers, be mindful of ingredients in cosmetics and skin care products, do not use pesticides around the home, keep the home free of dust that contains lead, pesticides, and flame retardants, use nontoxic cleaning products (www.prhe.ucsf.edu/prhe/tmlinks.html#cleaningproducts), choose plastics carefully to avoid BPA and products made with soft PVC, use VOC-free and water-based paints, use a digital thermometer, wash all fruits and vegetables, and eat organic and fresh products when possible.
